As a nonrelativistic particle constrained to remain on an N − 1 (N ≥ 2) dimensional hypersurface embedded in an N dimensional Euclidean space, two different components p_i and p_j (i, j = 1, 2, 3, ..., N) of the Cartesian momentum of the particle are not commutating with each other. In fact, the so-called fundamental quantum conditions [p_i, p_j] (≠ 0) depend on products of positions and momenta in uncontrollable ways, thus their physical consequences are little known. The local analysis technique is utilized to crack this long-standing problem. The first finding is that this noncommutativity on a local point of the hypersurface turns out to be transparent and the quantum conditions are then operator-ordering free and dependent on the local curvature of the surface. The second finding is that, for a small circle lying on each of the tangential planes covering the local point, the noncommutativity leads to a rotation operator and the amount of the rotation is an angle anholonomy; and along each of the normal sectional curves centering the given point the noncommutativity leads to a translation plus an additional rotation and the amount of the rotation is one half of the tangential angle change of the arc.

I. INTRODUCTION

In quantum mechanics there are so-called fundamental quantum conditions that include as the vital part the commutation relations between any pair of different components of momentum \( \mathbf{p} \), and the momentum operators in flat space are well understood. However, once the commutation relations for momentum yield non-trivial results, e.g., for the particle in curved space, the systems are far beyond fully understood because no reliable fundamental quantum conditions for the momentum can be obtained. The most simple model of curved spacetime is the curved hypersurface. Though Dirac proposed in 1950 the standard procedure of constructing the commutation relations for momentum, and the quantization of the motion for the particle on the surface has been studied for more than six decades \([2-12]\), the understanding of the commutation relations for momentum is still insufficient, through it has been extensively investigated theoretically and experimentally \([12-20]\). In order to make some significant progress, let us recall the importance of local analysis in the general relativity, which tells that the small region of globally curved spacetime is approximately flat. In fact, the local analysis is a powerful technique in differential geometry and non-linear differential equations, etc. In present study, such a technique is utilized to investigate the long-lasting noncommutative commutation relations for momentum.

For a nonrelativistic particle constrained to remain on an (N − 1)-dimensional smooth curved surface \( \Sigma^{N-1} \) in flat space \( \mathbb{R}^N \) (N ≥ 2), one can define the cartesian momentum \( p_i \) (hereafter \( i, j, l = 1, 2, 3, ..., N \)) corresponding to the corresponding cartesian coordinate \( x_i \). In classical mechanics, we know that two different components of the momentum \( \mathbf{p} \) do not commute with each other \([2, 4]\),

\[
[p_i, p_j] = \Pi_{ij} = \sum_{l=1}^{N} (n_j n_{i,l} - n_i n_{j,l}) p_l \neq 0, (i \neq j),
\]

where subscript \( D \) in the square bracket denotes the Dirac bracket, and \( n_i \) is the \( i \)-th component of the normal vector \( \mathbf{n} \) at a point of the surface \( \Sigma^{N-1} \) and symbol "', l" in the subscript stands for the derivative with respect to the coordinate \( x_l \), and so forth. Although derived more than six decades \([2, 4]\), this noncommutativity \([1]\) remains less understood except for very special case such as the spherical surface \([5, 14]\) and the flat plane.

However, if one attempts to start from the noncommutative relation \([1]\) to reach its quantum mechanical version for a small area of surface around a given point, only the right-hand side of the equation \([1]\) matters. Fortunately, the results turns out to be operator-ordering free, which is in sharp contrast to what the noncommutativity might

*Electronic address: quanhuliu@gmail.com
suggested. Results in section II show that the leading contribution of $\Pi_{ij}$ in [11] can be categorized into two classes. In section III we construct two geometrically infinitesimal displacement operators (GIDOs), and demonstrate that these two GIDOs can be divided into two groups of operators, in which one is purely rotational and another is translational plus rotational. Section IV presents conclusions and discussions.

II. A LOCAL EXPANSION OF THE SURFACE EQUATION AND NONCOMMUTATIVITY WITHOUT OPERATOR-ORDERING PROBLEM

Let us consider the surface equation $f(x) = 0$, where $f(x)$ is some smooth function of position $x = (x_1, x_2, \ldots, x_N)$ in $\mathbb{R}^N$, whose normal vector is $n \equiv \nabla f(x)/|\nabla f(x)|$. We can always choose the equation of the surface such that $|\nabla f(x)| = 1$, so that $n \equiv \nabla f(x)$. This is because physics does not depend on the specific form of the surface equations, and a simple and convenient form suffices.

At any point of the surface, let us put the origin $O$ of the hypersurface, and the surface equation around the origin $O$ can be so chosen $f(X) \equiv X_N - w(x_1, x_2, \ldots, x_{N-1})$ that $w(x_1, x_2, \ldots, x_{N-1})$ is Monge’s form of the hypersurface. What is more, we can always choose the coordinates such that the normal direction $n$ is along the $X_N$-axis and principal directions are along $N - 1$ coordinates $x_a (a, b = 1, 2, 3, \ldots, N - 1)$, respectively, and the hypersurface is asymptotically represented by the generalization of the two-dimensional Dupin indicatrix [21, 22],

$$f(X) = 0 \implies X_N \approx \frac{1}{2} \sum_{a=1}^{N-1} k_a x_a^2,$$

where $k_a$ is the $a$-th principal curvature of the curve formed by the intersection of the $X_aX_N$-plane on the hypersurface $\Sigma^{N-1}$ at the origin $O$, and the intersections from the normal sections, and there are in total $N - 1$ normal sections. A product $K_{ab} \equiv k_a k_b (a \neq b)$ is right the $ab$-th sectional curvature [21]. The normal vector near the origin $O$ is,

$$n \approx \nabla f(x) = (-k_1 x_1, -k_2 x_2, \ldots, -k_{N-1} x_{N-1}, 1), \quad \text{or}$$

$$n_a \approx -k_a x_a, \quad \text{and} \quad n_N = 1,$$

which at $O$ reduces to $n = (0, 0, \ldots, 0, 1)$. The derivative of the normal vector $n$ with respect to the coordinate $X_l$ gives,

$$n_{a,l} \approx \begin{cases} k_a (1 + o(X^2)) \delta_{l,a} & \text{if } a \neq l, \\ o(X^2) (1 - \delta_{l,a}) & \text{if } a = l, \end{cases}, \quad \text{and } n_{a,N} \approx o(X) (1 - \delta_{N,a}),$$

where $o(X)$ and $o(X^2)$ denote quantities of order $X$ and $X^2$, respectively. At $O$, we have, respectively, the mean curvature,

$$M \equiv -\sum_{i=1}^{N} n_{i,i} = \sum_{a=1}^{N-1} k_a,$$

and,

$$\sum_{i,j=1}^{N} (n_{i,j})^2 \approx \sum_{a=1}^{N-1} k_a^2.$$

The central results of the present study are, up to the leading term,

$$[p_a, p_b]_D = \sum_{i=1}^{N} (n_b n_{a,i} - n_a n_{b,i}) p_i \approx -K_{ab} L_{ab}, (a \neq b),$$

where $L_{ab} \equiv X_a p_b - X_b p_a$, and,

$$[p_a, p_N]_D \approx -k_a p_a.$$
In consequence, we have the \textit{local} commutation relations in quantum mechanics,
\[ [p_a, p_b] \approx -i\hbar K_{ab} L_{ab}, \quad \text{and} \quad [p_a, p_N] \approx -i\hbar k_a p_a. \] \tag{9}

These two sets of commutation relations are remarkable for they are free from operator-ordering difficulty.

Two immediate remarks on these local relations \( \mathbf{S} \) and \( \mathbf{T} \) follow. 1) They depend on the local geometric invariants of the surface such as \( K_{ab}, k_a, L_{ab} \) and \( p_a \) etc., so they hold irrespective of coordinates chosen. 2) The brackets \( \mathbf{T} \) and \( \mathbf{S} \) are zero once \( K_{ab} \) and \( k_a \) are zero respectively, as expected.

\section{III. Geometrically Infinitesimal Displacement Operators and Rotations}

Now we investigate the physical significance of the commutation relations \( \mathbf{II} \).

First, we construct a GIDO along a small circle which is approximated by a \textit{small square} in the tangential \( X_a X_b \)-plane around the origin \( O \); and let the small square be formed by four points at \( A(-\delta X_a/2, -\delta X_b/2), B(\delta X_a/2, -\delta X_b/2), C(\delta X_a/2, \delta X_b/2) \) and \( D(\delta X_a/2, -\delta X_b/2) \), with center at the origin \( O \) with \( |\delta X_a| = |\delta X_b| \). The initial and final points of the displacements coincide at point \( A(-\delta X_a/2, -\delta X_b/2) \), and order of the displacement is \( A \rightarrow B \rightarrow C \rightarrow D \rightarrow A \). We have a GIDO along a small square \( \square \) ABCD,
\[ G_{\square} \equiv e^{i\frac{\delta X_a p_a}{h}} e^{i\frac{\delta X_b p_b}{h}} e^{-i\frac{\delta X_a p_a}{h}} e^{-i\frac{\delta X_b p_b}{h}} \approx e^{\frac{i}{\hbar} \left( \delta X_a \delta X_b K_{ab} \right)} \] \tag{10}

In calculation, the Baker-Campbell-Hausdorff formula for two possibly noncommuting operators \( u \) and \( v \) as \( e^u e^v \approx e^{u+v} e^{[u,v]/2} \) is used. We see that the GIDO \( G_{\square} \) \( \mathbf{III} \) is a rotational operator on the \( X_a X_b \)-plane, and the angle of the rotation is \( \delta X_a \delta X_b K_{ab} \) which is the sectional anholonomy. It is originally defined by the angle of rotation of the vector as it is accumulated during parallel transport of the vector on a the hypersurface along the the small circle on the \( X_a X_b \)-plane. The angle anholonomy formed by a loop covering an finite area \( \Delta S \) on the hypersurface is given by,
\[ \sum_{a,b=1}^{N-1} \int_{\Delta S} K_{ab} dX_a \wedge dX_b, \] \tag{11}

where the finite area \( \Delta S \) is formed by infinitely many flat pieces covering the area, and \( \sum_{a,b=1}^{N-1} f K_{ab} dX_a \wedge dX_b = 2\pi \chi \), where \( \chi \) is the Chern number.

If the hypersurface is a two-dimensional spherical surface, the angle anholonomy is equal to the solid angle subtended by loop. If the surface is locally a saddle, the infinitesimal angle anholonomy is negative. If it is a cylinder whose gaussian curvature is vanishing, the angle anholonomy is zero.

Secondly, considering the \textit{small arc length} from \( E(-\delta X_a, -\delta X_N) \) via \( O \) to \( G(\delta X_a, -\delta X_N) \) along the small portion of the normal sectional curve on the \textit{normal} \( X_a X_N \)-plane at the origin, we immediately find that the commutator \( [p_a, p_N] \approx -i\hbar k_a p_a \) leads to a displacement plus an additional rotation. To see it, we construct following GIDO which shifts a quantum state along the arc from point \( E \rightarrow O \rightarrow G \),
\[ G_{\sim} \equiv \exp \left( -\frac{i}{h} \frac{\delta X_a p_a - \delta X_N p_N}{\hbar} \right) \exp \left( -\frac{i}{h} \frac{\delta X_a p_a + \delta X_N p_N}{\hbar} \right) \approx \exp \left( -\frac{i}{h} \frac{2\delta X_a p_a}{\hbar} \right) \exp \left( -\frac{i}{h} \frac{\delta X_a \delta X_N}{\hbar^2} [p_a, p_N] \right). \] \tag{12}

In right-handed side of this equation, we see two parts, and one is a simple translational operator \( \exp \left( -\frac{i}{h} \frac{2\delta X_a p_a}{\hbar} \right) \) and another is,
\[ \exp \left( -\frac{i}{h} \frac{\delta X_a \delta X_N}{\hbar^2} [p_a, p_N] \right) = \exp \left( \frac{i}{h} \frac{\delta X_a \delta X_N}{\hbar^2} k_a p_a \right). \] \tag{13}

The physical significance becomes evident. The arc length element of along \( E \rightarrow O \rightarrow G \) is \( ds \equiv 2k_a \sqrt{\delta X_N^2 + \delta X_a^2} \approx 2\delta X_a \) with noting that \( \delta X_N \approx k_a X_N \delta X_a = o(X) \delta X_a \) from \( \mathbf{II} \). The change of the tangential vector along the arc is \( -\theta \approx k_a ds \approx 2k_a \sqrt{\delta X_N^2 + \delta X_a^2} \approx 2k_a \delta X_a \), and we have from above equation \( \mathbf{III} \),
\[ \exp \left( \frac{i}{h} \frac{\delta X_a \delta X_N}{\hbar} k_a p_a \right) \approx \exp \left( -\frac{i}{\hbar} \frac{\delta \theta}{2} \right) L_{Na}, \] \tag{14}

where an angular momentum operator defined by a torque of momentum \( p_a \) with respective to point \( (0, -\delta X_N) \) is \( L_{Na} \equiv \delta X_N p_a \).
Let us move a quantum state along closed curves formed by piecewise smooth normal sectional lines, the rotation operator gives an accumulation of the rotational angle is \[ \sum \delta \theta = 2\pi. \] Specially, when the surface is a two-dimensional spherical surface, the normal sectional curves are great circles and the GIDO \( G_\sim \) for a great circle leads to that the total angular change is \( 2\pi \).

Thus, we have demonstrated that two seemingly different kinds of noncommutativity, given by (9), have the same crucial parts: rotation operators given by \( G \square (10) \) and \( (14) \) in \( G_\sim (12) \), respectively. The amount of the rotations depends on the curvature of the surface.

**IV. CONCLUSIONS AND DISCUSSIONS**

For a nonrelativistic particle constrained to remain on a hypersurface, Dirac brackets for two different components of momentum are not mutually commuting with each other. The noncommutativity \( \Pi_{ij} \) on a local point of the hypersurface is examined and results show that the noncommutativity is due to the local curvature of the surface. At the point, there are, respectively, \( (N - 1)(N - 2)/2 \) mutually perpendicular two-dimensional *tangential planes* and \( N - 1 \) mutually perpendicular *normal sectional curves*. In quantum mechanics, with GIDOs constructed on the base of the noncommutativity, we find that, at the point, for a small circle lying on each of the tangential planes covering the point the noncommutativity leads to a rotation operator and the amount of the rotation is an angle anholonomy, and for a short arc length along each of the intersecting curves centering the given point the noncommutativity leads to a translation plus an additional rotation and the amount of the rotation is one half of the tangential angle change of the arc. All results are obtained by examination of the noncommutativity, without necessarily knowing the form of the momentum.

In many aspects our results are in sharp contrast to what the intuition suggests. For instance, the locally approximated flatness of the surface suggests that the momentum might reduce to the usual one, but it is not the case for that the noncommutativity depends on the curvature. The noncommutativity of commutation relations for momentum operators on a local point remains, but the heavy operator-ordering difficulty is got rid of. There is no angular momentum operator in the commutation relations \[ [p_a, p_N] \approx -i\hbar \delta_{aa}, \] but they can certainly have quantum states on the surface angularly shifted.
