Abstract

This paper introduces the atomic Write and Read Next (WRN\(_k\)) deterministic shared memory object, that for any \(k \geq 3\), is stronger than read-write registers, but is unable to implement 2-processor consensus. In particular, it refutes the conjecture claiming that every deterministic object of consensus number 1 is computationally equivalent to read-write registers.

1 Introduction

Shared memory objects have been classified by Herlihy [9] by their consensus number, the number of processes which can solve wait-free consensus using any number of copies of an object and atomic read-write registers.

At the same time, it was also proved that \(n\)-consensus objects are universal for systems of \(n\) processes. However, the computational power of objects with consensus number \(n\) in systems of more than \(n\) processes is not completely understood. Recently, [1] have constructed an infinite sequence of deterministic Set Consensus objects of consensus number \(n \geq 2\), with strictly increasing computational power in systems of more than \(n\) processes. However, the case for \(n = 1\) remained an open question. And, it has been conjectured that any deterministic object of consensus number 1 is computationally equivalent to read-write registers, meaning that it cannot solve any problem that is not solvable by read-write registers.

For the nondeterministic case, [8] showed a counter example: a non-deterministic object with consensus number 1 that cannot be implemented from read-write registers. Deterministic Set Consensus objects, similar to the ones used in [1],
do not provide such a hierarchy for the case of \( n = 1 \), because they can be used to solve the consensus task for two processes. It is done by inspecting them as deterministic state machines, and initializing in a way that it is possible to predict the decided values for subsequent processors.

In this note, we refute the above conjecture by constructing a deterministic object, Write and Read Next (WRN\(_k\)), that solves \((k, k - 1)\)-set consensus, but cannot solve 2 processors consensus, for every \( k \geq 3 \). We define the WRN\(_k\) object in section 3. We show that these objects cannot solve 2-consensus for any \( k \geq 3 \) in section 4, and we show that they can be used to implement set consensus in section 5. The \( k \leq 2 \) case is briefly discussed in section 6.

2 The Model

We follow the standard asynchronous shared memory model, as defined in [1], in which processes communicate with one another by applying atomic operations, called steps, to shared objects. Each object has a set of possible values or states. Each operation (together with its inputs) is a partial mapping, taking each state to a set of states. A shared object is deterministic if each operation takes each state to a single state and its associated response is a function of the state to which the operation is applied.

A configuration specifies the state of every process and the value of every shared object. An execution is an alternating sequence of configurations and steps, starting from an initial configuration. A faulty process can stop taking steps, but, otherwise, must behave in accordance with the algorithm it is executing. If \( C \) is a configuration and \( s \) is a sequence of steps, we denote by \( Cs \) the configuration (or in the case of nondeterministic objects, the set of possible configurations) when the sequence of steps \( s \) is performed starting from configuration \( C \).

An implementation of a sequentially specified object \( O \) consists of a representation of \( O \) from a set of shared base objects and algorithms for each process to apply each operation supported by \( O \). The implementation is deterministic if all its algorithms are deterministic. The implementation is linearizable if, in every execution, there is a sequential ordering of all completed operations on \( O \) and a (possibly empty) subset of the uncompleted operations on \( O \) such that:

1. If \( op \) is completed before \( op' \) begins, then \( op \) occurs before \( op' \) in this ordering.
2. The behavior of each operation in the sequence is consistent with its sequential specification (in terms of its response and its effect on shared objects).

An implementation of an object \( O \) is wait-free if, in every execution, each process that does not crash completes each of its operations on \( O \) in a finite number of its own steps. The implementation is non-blocking if, starting from every
configuration in every infinite execution, some process completes one of its operations within a finite number of steps. In the rest of this paper, we discuss only deterministic, linearizable and wait-free implementations.

A task specifies what combinations of output values are allowed to be produced, given the input value of each process and the set of processes producing output values. A wait-free or non-blocking solution to a task is an algorithm in which each process that does not crash produces an output value in a finite number of its own steps such that the collection of output values satisfies the specification of the task, given the input values of the process.

In the consensus task, each process, $p_i$, has an input value $x_i$, and, if it is non-faulty, must output a value $y_i$ that satisfies the following two properties:

**Validity** Every output is the input of some process.

**Agreement** All outputs are the same.

We say that an execution of an algorithm solving consensus *decides a value* if that value is the output of some process. *Binary consensus* is the restriction of the consensus task in which each input value $x_i \in \{0, 1\}$.

The $k$-set consensus task, introduced by [5, 6], is defined in the same way, except that agreement is replaced by the following property:

**$k$-agreement** There are at most $k$ different output values.

Note that the 1-set consensus task is the same as the consensus task.

An object has *consensus number* $n$ if there is a wait-free algorithm that uses only copies of this object and registers to solve consensus for $n$ processes, but there is no such algorithm for $n + 1$ processes. An object has an infinite consensus number if there is such algorithm for each positive integer $n$.

For all positive integers $k < n$, an $(n, k)$-set consensus nondeterministic object [4] supports one operation, propose, which takes a single non-negative integer as input. The value of an $(n, k)$-set consensus object is a set of at most $k$ values, which is initially empty, and a count of the number of propose operations that have been performed on it (to a maximum of $n$). The first propose operation adds its input to the set. Any other propose operation can nondeterministically choose to add its input to the set, provided the set has size less than $k$. Each of the first $n$ propose operations performed on the object nondeterministically returns an element from the set as its output. All subsequent propose operations return $\perp$.

3 Write and Read Next Objects

For every $k \geq 2$, we introduce the WriteAndReadNext$_k$ (or WRN$_k$) object, that has a single operation – WRN. This operation accepts an index $i$ in the range $\{0, \ldots, k-1\}$, and a value $v \neq \perp$. It returns the value $v'$ that was passed in the previous invocation to WRN with the index $(i + 1) \mod k$, or $\perp$ if there is no such previous invocation.
Algorithm 3.1 A sequential specification of the atomic WRN operation of a WRN\(_k\) object.

1: function \texttt{WRN}(i, v) \triangleright i \in \{0, \ldots, k - 1\}, v \neq \bot
2: \hspace{1em} A[i] \leftarrow v
3: \hspace{1em} \text{return } A[(i + 1) \mod k]
4: end function

A possible implementation of WRN\(_k\) consists of \(k\) registers, \(A[0], \ldots, A[k - 1]\), initially initialized to \(\bot\). A sequential specification of the atomic WRN operation is presented in algorithm 3.1.

From now on, we assume \(k \geq 3\), unless stated otherwise.

4 WRN\(_k\) is Weaker than 2-Consensus

We follow the standard definitions of bivalent configuration, \(v\)-univalent configuration and critical configuration, as defined in [7, 9].

Lemma 4.1. For each \(k \geq 3\), there is no wait-free algorithm for solving the consensus task with 2 processes using only registers and WRN\(_k\) objects.

Proof. Assume such an algorithm exists. Consider the possible executions of the processes \(P\) and \(Q\) of this algorithm, while proposing \(0\) and \(1\), respectively.

Let \(C\) be a critical configuration of this run. Denote the next steps of \(P\) and \(Q\) from \(C\) as \(s_P\) and \(s_Q\), respectively. Without loss of generality, we assume that \(C_{s_P}\) is a 0-univalent configuration, and \(C_{s_Q}\) is a 1-univalent configuration.

Following [9], \(s_P\) and \(s_Q\) both invoke a WRN operation on the same WRN\(_k\).

\textbf{Case 1.} Both \(s_P\) and \(s_Q\) perform WRN with the same index \(i\).

The configurations \(C_{s_P}\) and \(C_{s_Qs_P}\) are indistinguishable for a solo run of \(P\), but a solo run of \(P\) from \(C_{s_P}\) decides 0, while an identical solo run of \(P\) from \(C_{s_Qs_P}\) decides 1. This is a contradiction.

\textbf{Case 2.} \(s_P\) and \(s_Q\) perform WRN with different indices, \(i_P\) and \(i_Q\), respectively.

Since \(k \geq 3\), either \(i_P \neq i_Q + 1 \mod k\) or \(i_Q \neq i_P + 1 \mod k\). Without loss of generality, assume that \(i_Q \neq i_P + 1 \mod k\). So the configurations \(C_{s_Ps_Q}\) and \(C_{s_Qs_P}\) are indistinguishable for a solo run of \(P\). However, the identical solo runs of \(P\) from the configurations \(C_{s_Ps_Q}\) and \(C_{s_Qs_P}\) decide 0 and 1, respectively, which is a contradiction.

Both cases resulted in a contradiction, and therefore no such algorithm exists.

\[ \square \]

Corollary 4.1. The consensus number of WRN\(_k\) is 1, for every \(k \geq 3\).
Algorithm 5.1 \((k-1)\)-Set consensus using a \(WRN_k\) object.

1: function Propose\((v_i)\) \(\triangleright\) For process \(P_i, 0 \leq i < k\)
2: \begin{align*}
& t \leftarrow \text{WRN}(i, v_i) \quad \triangleright t \text{ is a local variable.}
& \text{if } t \neq \perp \text{ then return } t
& \text{else return } v_i
& \text{end if}
& \text{end function}
\end{align*}

5 WRN\(_k\) Solves \((k, k-1)\)-Set Consensus

5.1 Solution in a System of \(k\) Processes

For any \(k \geq 3\), a WRN\(_k\) object can solve the \((k, k-1)\)-set consensus task for \(k\) processes with unique ids taken from \(\{0, \ldots, k-1\}\), using the following algorithm (also described in algorithm 5.1): Assume the processes are \(P_0, \ldots, P_{k-1}\), and their values are \(v_0, \ldots, v_{k-1}\). Process \(P_i\) invokes a WRN with index \(i\) and value \(v_i\). If the output of the operation, \(t\), is \(\perp\), \(P_i\) decides \(v_i\). Otherwise, it decides \(t\).

Claim 5.1. Algorithm 5.1 is wait free.

Claim 5.2. The first process to perform WRN decides its own proposed value.

Proof. Since it is the first one to invoke WRN, the output of WRN is \(\perp\), and hence the process decides on its own proposed value.

Claim 5.3. Let \(P_i\) be the last process to perform WRN. So \(P_i\) decides the proposal of \(P_{(i+1) \mod k}\).

Proof. Since \(P_i\) is the last one to invoke WRN, \(P_{(i+1) \mod k}\) has already completed its WRN invocation. Theretofore, \(P_i\) receives \(v_{(i+1) \mod k}\) as the output from WRN. Hence, \(P_i\) decides the value of \(P_{(i+1) \mod k}\).

Claim 5.4 (Validity). A process \(P_i\) can decide its proposed value, or the proposed value of \(P_{(i+1) \mod k}\).

Claim 5.5. A process \(P_i\) decides its own proposed value if \(P_{(i+1) \mod k}\) have not invoked WRN yet.

Corollary 5.1 \(((k-1)\)-agreement). Assume the proposals are pairwise different (there are exactly \(k\) different proposals). So at most \(k-1\) values can be decided.

Proof. Let \(P_i\) be the first process to invoke WRN, and \(P_j\) be the last process to invoke WRN. From claim 5.2, \(P_i\) decides its proposal. From claim 5.3, \(P_j\) decides the proposal of \(P_{(j+1) \mod k}\). From claim 5.5, no process decides the proposal of \(P_j\).

Corollary 5.2. Algorithm 5.1 solves the \((k-1)\)-set consensus task for \(k\) processes.
Algorithm 5.2 \((k - 1)\)-Set consensus for unnamed processes using \(WRN_k\) objects.

1: function Propose\((v)\) 
2: \(j \leftarrow \text{Rename}\) \(\triangleright j \in \{0, \ldots, 2k - 2\}\)
3: for \(\ell = 1, \ldots, (2k - 1)^k\) do
4: \(i \leftarrow f_\ell(j)\) \(\triangleright i \in \{0, \ldots, k - 1\}\) is a local variable.
5: \(t \leftarrow O_\ell.WRN(i, v)\) \(\triangleright t\) is a local variable.
6: if \(t \neq \perp\) then return \(t\)
7: end if
8: end for
9: return \(v\) \(\triangleright\) Reaching here means \(t\) was \(\perp\) in all iterations
10: end function

Corollary 5.3. \(WRN_k\) solves \((n', h)\)-set consensus task for any \(n'/h \leq 3/2\) in a system with \(n'\) processes.

Corollary 5.4. \(WRN_k\) cannot be implemented from atomic read-write registers. Hence, \(WRN_k\) is stronger than registers.

5.2 Solution in a System with \(k\) Participating Processes Out of Many

Assuming that each process has a unique name in \(\{0, \ldots, k - 1\}\) might be a strong limitation in some models. In this section, we assume we have at most \(k\) participating processes, whose names are taken from \(\{0, \ldots, M - 1\}\), where \(M \gg k\).

In [2, 3] wait-free algorithms have been shown that use registers only to rename \(k\) processes from \(\{0, \ldots, M - 1\}\) to \(k\) unique names in the range \(\{0, \ldots, 2k - 2\}\). So we shall relax our assumption, and assume now we have at most \(k\) participating processes, whose names are in \(\{0, \ldots, 2k - 2\}\). Let us consider the set of functions \(\{0, \ldots, 2k - 2\} \rightarrow \{0, \ldots, k - 1\}\), call it \(\mathcal{F}\). So \(|\mathcal{F}| = (2k - 1)^k\) is finite, and we can fix an arbitrary ordering of \(\mathcal{F} = \{f_1, \ldots, f_{(2k - 1)^k}\}\).

The \((k - 1)\)-set consensus algorithm for \(k\) processes is described in algorithm 5.2. It uses \((2k - 1)^k\) \(WRN_k\) objects, \(O_1, \ldots, O_{(2k - 1)^k}\). First, the process name is renamed to be \(j \in \{0, \ldots, 2k - 2\}\). Then, for each \(\ell \in \{1, \ldots, (2k - 1)^k\}\) (in this exact order for all processes), the process invokes \(WRN\) operation of \(O_\ell\) with the index \(f_\ell(j)\), and the proposed value \(v_j\). If the result of a \(WRN\) operation returns a value different than \(\perp\), the process immediately decides on this returned value, and does not continue to the next iterations. If the process received \(\perp\) from all the \(WRN\) operations on \(O_1, \ldots, O_{(2k - 1)^k}\), it decides its proposed value.

The full proof is left for the full paper, below is a sketch of proof. The first process to perform \(WRN\) in each iteration continues to the next one, and hence the first process to perform \(WRN\) in the last iteration decides on its own value.
Algorithm 6.1 Solving consensus for two processes using a WRN$_2$ object.

<table>

</tbody>
</table>

We claim that at most $k - 1$ different values are decided by $k$ processes that perform Propose. If at most $k - 1$ processes returned, we are done. Assume that all $k$ processes have returned. Let $\ell$ be the first (smallest index) iteration in which a process returned, and let $P$ be the last process that returned from this iteration. Clearly, process $P$ did not return its proposed value, and no other process returns $P$’s proposed value. Such an iteration exists, because there is a mapping $f_{\ell'}$, where $\ell'$ is not the last iteration, i.e., $\ell' < (2k - 1)^k$, that maps the processes exactly onto $\{0, \ldots, k - 1\}$, and some process must have returned in $\ell'$ or before.

6 The $k \leq 2$ Case

WRN$_1$ is simply a SWAP object, in which every call to WRN returns the previous stored value, and swaps it with the new value. [9] showed that the consensus number of SWAP is 2.

Algorithm 6.1 solves the consensus task for two processes using a WRN$_2$ object. The process $P_i$ ($i \in \{0, 1\}$) invokes the WRN operation of the WRN$_2$ object with the index $i$ and its proposed value. If the operation returns $\bot$, then $P_i$ decides its proposed value. Otherwise, it decides the returned value.

It is easy to see that the invocation of WRN by the first process returns $\bot$, while the second one returns the proposal of the first process. Hence, the first process to perform WRN “wins”, and the second one “loses”, and the agreement criterion is achieved. It is also clear that validity is preserved; since a process returns only its proposed value, or the proposal of the other process.
