Multiple Exciton Generation in Nanostructures for Advanced Photovoltaic Cells

Nicholas Siemons, Alessio Serafini

June 7, 2018

Abstract

This paper reviews both experimental and theoretical work on nanostructures showing high quantum yields due to the phenomenon of multiple exciton generation. It outlines the aims and barriers to progress in identifying further such nanostructures, and also includes developments concerning solar devices where nanostructures act as the light-absorbing component. It reports on both semiconductor and carbon structures, both monocomposite (of various dimensionalities) and heterogeneous. Finally, it looks at future directions that can be taken to push solar cell efficiency above the classic limit set by Shockley and Queisser in 1961.

1 Introduction

Current solar energy conversion inefficiency is considered by many to be the greatest barrier to sustainably meeting modern day energy needs. Since the early 20th century there has been increasing interest in solar voltaics, with early models of p-n junction solar cells manufactured since the 1950’s (see figure 1). In 1961 William Shockley and Hans Queisser discovered a fundamental limit to the efficiency of a traditional p-n solar cell of 30%[1]. At the end of the 20th century second generation solar cells were manufactured which use multiple layers of semiconducting material. These devices absorb a greater range of frequencies and do surpass this limit, pushing the theoretical limit to a 68% efficiency. However, the manufacture of such multi-junction solar cells is too expensive for large scale commercial use[2]. Theory and experiments show there is potential to overcome the Shockley-Queisser limit using quantum effects for a new cheap third generation solar cell[3, 4] (figure 2). In fact, it is known that impact ionisation in bulk semiconductor materials allows for a hot excitons to relax to the valence band, in turn exciting another exciton[5]. However, in bulk, this does not occur at the typical frequencies of solar photons. Therefore, intensive research is being done to the aim of increasing the quantum yield (QY) of photovoltaic cells by enhancing biexciton creation in nanostructures, which allow for a significant response to a wider frequency spectrum. Such structures include nanosheets, or “platelets”, nanorods, nanowires and, notably, quantum dots (QDs). In nanostructures, electron-hole pair multiplication, whereby more than one (typically two) electron-hole pairs are generated by impact with a single incoming photon, is referred to as multiple exciton generation (MEG), to differentiate it from bulk impact ionisation. Let us mention that alternative
terminologies, such as ‘carrier multiplication’ (CM) or ‘multiple exciton collection’ (MEC) are also in use in the literature. It is also worth knowing that 0-dimensional structures (quantum dots) may also be referred to as “nanocrystals”.

This review paper is organised as follows: in Sec. 2, the notion of multiple exciton generation is cursorily recalled, along with some basic related terminology; Sec. 3 covers MEG in zero-dimensional (quantum dots) structures, with an emphasis on Pb and Si based dots; Sec. 4 moves on to one-dimensional structures, in particular to nanorods, nanotubes and nanoribbons; Sec. 5 is devoted to two-dimensional structures, such as generic nanosheets and graphene sheets; Sec. 6 completes our survey focusing on hybrid type II heterostructures, which have drawn interest in this context; finally, in Sec. 7, we include a summary and a few conclusive remarks.

2 Multiple Exciton Generation

The creation of additional carriers from hot excitons has been observed in bulk semiconductors such as PbS, PbSe and Si and was not included in the seminal analysis by Shockley and Queisser. Theoretical work by De Vos et. al. has however shown that a QY higher than unity is beneficial for increasing solar device efficiency. In a p-n junction solar cell, it has been shown that efficient impact ionisation occurs when the incident photon energy is in excess of five times the energy $E_g$ required to excite an exciton to the valence band. Typically, this is high energy ultra-violet light outside the solar spectrum. Hence, a key aim in order to exploit this effect is to reduce the threshold energy $\hbar \omega_{th}$ for it to take place, so that quantum yields (i.e., the number of excitons per incoming photon) greater than unity can be reached with solar photons. Before 2002, MEG was often referred to as ‘down-shifting’ or ‘down-conversion’ of hot excitons, and devices were theorized which would facilitate this process. In 2002 however, Nozik was the first to propose that MEG could be enhanced by using nanostructures. Research published soon after by Shaller and Klimov showed evidence for low threshold MEG in PbSe QDs. Since then, MEG has been observed repeatedly in a variety of QDs such as PbSe, PbS and Si, while some semiconductor QDs such as InAs have as of yet shown no signs of MEG. Notably, MEG has also been demonstrated in C structures, such as nanotubes, nanoribbons and graphene.

It is worth noticing that such studies are typically carried out in a colloidal environment, using either photoluminescence, transient absorption or, more recently, pump-probe spectroscopy. All of these methods are labour intensive and difficult and, indeed, the lack of quick and easy MEG tests is arguably one of the major barriers in the field. As a consequence, it is only recently that nanostructures have been put into actual devices. The study of such devices is arguably a new field in itself, involving practical and technical considerations that elude the main scope of this review. Although we shall mention several of the most important advances concerning devices, the reader is referred to C. Stolle for a more detailed and exhaustive account.
Figure 2: Multiple Exciton Generation in a photovoltaic device, adapted from [22, H. Jaeger].

The early reported QYs of experiments (2005-1010) varied widely up to extremes of 300%. It was later discovered that some suspiciously optimistic results were due to photo-charging, whereby electrons delocalise from parent QDs. This gives a deceptive MEG-like signature in the spectroscopic data. Subsequently, it was found that this effect could be nullified simply by stirring the sample solution. Another hurdle in the assessment of QYs for specific structures is clearly the large number of variables involved and relevant to these effects, such as size, composition, shape and method of observation. It is uncommon for studies to be done on like-for-like samples, so that corroborative results are rare. The complicated interplay between the phonon cooling rate and the nanostructure dimensions is also an important reason for the wide variety in reported QY values. In fact, there is still no general, unified theoretical framework for describing MEG. Nevertheless, all of the studies in the area agree on two key factors: the enhancement of the Coulombic coupling between exciton and biexciton states and the suppression of excitons’ radiative relaxation pathways (predominantly phonon emission) are critical for increasing QY. Such conditions can be achieved by reducing the size of the basic structures, as quantum confinement favours both of them.

As far as the general theory of MEG is concerned, it should be noted that the intriguing possibility of mechanisms hinging on coherent superpositions of multiple excitonic states has been put forward, but it does not agree with all experiments. More recently ‘window of opportunity’ models have been used which allow for more predictive power than previous modelling. They rely on splitting relaxation times into discrete amounts, and are often complemented with computer simulations. The main aim in these studies is identifying conditions whereby the threshold photon energy for multiple excitation, \( \hbar \omega_{th} \), and the electron-hole pair energy \( \epsilon_{eh} \) (the energy required for a further exciton to be created) are minimised. In the ideal case scenario, they would approach the limit set by the conservation of energy, when \( \hbar \omega_{th} = 2E_g \) and \( \epsilon_{eh} = E_g \), \( E_g \) being the band-gap energy. This produces a staircase function when plotting pump energy against QY, which is often taken as an optimal reference.

It should be mentioned that, when discussing in-situ structures, the observed QY is sometimes also termed “quantum efficiency”. When dealing with devices, however, one is typically only interested in their quantum efficiency. This is further qualified as either ‘external’ or ‘internal’ quantum efficiency. The former is the ratio of generated electrons to incident photons, whilst the latter is the ratio of electrons to absorbed photons, which takes into account reflection and transmission, and is always lower. Furthermore, let us remark that, in understanding

Figure 3: Generation of multiple excitons from highly excited electron-hole pairs. Left: in bulk semiconductor, were the excited electron relaxes to the band gap. Right in QD’s impact ionisation is the inverse of the Auger process, and the rate of this is much larger than in bulk. It is usually referred to as MEG in QDs. Adapted from [29, A. Shabaev].
the relationship between in-situ structures and devices, the exciton lifetime $\tau$ plays a key role, as a larger $\tau$ allows for excitons to be ‘collected’, thus increasing the device’s quantum efficiency.

3 Quantum Dots

Due to their comparative topological simplicity and ease of fabrication, QDs are the best understood class of nanostructures. It is thus not surprising that efforts have been made to design effective ways to assemble devices from QDs and for turning excitons into carriers.

In order to be competitive candidates for solar voltaic devices, QDs must have $E_g$ within the infrared region, high QY, and be stable in the cell environment. For these reasons, PbS, PbSe, PbTe, Si and TiO$_2$ QDs have received the most attention (figure 4). Computational methods are used in order to identify further possible options. Typically, such methods adopt density-functional theory, which provides a satisfactory compromise between accuracy and scale. In Si, the MEG dynamics in QDs was probed using density-functional theory, placing the threshold for efficient MEG at about $3E_g$, which, for Si, lies within the visible spectrum. Such computational techniques are bound to furnish additional insight as methods and machines improve. On the other hand, computational methods are typically not designed explicitly to resolve the excited states occupied by biexcitons, which poses challenges and limitations to this approach.

As pointed out above, it is important that photovoltaic structures exhibit quantum confinement. In this regard, theory suggests that for this to be the case the radius of the QD should be less than the bulk exciton Bohr radius, calculated as $a_B = \epsilon \hbar^2 / \mu e^2$, with $\epsilon$ and $\mu$ being, respectively, the dielectric constant and the reduced mass of electron and hole. Typical values for such Bohr radii are $a_B$(PbSe) = 46nm, $a_B$(PbS) = 20nm and $a_B$(Si) = 4.7nm. QDs of these sizes can now be synthesised easily.

3.1 PbX Quantum Dots

Lead based QDs have been studied intensively, as here $E_g$ is in the low infra-red spectrum, fabrication is easily scalable, reproducible and low-cost and, most importantly, the Bohr-exciton radius tends to be large. After initial studies in 2009 it was doubted that PbSe QDs, which, it should be mentioned, feature the added complication of being unstable in air, would exhibit MEG at all. However, in 2010 Beard et al. showed sufficient evidence for MEG, and now PbSe QDs are possibly the most studied structures in this arena. In 2014, an improvement in PbSe synthesis was introduced that allowed the QDs to survive for up to thirty days in air, showing an increase of orders of magnitude over previous lifetimes. This was made possible by a novel synthetic method whereby PbSe QDs are made directly from CdSe QDs by displacing the Cd with Pb, creating a protective Cl and Cd ion surface on the subsequent PbSe QD film (in order to check that the other characteristics of the QD films were the same as standard ones direct comparisons were carried out, showing that the MEG dynamics are unchanged).

In a 2016 study the QY of PbSe QDs of three different sizes were determined, see Table 1 for radii of $1.8 \pm 0.2$nm, $1.9 \pm 0.3$nm and $2.2 \pm 0.3$nm respectively – all much smaller than the PbSe Bohr radius, and thus in the strong quantum confinement region. The peaks
in transition absorption observed in the experiment may be associated to specific, previously known orbital energies.\(^{32}\) In particular, the so-called Σ transitions to the ‘Brillouin Zone’ (unique to PbSe), a set of electronic transitions where MEG is expected to be particularly strong due to an enhanced phonon bottleneck, were investigated by probing the biexciton dynamics through transient absorption. The measures of the QY of each QD at three different pump energies thus highlighted the central role played by electron excitation to the Σ levels in increasing efficiency, in agreement with the related theory.

PbX QDs share similar crystal structure, and so systematic, comparative investigations may be launched where the second element is changed, in order to isolate the impact of different variables on the overall yields.\(^{33}\) A 2011 study made the comparison between PbSe and PbS to determine why QY for PbSe seemed much higher.\(^{34}\) These two QD’s are studied particularly as PbS QDs are stable in air and have the same structure as PbSe QDs which, as already mentioned, are relatively unstable in air. By looking at excited-state lifetimes it was established that the exciton-biexciton Coulomb coupling was very similar in both QDs. After observing a dependency of QY on the QD size for PbS but not for PbSe, it was also possible to infer that other relaxation channels, specifically the phonon relaxation rate, must be the dominant factor at play in determining the different QYs. This result was instrumental in leading to the first medium-scale collection of QY data on a variety of lead-based QDs of different sizes (Figure 5). In this paper, the accompanying theory is refined with the introduction of the parameters η, an MEG efficiency value independent of the pump rate, and P, a factor which describes the competition between the rate of MEG (κMEG) and the rate of non-useful cooling (κcool). In PbSe, MEG occurs at about 2.8Eg, which is described by a η value between 0.4 and 0.5 (Figure 6). The following empirical equation relates P with the photon energies involved:

\[
\frac{\kappa_{MEG}}{\kappa_{cool}} = P \left( \frac{h\nu_{ex}}{h\nu_{th}} \right)^s
\]

where s is a factor which describes how MEG changes with hνth and the excess pump photon energy hνex. Here, s is found to be around 2.2 for lead based QDs. The study by Midgnett et al., in agreement with previous relevant literature,\(^{35, 37}\) also reports on properties for a variety of PbS\(_x\)Se\(_{1-x}\) alloy QDs, with varying composition and radius, allowing one to draw conclusions about the size-dependance of η for the different compositions of QDs (see figure 6). It is suggested that higher MEG might be achievable in non-spherical crystal structures, although more data needs to be collected to explore such configurations.

### 3.2 Si Quantum Dots

Silicon is abundant in nature. It makes up over 90% of solar voltaic devices currently in use and plays a huge role in electronics and technology. It poses no environmental issues and Si membranes are optically transparent to non-bandgap energy photons, such that it would be possible to create Si multilayer cells of different sizes in order to span a wider absorption spectrum and achieve greater efficiency.\(^{40}\) It also has QD Eg within the infrared making it potentially an ideal material for 3rd generation solar cells.

QY above unity with silicon QDs was first reported in 2007 by Beard et al.\(^{16}\) who tested QDs of two different diameters, one in the strong confinement region (below the Bohr exciton radius for Si of 4.9 nm) and one in the weak-intermediate confinement region (about double the Bohr exciton radius). MEG was thus observed in a colloidal environment for both of these QDs at a pump energy of 0.86 eV. The reconstructed value for the electron-hole energy was ε\(_eh\) = (2.4 ± 0.1)Eg (close to the energy-conservation limit of 2Eg), with a reported QY of 2.6 ± 0.2 at 3.4Eg. Other relaxation pathways other than phonon emission were also taken into account in this study, such as charge transfer and radiative recombination.\(^{31}\)

In 2016, Bergren et al. used pump-probe spectroscopy to study a range of differently sized Si QDs.\(^{40}\) As will be discussed below, in recent years emphasis has been on trying to extend biexciton lifetimes, which is the angle taken by Bergren and coworkers in this work. Thus they found that, as one should expect, biexciton lifetimes

Table 1: An example of recent data collected for QD QYS for three sizes of PbSe QDs from\(^{29}\) r(QD\(_1\)) = 1.8 ± 0.2nm, r(QD\(_2\)) = 1.9 ± 0.3nm, r(QD\(_3\)) = 2.2 ± 0.3nm in diameter.
increase as the diameter is reduced, and postulate that the increase in the quantum confinement is reducing the coupling to the phonon relaxation channels. This is consistent with evidence for other QDs.

Study into Si QD films is also intensive due to easy access to high-grade samples. In [47, M. Trinh], a novel way to induce MEG in an array of Si QDs was described, showing that if the QDs are in close proximity, hot excitons can excite excitons in neighbouring QDs rather than in their parent QD. Specifically, this experiment used Si QDs of around 1.8 nm embedded in an SiO$_2$ matrix. MEG obtained through such a thermal exciton propagation enjoys a reduced chance of Auger recombination and an exciton lifetime prolonged by up to six orders of magnitude. A recent paper by Kryjevski et al. [48] adopts density functional theory to evaluate the effect of changing the internal structure of the QDs in amorphous QDs, as opposed to crystalline ones: such computer simulations predict a considerable change in dynamics in the 2-dimensional density limit present in films. They suggest that in this case, amorphous QDs may show a marked improvement in QY, along with better carrier mobility.

Recently, research has increasingly focused on novel structures rather than mere manipulation of the QD size. The production and characterisation of multi-layer all Si cells with different band gaps due to different levels of P dopant, rather than due to different sizes, have been first explored. [49] High levels of MEG in GeX QDs and higher QYs than in bulk GeX were subsequently observed in these structures, with external quantum efficiency exceeding 120% for PbTe QDs. It is perhaps worth noting that such studies, which focus on external QYs, are key to showing that the in-situ studies feature behaviours can be replicated for real-world usage.

## 4 One-Dimensional Structures

Over the last few years, one-dimensional structures have started to draw attention as candidates for photovoltaic devices alternative to quantum dots. Whilst clearly more challenging to synthesise than zero-dimensional dots, higher-dimensional structures entail a breaking of the
spherical symmetry that lifts some of the energy level
degeneracies and thus allows for additional excitations.
Besides, theoretical models suggested that, despite the
increased volume of 1-dimensional structures such as
nanorods, they would still lie in the quantum confine-
ment region, as the effect of quantum confinement de-
pends not merely on the total volume of a structure but
rather on its effective cross sectional area. In terms
of MEG, nanowires have only been considered in pre-
liminary computational studies. On the other hand
cell architectures based on nanorods and nanotubes have
received some attention.

4.1 Nanorods

Pb-based nanorods were the first non-spherical struc-
tures to be studied for MEG, which was made possible
by synthetic methods developed in 2010. Initial re-
ports showed the first evidence of MEG.

In particular, in a paper by Cunningham et. al. indicating that higher
efficiency may be due to increased Coulombic couplings at certain \( \rho \), as suggested in \cite{51, A. Bartnik}. After testing samples with different \( \rho \) and \( E_g \), it was
found that the QY has a nonlinear, non-monotonic de-
pendence with \( \rho \), and \( \eta \), displaying an almost threefold-
increase at certain \( \rho \) values - see Figure 7; in particular,
the efficiency peaks at \( \rho = 6 - 7 \) give a two-fold increase
in QY over PbSe QDs. The ‘enhancement factor’ (de-
finied as \( \eta_{\text{nanorod}} / \eta_{\text{QD}} \) for the same composition), varies
significantly across the literature. In late 2015, Davis et
al. measured an external quantum efficiency exceeding
unity for PbSe nanorods. More specifically, external
QYs of \( 109 \pm 3\% \), \( 113 \pm 3\% \) and \( 122 \pm 3\% \) were mea-
sured for devices containing nanorods of \( E_g = 1.05 \text{ eV} \),
\( E_g = 0.95 \text{ eV} \) and \( E_g = 0.80 \text{ eV} \). This is a promising
result, which gives confidence that the same structures
could be used in future devices. In the same study, the
internal QY is shown to be in very good agreement with
pre-existing experimental and theoretical literature.

4.2 Carbon Nanotubes and Nanoribbons

Theoretical work from 2004 suggested strong Coulom-
bic interactions between carriers would be present in
single-walled carbon nanotubes (SWCNTs). This
and other characterstics such as interesting photo and
electric properties, as well as strong photon absorption,
imply that such structures have the potential for MEG.
Despite being considered a 1d material, the dynamics
that govern MEG in SWCNTs is different to nanorods
or nanowires. This is because excitons are confined to
the surface of the SWCNTs rather than at their centre,
which implies a quasi-2d behaviour.

An initial 2008 study tested a SWCNT sample with
mixed chiralities showing a QY of 130% for \( h \omega = 3.7E_g \). A paper published two years later performed
5.1 Graphene

A more readily available 2d structure with well-established synthesis is graphene, whose promise for useful optoelectric properties, such as high carrier densities and charge mobility, is well known. Between 2010 and 2012, theoretical work by Winzer et al. showed that graphene...
has the potential for MEG. Only a year later, Tielrooij et al. carried out a study on MEG biexciton creation in graphene through methods similar to those that would then be used in PbSe on PbSe nanosheets. Such a study identifies two dominant processes: carrier-carrier scattering, leading to MEG, and phonon-assisted cooling, as well as a branching ratio between the two, which is shown to be highly favourable for MEG. This study employed doped graphene, and suggests a dependance of the results on the doping levels, which would open the additional possibility to alter the threshold energies for MEG by changing the amount of dopant as with Si.

Soon after, in 2014, MEG was detected in low-doped graphene too.

It should be mentioned that graphene has been studied in a wide variety of roles inside devices, not only as the light-absorbing component. To find out more about its role in enhancing photo-induced voltage in dye sensitised solar cells and QD cells, see the review paper [84, C. Ubani].

6 Type II Heterostructures

New QD structures that aim to separate the hole and electron wavefunctions have emerged recently. The wavefunction separation suppresses Auger Recombination and thus increases the exciton lifetime. These ‘type II’ heterostructures are created by using multiple different compositions in the same structure (figure 9).

A prominent example of a heterostructure is represented by core-shell QDs, such as those studied in Cirloganu et al. on the basis of a phenomenological model for MEG proposed by John Stewart, which suggests that slowing down hot carrier relaxation might be even more important than previously thought. In general, this work has spurred an interest in cooling-rate engineering for nanostructures, and in turn much research into how the separation between electron and hole wavefunctions may be increased.

Cirloganu et al. propose that the electron wavefunctions are spread over the whole structure, while the hole wavefunctions are localised around the core creating the desired spatial separation, and proceed to study QDs with a PbSe core and a CdSe shell of varying sizes; such dots can be characterised by an aspect ratio $\rho$, defined as the ratio of shell thickness to the overall radius. Thus, consistently higher MEG rates than reported for PbSe QDs were observed for core-shell QDs. A critical aspect ratio, which would provide the energy-conservation limit of $\eta = 1$, is predicted to lie in the interval $\rho_c = 0.45 - 0.7$. Further related analysis on the effect of core-shell aspect ratio, as well as of the degree of alloying between the core and the shell and its spectrographic implications can be found in the review.

In the same year, Eshet et al. looked at heterostructured nanorods of CdSe and CdS created by a seeded-growth approach. They analysed both seeded and core/shell structures, obtaining results which comply with the standard behaviour above $\hbar\omega$ : for the seeded structures, the efficiency $\eta$ increases with the seed size, while for the core/shell structures $\eta$ increases as the core-diameter decreases. However, when probing the samples in the non-MEG regime ($\hbar\omega < \hbar\omega_{th}$), it was found that, unexpectedly, $\eta$ actually decreases with decreasing core size, which is converse to theoretical prediction as well as mono-composite QD behaviour. A 2016 paper by Eshet et al. furthered the inquiry into how $\hbar\omega_{th}$ could be lowered from previous values of around $3E_g$ by analysing the dynamics of nanorod heterostructures whose composition changes from one to the other end of the rod. Theory suggests that in this class of heterostructures the internal electric field generated from photon pumping would aid MEG. When pumping around the energy-conservation limit of $\hbar\omega = 2E_g$ MEG efficiencies of 10%-20% were observed.

No semiconductor heterostructures were investigated in 2D confined systems. However, there has been research into the so-called ‘Van der Waals’ graphene heterostruk-
Figure 10: An example of a graphene Van der Waals structure, using blocks as analogy. Adapted from [89, A. Geim]. Grey - graphene, purple - hBN, blue - MoS$_2$, green - WSe$_2$.

These consist of layers of graphene separated by nanosheets of other materials, such as MoS$_2$ or WSe$_2$. MEG studies on this kind of ‘material stacks’ proved inconclusive, and further research is needed to shed light as to their potential.

7 Summary and Outlook

The technology required to create new generations of cheap and efficient solar cells is still a way off its ultimate goal. Despite this, since 2002 there have been significant breakthroughs in the study of nanostructures to overcome the Shockley-Queisser Limit. Through generating multiple pairs of excitons per incident photon, efficiencies have been measured strongly indicating that this goal should be achievable. As this compact review strived to show, experimental progress has led to a better understanding of the dynamics which govern excitons experiencing 0-, 1- and 2-dimensional quantum confinement. Work by computational and theoretical groups have led to research which allows for better prediction in future candidates for MEG, and better prediction of the effect various factors such as aspect ratio or size might have.

Quantum Dots in a colloidal environment have now moved on to being studied in device environments. To some extent, monocomposite QDs are being put to one side in favour of studies into heterostructures. The most state-of-the-art and applicable results have come from the creation of actual devices and measurement high external quantum efficiencies. Whilst they have yet to show voltages exceeding the Shockley-Queisser Limit, such devices have given external QYs showing MEG does work when turning excitons into carriers. To these aims, the potential of carbon structures is still not well understood in the 1- and 2-dimensional regimes. However, research has conclusively shown that higher-dimensional architectures do reach extremely high efficiencies at threshold frequencies outside the solar spectrum. Attempts to reduce the threshold energy by using ribbons, multi-layers of graphene and other systems are underway.

Future investigation into the possibility of creating nanorods and nanosheets devices seem to be in order, as well as into the effect of the nanostructure environment on the MEG efficiency. In particular, a better understanding of the latter seems key to really appreciate the impact these combined advances might have toward potentially revolutionary results. It should also be noted that MEG itself is unlikely to be the only pathway towards third generation solar cells. It is one of the many phenomena being explored that could come together in order to create such devices. It seems fair to predict that, when combined with work into the effect of electric fields on solar voltaic performance, or tandem cells, the application of nanostructures to light harvesting might achieve enhanced efficiencies in both proof of principle experiments and operational devices in the short or medium term.
