(Dated: October 15, 2018)

We present two band models for free fermion with charge conjugation symmetry in three dimensions. Without time reversal symmetry (TRS), the weak pairing gapless $A$-phase is a Majorana fermion $p_x + ip_y$ wave FFLO state while the strong pairing gapped $B$-phase belongs to topologically trivial Class $D$. With TRS, there is a Majorana fermion $B$-phase belonging to Class $DIII$ with a non-zero Hopf invariant. The TRS $A$-phase is also a Majorana fermion FFLO state with TRS. The surface states of the TRS $B$-phase are either a valley-momentum locked Majorana-Dirac cone or a linear-quadratic mixed cone for a specific surface. The surface states of the $A$-phase on one surface are topologically nontrivial, either having $Z$ or $Z_2$ invariant depending on whether the system is TRS or not. The edge states of that surface are gapless Majorana modes. The Majorana fermion gapless FFLO states can be realized in critical Weyl semimetals (WSM) in which dual single Wey nodes form dipoles and are nearly annihilated. The gapped $B$-phase emerges when Weyl node dipoles are about to be created. The WSM TaAs-family, a type-II WSM series $\text{Mo}_x\text{W}_{1-x}\text{Te}_2$-family, possible WSM $\text{La}/\text{LuBi}_{1-x}\text{Sb}_x\text{Te}_3$ and topological crystalline insulators $\text{Sn}_{1-x}\text{Pb}_x(\text{Te,Se})$ are candidates to be manipulated into these critical states based on Majorana fermion models.

\textbf{Introductions.} Searching for Majorana fermions in condensed matter systems has been on-going since the concept of Majorana fermion was reintroduced to the condensed matter physics community by Moore and Read [1]. It gains a wide interest in the physics community because the Majorana bound state which is a bound state of a vortex and a zero mode of the Majorana fermion carries a qubit of topological quantum computation [2].

Majorana fermion was used in a well-know exactly soluble model a long time ago, namely, the Ising model for classical spins which has a Majorana fermion representation. Moore and Read showed that the Majorana fermion may appear in $\nu = \frac{5}{2}$ fractional quantum Hall effect and the non-abelian anyon introduced by them is conformally equivalent to the vortex in the Ising model [1].

Read and Green (RG) proved that the asymptotic limit of Moore-Read Pfaffian state of $\nu = \frac{5}{2}$ fractional quantum Hall effect is the Majorana fermion in a $p_x + ip_y$ wave weak-pairing phase, the chiral $p$-wave superconductor [3]. A direct generalization of the chiral $p$-wave Dirac equations to the three-dimensions is by adding a non-relativistic kinetic energy term, and the Dirac fermion is still the Majorana one [3,8]. In this sense, the three-dimensional Majorana fermion exists, e.g., in a $^3\text{He}$ superfluid. The Bogoliubov quasiparticles are the Fourier modes of the Majorana fermion. However, this kind of three-dimensional Majorana fermion is emerged from a two-dimensional relativistic theory in which the non-relativistic quadratic kinematic term serves as a momentum dependent mass. We call this kind of Majorana fermion RG’s Majorana fermion. It is still a task to look for the relativistic Majorana fermion in 3+1 dimensions that Majorana originally proposed in 1937 [9], because a relativistic generalization of the RG’s Bogoliubov-de Genes (BdG) equations to three dimensions does not support a 3+1 relativistic Majorana fermion.

Besides the $p$-wave superconductor, there are many continuous persistent efforts in finding the Majorana fermion, Majorana zero mode and Majorana bound state in one- and two-dimensional condensed matter systems, both theoretically and experimentally [10–16].

In this article, we would like to propose a generic RG’s Majorana fermion model in three dimensions, which is a two band free fermion model with a charge conjugation symmetry. If the time reversal symmetry(TRS) is broken, it is a direct generalization of the RG’s BdG system. The ground state of the weak pairing gapless phase ($A$-phase) is a $p_x + ip_y$ wave Fulde-Ferrell-Larkin-Ovchinnikov (FFLO) state [17, 18]. The strong pairing gapped phase ($B$-phase) is in Class $D$ and topologically trivial [17–21]. For the system with TRS, the FFLO $A$-phase is gapless and modulated by two TRS paired finite wave vectors which label Majorana points. This is a chiral symmetric system as the FFLO state at one Majorana point is the left chiral $p$-wave’s while it is a right chiral $p$-wave’s at the TRS dual Majorana point. Topological classification of the gapped $B$-phase belongs to Class $DIII$ [10, 21] and the topological invariant is the Hopf invariant, an integer $Z$, which resembles the superfluid of $^3\text{He}$ [22].

For the TRS $B$-phase, there are single Majorana-Dirac cones with valley-momentum locking on one surface while linear-quadratic mixed cones can be observed on the other orthogonal surfaces. The number of the cones are determined by the bulk Hopf number. For the $A$-phase,
there is a gapped topologically nontrivial surface while the states on other two orthogonal surfaces are trivial. The topological invariant on that nontrivial surface is either \( \mathbb{Z} \) or \( \mathbb{Z}_2 \) depending on whether the system is TRS or not. The edge states are either chiral gapless Majorana mode or two Majorana modes with opposite chiralities.

It is difficult to find a real material whose global band structure has a charge conjugation symmetry without interaction. It may exist in the vicinity of a Majorana point in Brillouin zone in the long wave length limit which we will discuss below. It was known that a Weyl node is a Berry curvature monopole in momentum space and a Fermi arc can be seen at the surface of a Weyl semimetal (WSM) \(^{23}\). We will show that the Majorana point may appear either when two dual single Weyl nodes are nearly annihilated in a WSM or such a pair of Weyl points is nearly created. We call these materials critical WSM and discuss the material realizations by manipulating Weyl nodes.

**Models and Majorana valleys.** We study a generic two band model whose spectrum can be expanded at a given point \( k^m = (k_{x}^{m}, k_{y}^{m}, k_{z}^{m}) \) in Brillouin zone. The second quantized Hamiltonian is given by \( \hat{H} = \sum_{\mathbf{q}} \psi_{\mathbf{k}}^{\dagger} H(k^{m}, \mathbf{q}) \psi_{\mathbf{k}} \) where \( \mathbf{q} = \mathbf{k} - k^{m} \); \( \psi_{\mathbf{k}}^{\dagger} = (\psi_{1k}, \psi_{2k}) \) with \( \psi_{\mathbf{k}} \) the fermion annihilation operator and the Hamiltonian matrix \( H \) reads

\[
H(k^{m}, \mathbf{q}) = f_{0}(k^{m}, \mathbf{q})\sigma^{0} + f_{i}(k^{m}, \mathbf{q})\sigma^{i},
\]

where \( \sigma^{i} \) are Pauli matrices and \( \sigma^{0} \) the \( 2 \times 2 \) identity matrix; \( f_{\mu} \) may be expanded as a power series of \( \mathbf{q} \)

\[
f_{\mu}(k^{m}, \mathbf{q}) = f_{\mu}(k^{m}, 0) + \left( \frac{\partial f_{\mu}}{\partial k^{m}} \right)_{k^{m}} q^{i} + \frac{1}{2} \left( \frac{\partial^{2} f_{\mu}}{\partial k^{m}\partial k^{n}} \right)_{k^{m}} q^{i}q^{j} + \cdots .
\]

They are convergent in Brillouin zone. Let us consider a special kind of \( f_{\mu} \) that obeys the following three conditions:

(i) All even terms in \( f_{0} \) are zero \(^{24}\). The chemical potential is then zero and the electrons are at half-filling;

(ii) keep only the even terms in one of \( f_{i} \). Without loss of generality, we take \( f_{i} = f_{x,y} \);

(iii) there are only odd terms in other two \( f_{i} = f_{x,y} \).

For the reason given below, we call \( k^{m} \) Majorana point if \( f_{a} \) satisfy these three conditions. The neighborhood in the vicinity of the Majorana point is called a Majorana valley. Notice that the number of the Majorana points does not suffer the lattice doubling for the numbers of Dirac or Weyl points \(^{25}\). A simple example of such kind of systems is a two band tight-binding model in a cubic lattice which is used to construct a general Weyl semimetal \(^{26},^{27}\). This system is a general RG’s Hamiltonian with a \( k \)-dependent mass term \(^{28}\) and then describes a \( p \)-wave superconductor. It may satisfy the three conditions and the Majorana point is at \( \Gamma = (0,0,0) \). Another example is Weyl metal defined in

\[
\frac{i}{\hbar} \frac{\partial \psi_{\mathbf{r}(t)}}{\partial t} = H(\mathbf{r})(\psi_{\mathbf{r}(t)}),
\]

where \( H(\mathbf{r}) = f_{\mu}(k^{m}, -i\nabla)\sigma^{\mu} \). The charge conjugation operator \( C \) is defined by \( C\psi C = \psi^{c} = C\psi = \sigma^{2}K\psi = \sigma^{2}\psi^{\ast} \) where \( \psi^{\ast} = (\psi^{\dagger})^{T} \) and \( C^{2} = 1 \) \(^{31}\). Explicitly,

\[
\psi_{1}^{c} = \psi_{2}, \quad \psi_{2}^{c} = \psi_{1}.
\]

Write Eq. (5) as the generalized Dirac equations of RG’s Dirac equations \(^{1}\)

\[
\frac{i}{\hbar} \frac{\partial \psi_{1}}{\partial t} = (f_{0} + f_{x})\psi_{1} + (f_{x} - if_{y})\psi_{2},
\]

\[
\frac{i}{\hbar} \frac{\partial \psi_{2}}{\partial t} = (f_{0} - f_{x})\psi_{2} + (f_{x} + if_{y})\psi_{1}.
\]
Following Read and Green [4], \( \psi_1^\dagger = \psi_2 \) is a necessary condition for any solution of (4) with the three conditions. Substituting this to Eq. (5), we see that the fermion field automatically obeys Majorana condition

\[
\psi^c = \psi \text{ or } \psi_2^\dagger(r,t) = \psi_1(r,t), \quad \psi_{2,k^m+q} = \psi_{1,k^m-q}. \quad (8)
\]

This means that the two-band model obeying the three conditions is a Majorana fermion model. In fact, this is a result of the charge conjugation invariance of the Hamiltonian matrix \( H(r), CH(r)C = H(r) \).

**Topological properties and time reversal symmetric model.** The Hamiltonian (11) does not have TRS, i.e., \( \Theta H \Theta^{-1} \neq H \text{ for } \Theta = i\sigma^yK \). This model belongs to Class D as a chiral \( p \)-wave superconductor [19, 21]. In three dimensions, this Class is topologically trivial. Precisely, it is an FFLO state because of the finite wave vector of the Cooper pairs [17, 18].

We now consider \( H_{2MP} \), Eq. (1). When \( m > 0 \), the spectrum of \( H_{2MP} \) is fully gapped while there are four nodes if \( m < 0 \), which resembles the \( B \)-phase and \( A \)-phase in superfluid \(^3\text{He} \) respectively [22]. This Hamiltonian owns two TRS dual Majorana points and it is TRS, i.e., invariant under \( H_\pm \to \Theta H_\pm \Theta^{-1} \) and \( \psi_k \to \Theta \psi_{-k} \).

It is also of a chiral symmetry and is charge conjugation invariant in the sense of \( CH_\pm(r)C = H_\pm(r) \) with \( C = \sigma^xK \). The ", \ldots, " in \( H_{2MP} \) may break this charge conjugation symmetry but they are far from the Fermi level and can be neglected when studying the long wavelength physics.

The topological classification of \( H_{2MP} \) belongs to Class \( DIII \). In three dimensions, this Class labels chiral symmetric \( p \)-wave topological superconductor with a topological number belonging to \( Z \) [19, 22]. Here, the ground state is a chiral symmetric \( p \)-wave FFLO state. To define the topological invariant, we compactify the long wavelength wave vector space \( \{ \mathbf{q} \} \) into a three sphere \( S^3 \).

The Hamiltonian \( H_{2MP} \) induces a map from \( f : S^3 \to S^2 \), a Hopf mapping. The homotopy group \( \pi_3(S^2) = \pi_1(Z) = Z \) gives a topological invariant, the Hopf invariant which describes the linking number between two curves in \( \{ \mathbf{q} \} \) [22]. A circle \( S^1 \) of \( S^3 \) is mapped to a point on \( S^2 \). For example, \( S^1_+ \) and \( S^1_- \) with reference points \( (\hat{q}_z, \pm \hat{q}_y, \pm \hat{q} \sin \varphi_0, \hat{q} \cos \varphi_0) \) where \( \hat{q} = [1 - q_z^2 - q_y^2]^{1/2} \) are mapped to points in the neighborhoods of the north and the south poles of \( S^2 \), respectively:

\[
f : \quad S^1_\pm = \{(q_z, \pm q_y, \pm q \sin(\varphi + \varphi_0)), q \cos(\varphi + \varphi_0))\} \to \frac{(q_z, \pm q_y, \pm |m + q_z^2|)}{\sqrt{q_z^2 + q_y^2 + (m + q_z^2)^2}}, \quad (9)
\]

where \( \varphi \) runs from 0 to \( 2\pi \) and \( q_z = A(\varphi_0) \) is a real function of \( \varphi_0 \). In the \( B \)-phase, \( m > 0 \), two neighborhoods can connect and make a two sphere \( S^2 \). The Hopf invariant is \(+1\). In the \( A \)-phase, \( m < 0 \), the point \((0,0, \pm |m + q_z^2|)\) is a null point if \( q_z^2 = |m| \). This means that \( f \) maps \( S^3 \) to a topologically trivial space. Thus, the \( A \)-phase is topologically trivial. The topological properties of the \( A \)- and \( B \)-phases here resemble those in the \( A \)- and \( B \)-phases of superfluid \(^3\text{He} \) [22].

If there are multi-pairs of the TRS dual Majorana points, every pair contributes one to Hopf invariant and the total Hopf invariant is given by the number of the pairs of the dual Majorana points.

**Surface states.** The surface-bulk correspondence can verify the topological properties. The surface states of the Hamiltonians (3) and (1) can be easily solved. There are no topologically protected stable gapless surface states of (3) as expected. For the TRS system, the surface states of the \( B \)-phase on the \([001]\) surface is described by the effective Hamiltonian \( H_{[01]} \propto v_x q_x \tau^x + v_y q_y \tau^y \) where the Pauli matrices \( \tau^x,y \) respect the valley degrees of freedom [23]. Analogous to the surface states of \( Z_2 \) topological insulator [24], there is a Majorana-Dirac cone with valley-momentum locking (See Fig. 2 and 31). On each other surface, \( H_{surface} \propto v_x q_x \tau^x + v_y q_y \tau^y \) as expected. This gives a linear-quadratic mixed cone. Due to TRS, these cones are stable to a perturbation with TRS. For multi-pairs of the Majorana points, there will be multi-surface cones on a surface. Counting the number of the cones on a given surface gives the Hopf invariants of the bulk.

There is no topological protected two-dimensional gapless states on the surface of the \( A \)-phase while the edge states of the surface may be topologically protected. Consider a semi-infinite system with \( x_a = 0 \) surface. For the Hamiltonians (3) and (1), the Dirac operator is reduced to a one-dimensional one which is topologically trivial on a two-dimensional surface. On the \( z = 0 \) surface, the \( x-y \) plane, the system is a gapped two-dimensional FFLO state which is topologically nontriv-
tions. We study the Hamiltonian \( H \) of the system are FFLO states by using the BdG equations. We study the Hamiltonian \([\text{1}]\) and denote \( \psi_k = (\psi_{1k^m+q}, \psi_{2k^m+q})^T = (c_{1q}, c^\dagger_{2q})^T \) and do a unitary transformation by

\[
\alpha_q = u^+_{+q}c_{1q} + v^+_{+q}c^\dagger_{2q}, \quad \beta_q = u^-_{-q}c^\dagger_{1q} + v^-_{-q}c_{2q}.
\]

so that the Hamiltonian are diagonalized as \( \tilde{H} \propto \sum_q E_q(\alpha_q^\dagger \alpha_q + \beta^\dagger_q \beta_q). \) Then, \( (u_{\pm q}, v_{\pm q}) \) are the positive and negative energy solutions of the following equations corresponding to Eq. \([\text{7}]\).

\[
E_{u_q} = (f_{0q} + f_{2q})u_q + (f_{xq} - if_{yq})v_q, \\
E_{v_q} = (f_{0q} - f_{2q})v_q + (f_{xq} + if_{yq})u_q.
\]

One may immediately checked that there are the Majorana relations between the positive and negative solutions \( u_{-q} = v^\dagger_{+q}, \quad v_{-q} = u^\dagger_{+q}. \) This means that \( \beta_q = v^\dagger_{+q}c^\dagger_{1q} + u^\dagger_{+q}c^\dagger_{2q} \) is not independent of \( \alpha_q. \) It turns out \( \beta^\dagger_q = \alpha^\dagger_{-q}. \) The correct Hamiltonian is \( \tilde{H} = \sum_q E_q \alpha_q^\dagger \alpha_q \) with \( \alpha_q = u^\dagger_{+q}c_{1q} + v^\dagger_{+q}c^\dagger_{1,-q}. \) The ground state of the system is annihilated by \( \alpha_q, \) i.e.,

\[
|\text{FFLO}\rangle \propto \prod_q \alpha_q^\dagger ||0\rangle \propto \prod_q (u_{+q} + v^\dagger_{+q}c^\dagger_{1q}c^\dagger_{1,-q})||0\rangle.
\]

Notice that \( c_{1q} = \psi^\dagger_{1k^m+q}, \) the ground state is a \( p \)-wave pairing FFLO state. The phase with \( m < 0 \) is the weak pairing \( A \)-phase \([\text{3}]\). It is gapless in three dimensions. A finite center-of-mass momentum of a Cooper pair leads to a spatial modulation of the superconductor order parameter and than the spatial alternation of the superconducting and normal conducting areas. This may be detected by NMR \([\text{38–39}]\) and heat capacity measurement \([\text{38–40}]\). The positive \( m \) \( B \)-phase is the strong pairing phase \([\text{3}]\) which is a trivial insulator.

For the TRS model, each pair of Majorana points has two FFLO momenta with opposite signs. In the gapless \( A \)-phase, the \( p \)-wave FF-type state gives rise to a spatial modulated order parameter \( \Delta(r, q) \sim \Delta(q_x \cos(k^m \cdot r) + q_y \sin(k^m \cdot r)). \) We hope this anisotropic modulation to \( q_x \) and \( q_y \) can be observed in the \( A \)-phase.

**Critical Weyl semimetals and material’s realization.** The Majorana points may exist in critical WSM. The critical WSM is named when two dual single Weyl nodes form a dipole and are nearly annihilated in WSM. In this critical region, both Weyl valley and band degrees of freedom cannot be detected as the Weyl nodes are not independent. The physical degrees of freedom reduce to one and thus the quasiparticle and quasihole bands are related by the Majorana constraint, i.e., a particle is also its anti-particle. The ground state in the Majorana valley is an FFLO state, the \( A \)-phase. Opposite to the annihilation of a pair of Weyl nodes, a Majorana point can also be created when a pair of Weyl points is about to emerge in an insulator with nearly closed gap. We call this the \( B \)-phase of the critical WSM. The Hamiltonian of the critical WSM is in general given by Eq. \([\text{1}]\). e.g., the spectrum in the neighborhood of the Majorana point is of the shapes given in Fig. \([\text{1}]\). For a critical WSM with TRS, there at least two pairs of Weyl nodes due to TRS, which results a TRS dual pair of Majorana points.

The candidate materials of the critical WSM have already existed when the inversion symmetry breaking WSM with TRS was predicted and experimentally discovered \([\text{41–42}]\). A pair of dual Weyl nodes in momentum space are very close in the type-I WSM, TaAs family. The spectra of TaAs family near the bottom of the band may asymptotically described by the Hamiltonian \([\text{1}]\) and are of the shape similar to Fig. \([\text{1}]\) in long wavelength limit, with coordinates’ redefinition. The Berry curvature dipolar structure of a pair of Weyl point was studied and its effect, quantum nonlinear Hall effect, was found \([\text{17}]\). Recently, an \textit{ab initio} study showed that the Berry curvature dipoles may exist in two WSM series, TaAs-family and type-II WSM MoTe\(_2\)-family \([\text{43}]\). Thus, the latter is also a possible candidate of the critical WSM.

For TaAs family, there are 12 pairs of Weyl points \([\text{41}]\) and they may form 12 Berry curvature dipoles. Four pairs of Weyl nodes 1 are exactly at \( k_z = 0 \) plane, say, \((0,0,\pm 0.949, \pm 0.014)\) and \((0,0,\pm 0.014, \pm 0.949)\) for TaAs. If a pressure or an external magnetic field is applied, two pairs of Weyl nodes may be annihilated, say, \((0,0,\pm 0.949, 0.014) \rightarrow (0,0,\pm 0.949, 0.0)\) and then a pair of TRS dual Majorana points appear. For \( \text{Mo}_x \text{W}_{1-x} \text{Te}_2 \), there are eight Weyl nodes at \((0,0,\pm k^m, \pm k^m \pm \delta^{(1,2)}(2))\) with \( \delta^{(1)} < \delta^{(2)} \). When \( \delta^{(1)} = 0 \), we have a pair of Majorana points. Furthermore, the gap opens when the external pressure or the magnetic field increases. A topological non-trivial \( B \)-phase appears. In TaAs family, there are eight pairs of Weyl nodes 2. Manipulating those Weyl nodes may lead to a Hopf invariant 2. To ensure the particle-hole symmetry, we require the Weyl point to be as close to the Fermi surface as possible.

There were already attempts to manipulate the Weyl nodes by high-pressure \([\text{50–52}]\). In Ref. \([\text{52}]\), there were evidences that topological crystalline insulator \( \text{Pb}_1 - x \text{Sn}_x \text{Te} \) becomes a WSM under pressure and Weyl nodes re-annihilate as pressure increases. In Ref. \([\text{53}]\), the critical WSM region in TaAs has already been reached under a high magnetic field. The annihilation of Weyl nodes and a gap opening were shown.

Doping is also a tool to manipulate WSM. Topological insulators \( \text{LaBiTe}_3 \) and \( \text{LuBiTe}_3 \) doped by Sb were
predicted to be WSM LaB$_{1-x}$Sb$_x$Te$_3$ and LuB$_{1-x}$Sb$_x$Te$_3$ for $x \approx 38.5\% - 41.9\%$ and $x \approx 40.5\% - 45.1\%$, respectively [54]. A topologically trivial state to type-II WSM transition was found in Mo$_x$W$_{1-x}$Te$_2$ at $x \approx 7\%$ [55]. The magnetically-doped (Mn, Eu, Cr, et al) Sn$_{1-x}$Pbx(Te,Se) topological crystalline insulators are possible to be transformed into a TRS breaking WSM [56]. In the critical region, one expects to find the critical WSM. The disorder may lead to the annihilation and creation of Weyl nodes and the WSM-insulator transition [57].

The Majorana representation. It is worth mentioning that if we take $f_i = f_j$ in (ii) of the three conditions, say $f_j = m + q^2$, the charge conjugation operator becomes $\overline{C} \psi = \psi^*$ and the necessary condition of a solution of the equations of motion becomes a familiar one

$$\psi_1^*(r, t) = \psi_1(r, t), \quad \psi_2^*(r, t) = \psi_2(r, t),$$

i.e., $\psi_1$ and $\psi_2$ are "real" fermions. This is the Majorana representation. The unitary transformation [10] becomes

$$\begin{align*}
a_q &= u_+ q c_{1q} + v_+ q c_{2q}, \\
b_q &= u_- q c_{1q} + v_- q c_{2q},
\end{align*}$$

where $u_{\pm, q}$ and $v_{\pm, q}$ are real and the Majorana condition reads $c_{\pm, q} = c_{1q}^\dagger$. The ground state is then a three-dimensional Kitaev chiral spin liquid, which was widely studied recently [58]. We thus predict the critical WSM as an alternative kind of Kitaev materials besides the iridates and $\alpha$-RuCl$_3$ [59, 60].

For $f_i = f_x$ in (ii), the charge conjugation operator is $\overline{C} \psi = \sigma^z \psi^*$. The Majorana condition becomes $\psi_1^*(r, t) = s \psi_1(r, t)$.

Conclusions. We proposed three-dimensional RG’s Majorana fermion models whose weak pairing ground state is the $p$-wave FFLO state. For a TRS model, the $B$-phase is topologically nontrivial with a nonzero Hopf invariant. Exotic gapless Majorana surface states were found. The number of surface cones counts the Hopf invariant. The topologically nontrivial surface states of the $A$-phase were found and the gapless Majorana edge modes were shown. We predicted that these Majorana states can be realized in existed and expected WSM systems with external field, pressure or doping manipulations.

If there exists a charge conjugation operator $C : \psi \rightarrow \psi^c$, such that $\psi^c$ satisfies,

$$i\partial_0 \psi^c = (H(k^m, -i\nabla + eA) - eA_0)\psi^c,$$

then the Hamiltonian $H$ \textbf{(A1)} has a charge conjugation symmetry. Indeed, such an operator $C$ can be found when all three conditions are satisfied. For example, $f_z$ only contains even terms in momentum $q$ and the other three coefficients only contain odd terms. Then $C = e^{i\theta}\sigma^z$, where $K$ is the complex conjugation operator, $\theta$ is a global phase and $C^2 = 1$.

Furthermore, if the equations of motion for $\psi$ is governed by the Hamiltonian \textbf{(A1)} then $\psi^c$ satisfies the same equations of motion with the same Hamiltonian. Since the Hamiltonian \textbf{(A1)} is a two level system without degeneracy, then $\psi$ and $\psi^c$ should be the same state up to a global phase which can be absorbed in the definition of charge conjugation. Therefore $\psi$ and $\psi^c$ satisfy the Majorana condition $\psi = \psi^c$ and $\psi$ becomes a Majorana quasi-particle. The emergence of the Majorana quasi-particle is a direct 3D generalization of Read and Green’s quasi-particle. The emergence of the Majorana fermion in 2D particle is a direct 3D generalization of Read and Green’s quasi-particle.

To illustrate this point further, we consider the second quantization of $\psi$. Firstly transform $\psi$ and $\psi^c$ into momentum space, i.e.,

$$\psi = \int \frac{d^3q}{(2\pi)^3} \begin{pmatrix} c_{1q} \\ c_{2q} \end{pmatrix} e^{-iq \cdot x},$$

$$\psi^c = \int \frac{d^3p}{(2\pi)^3} \begin{pmatrix} c_{1q}^\dagger \\ c_{2q}^\dagger \end{pmatrix} e^{iq \cdot x},$$

where $(c_{1q}, c_{2q}) = (\psi_{1k=m+q}, \psi_{2k=m-q})$ are the Fourier components of the Majorana fermion. From the Majorana condition $\psi = \psi^c$, the Fourier components $(c_1, c_2)$ satisfy, $(k^m)$ does not change to $-k^m$.

$$c_{1q} = c_{2q}^\dagger, \quad c_{2q} = c_{1q}^\dagger.$$  \textbf{(A7)}

In the language of second quantization, the field $\psi$ can be written as,

$$\psi = \int \frac{d^3q}{(2\pi)^3} \sqrt{2} (\phi_+, q \alpha_q + \phi_-, q \beta_q^\dagger) e^{-iq \cdot x},$$

where $\phi_\pm = (u_\pm^+, v_\pm^+)^T$ are the normalized eigen functions of the Hamiltonian \textbf{(A1)} associated with the eigen energy $\pm E(q)$, and $\alpha (\beta)$ is the annihilation operator of the quasi-particles (holes). If $\alpha$ and $\beta$ satisfy the anti-commutation relation with the only non-zero anti-commutator,

$$\{\alpha_q, \alpha_q^\dagger\} = (2\pi)^3 \delta^{(3)}(q-q'),$$

$$\{\beta_q, \beta_q^\dagger\} = (2\pi)^3 \delta^{(3)}(q-q'),$$

\textbf{(A9)}

\textbf{Appendix A:} Charge conjugation symmetry at one Majorana valley and FFLO ground state

The effective Hamiltonian near a Majorana valley $k^m$ in the Brillouin zone can be written as,

$$H(k^m, q) = f_0(k^m, q)\sigma^0 + f_1(k^m, q)\sigma^1,$$

\textbf{(A1)}

where the coefficients $f_0$ satisfies the three conditions as in the main text. Therefore, after the Peierls substitution (or minimal coupling) of the external electromagnetic field,

$$H(k^m, q) \rightarrow H(k^m, q - eA) + eA_0,$$

\textbf{(A2)}

The equations of motion for the wave function $\psi(r, t)$ becomes,

$$i\partial_0 \psi = (H(k^m, -i\nabla - eA) + eA_0)\psi.$$

\textbf{(A3)}
the material. In the $x$-$y$ plane $q_x$ and $q_y$ are still good quantum numbers while $q_z \rightarrow -i \partial_z$. In order to find the gapless surface state, we choose $q_z = q_y = 0$, and seek the zero energy solution. The equations of motion for the zero energy solution read

$$v_z (m + (-i \partial_z)^2) \sigma_z \psi_0(z) = 0 \quad (B1)$$

The normalizable solution in the $z > 0$ region reads,

$$\psi_0(z) = e^{-z/\lambda}(a, b)^T, \quad (B2)$$

where the decaying length $\lambda = 1/\sqrt{m}$ and $a, b$ are normalizing constants. Because of the charge conjugation symmetry, $a$ and $b$ are not independent of each other. Removing the redundant antiparticle degrees of freedom and considering the valley degrees of freedom, the zero-energy states are given by

$$\Phi_1 = e^{-z/\lambda} \begin{pmatrix} c_+ \\ d_+ \\ 0 \end{pmatrix}, \quad \Phi_2 = e^{-z/\lambda} \begin{pmatrix} 0 \\ -d_+^* \\ -c_-^* \end{pmatrix}, \quad (B3)$$

where $\Phi_1$ and $\Phi_2$ are related through time reversal operation and the subindex $\pm$ stands for $(k_x^\pm + q_x, k_y^\pm + q_y)$. Without loss of generality, we can choose the functions $c, d$ to be real. Then the projected surface Hamiltonian reads

$$H^{\text{surface}}_{q_z}(q_x, q_y) = \langle \Phi_1 \mid H_{2MP} \mid \Phi_2 \rangle = A (v_x q_x \tau^x + v_y q_y \tau^y), \quad (B4)$$

where $A = -\langle c_+ d_+ + c_- d_-; \rangle$; the Pauli matrices $\tau^x$ respect for the valley degrees of freedom. Through this qualitative analysis, we discover a Majorana-Dirac cone and a valley-momentum locking phenomenon of the surface state in the $x$-$y$ plane (See Fig. 3(a)). Analogous to the surface Dirac cone and spin-momentum locking in the topological insulator $^2$, this Majorana-Dirac cone is also protected by time reversal symmetry. If there are multiple pairs of Majorana points in the bulk, each pair of them will generate a Majorana-Dirac cone on the surface. Unlike the $\mathbb{Z}_2$ classification of surface states in 3D topological insulator, the classification is $\mathbb{Z}$ for Majorana-Dirac surface states because they belong to different valleys and the inter scattering between different valleys are difficult. This $\mathbb{Z}$ classification also shows the well known bulk-edge correspondence because the surface topological number is inherited from the bulk Hopf invariant as discussed in the main text.

The surface states on the other surfaces can be considered similarly. For example, on the $x$-$z$ plane, the effective Hamiltonian reads $A_1 q_x \tau^x - A_2 q_z^2 \tau^z$, where $A_1, A_2$ are constants. The dispersion of surface states are shown in Fig. 3(b).

[2] See e.g., Xiao-Liang Qi and Shou-Cheng Zhang, Rev. Mod.

\begin{equation}
\psi^\dagger H \psi \propto \int \frac{d^3q}{(2\pi)^3} \frac{E}{2} (\alpha^\dagger \alpha + \beta^\dagger \beta), \quad (A10)
\end{equation}

where we have dropped a constant zero point energy. Now comparing Eq. (A5) with Eq. (A8),

$$\alpha_q = u^+_q c_1 q + v^+_q c_2 q \quad (A11)$$

$$\beta^\dagger_q = u^-_q c_1 q + v^-_q c_2 q. \quad (A12)$$

Because of the charge conjugation symmetry of the Hamiltonian (A1), $u^+_{-q} = v^+_q$, $v^-_{-q} = u^-_q$, together with Eq. (A7), one can check that $\alpha_q = \beta^\dagger_{-q}$ which satisfies the Majorana condition on creation and annihilation operators, namely, the quasi-particles are Majorana fermions. And the vacuum is the FFLO vacuum, i.e.,

$$\forall \alpha_q, \quad \alpha_q |FFLO\rangle = 0, \quad (A13)$$

or equivalently,

$$|FFLO\rangle \propto \prod_q (u^+_q + v^+_q c^\dagger_1 q c^\dagger_2 q)|0\rangle. \quad (A14)$$

If $f_y$ in (A1) contains only even terms in momentum $q$ and the other three coefficients contain only odd terms, one can check that $C = K$. This gives Majorana representation and the Majorana condition is $\psi^\dagger_s (r, t) = \psi^\dagger_s (r, t) = \psi_s (r, t)$ for each band index $s$. And if $f_x$ contains only even terms in momentum $q$ and the other three coefficients contain only odd terms, $C = \sigma^z K$ and $\psi^\dagger_s (r, t) = s \psi^\dagger_s (r, t) = \psi_s (r, t)$.

\section*{Appendix B: Surface states of Hamiltonian $H_{2MP}$.

Let us consider the surface state of $H_{2MP}$ in the $x$-$y$ plane, i.e., $z > 0$ area is the vacuum and $z < 0$ is
