According to our current conception of physics, any valid physical theory is assumed to describe the objective evolution of a unique external world. However, this assumption is challenged by quantum theory, which suggests that physical systems should not always be understood as having objective properties which are simply revealed by measurement. Furthermore, as argued below, several other conceptual puzzles in the foundations of physics and related fields point to possible limitations of our current perspective and motivate the exploration of alternatives.

Thus, in this paper, I propose such an alternative approach which starts with a (rigorously formalized) concept of “observer state” as its primary notion, and does not from the outset assume the existence of a “world” or physical laws. It can be subsumed under a single postulate: namely, that Solomonoff induction correctly predicts future observations. Using tools from algorithmic information theory, I show that the resulting theory predicts, as a consequence of this, that it appears to observers as if there is a world that evolves according to algorithmically simple, computable, probabilistic laws. In contrast to the standard view, objective reality is not assumed on this approach but rather provably emerges as an asymptotic statistical phenomenon. The resulting theory dissolves puzzles like cosmology’s Boltzmann brain problem, makes concrete predictions for thought experiments involving the duplication and computer simulation of observers, and predicts novel phenomena such as “probabilistic zombies” governed by observer-dependent probabilistic chances. It identifies some phenomena of quantum theory (Bell inequality violation and no-signalling) as typical consequences of information-theoretic features of an agent’s memory, and suggests that we shift our attention in the foundations of quantum mechanics from “what is really going on?” to questions about algorithms, causality and computational models.

This work is not intended to be a “theory of everything”, but rather represents a blueprint and proof-of-principle for a novel way of approaching fundamental issues which puts subjective observation at center stage.

Note. A further significant update of this paper, including several simplifications and clarifications, is currently in preparation.
1. INTRODUCTION

Theoretical physics is more than just a fixed framework that allows us to predict measurable quantities. Ever since the first philosophers have wondered what our universe is made of, the very nature of the questions that we ask in physics has been continuously evolving. Novel discoveries and problems have led to completely new concepts that did not even make sense within earlier theories. For example, the problem of ether and of the Lorentz transformations in electrodynamics have ultimately led us to a framework (relativity) in which the structure of spacetime itself is dynamical, which is an idea that could not even have been formulated within Newtonian mechanics.

The starting point of this work is the hypothesis that we are perhaps at a point where we may want to consider another substantial revision of some traditional aspects of our worldview, at least in certain contexts. We are facing several conceptual problems, some of them of enormous importance, for which systematic problems and difficulties arise when we try to address them with standard approaches. While some of these questions are simply free-floating expressions of human curiosity (like “Why are there simple laws of physics at all?”), others have emerged as notorious and persistent problems in physics and related areas. They seem to show us in a rather annoying way that there is something that we fundamentally do not understand (see Table 1 for an overview).

For example, consider some questions that are currently being discussed in the context of cosmology: what if the universe is really large (as in eternal inflation) and contains a multitude of copies of every observer [1]? How can we assign probabilities to properties of “possible worlds” [2]? What if thermal fluctuations produce a massive amount of randomly appearing “Boltzmann brains” [3, 4] — can we use the assumption that we are not the result of such fluctuations to constrain our cosmological models? Independently, philosophers are discussing questions related to agents or observers that seem at first sight to be of a very different category, like: What happens if we simulate an intelligent agent to excel accuracy on a computer — would the simulation be “alive” [8]?

The distinction between these fields may not be as clear-cut as it first seems. Arguably, a Boltzmann brain is conceptually not so different from a simulated brain on a computer. Thus, physical theories that claim to make meaningful statements about the former should not be expected to be completely silent about the latter. As I argue in more detail below, these are not the only two questions that are conceptually related along these lines; some others are listed in Table 1. This suggests an exciting possibility: could there be a fundamental framework, or theory, that allows us to address aspects of all these questions in a unified way?

Such a theory would be extremely useful: while problems like the brain emulation question above do not seem to be directly amenable to empirical science\(^1\), a unified framework as described could allow us to test our ideas about these problems empirically, albeit indirectly, instead of relying exclusively on philosophical argumentation. Namely, if that theory made successful empirical predictions in the regime of physics, then this would justifiably increase our trust in its predictions in the more speculative realm.

- **Quantum theory.** “Unperformed experiments have no results” [5, 6]; measurement problem [7].
- **Cosmology.** Boltzmann brain problem [3, 4]; self-locating uncertainty [1]; measure problem [2].
- **Philosophy of mind / future technology.** “Are you living in a computer simulation?” [8], puzzles of personal identity like “A Conversation with Einstein’s Brain” in Hofstadter’s and Dennett’s “The Mind’s I” [9], or Parfit’s teletransportation paradox [10].
- **Fundamental curiosity.** Why is there a “world” with “laws of nature” in the first place?

\(\text{P}(\text{next observer state} | \text{previous observer states})\)

| TABLE 1. Some questions that motivate the approach of this paper. As explained in more detail in the main text, even though these conceptual puzzles are rooted in very different fields, they have a common feature: they can all in principle be reformulated in terms of the question of which probabilities we should assign to our future state (including memory, momentary observations and everything else), given our previous observer state(s). This motivates the attempt to formulate a framework for which these first-person conditional probabilities are fundamental, and which does not assume that they come from an external world. This paper intends to give a proof of principle that it is possible to have such a theory which is consistent with physics as we know it, and which also allows making non-trivial statements about some aspects of the questions listed above. |

---

1 After all, we cannot directly empirically test any predictions of the form “Yes, if we do a simulation of this or that kind, then the simulated mind really has an inner life in the same way that we do”. Simply observing the simulated mind, or asking it, will not allow us to draw any ultimate conclusions; see e.g. the philosophical discussion around “zombies” [47]. Of course we can (and should) study other aspects of this problem empirically, e.g. via neuroscience.

2 Note that this is not supposed to be a “theory of everything”; in fact, the theory predicts its own limitations. By construction, it will have to say nothing about most things. For example, it will not be useful (at least not directly) in the search for a theory of quantum gravity or other areas of high-energy physics or particle physics.

3 In line with Rovelli [11], here the word “observer” is by no means restricted to human observers, and it is not (at least not directly) related to the notion of “consciousness”. The question of consciousness is irrelevant for this paper; my notion of “first-person perspective” is by no means meant to be equivalent to consciousness. The former (but probably not the latter) describes a very general, technically formalizable notion that is agnostic about the question “what that perspective really feels like”. As a rough analogy, note that computer

\[\text{P}(\text{next observer state} | \text{previous observer states})]
with a mathematical formulation of “experience” or “observation”) as a primitive notion, and drop all mention of an “external world”. A moment’s thought shows that such a move is unavoidable if we want to address questions like those mentioned above. For example, if we ask “why is there a “world” with “laws of nature” at all?, then we must have a starting point that does not assume the existence of such a world from the outset. Similarly, if we do not think that the identification of “things in the world” helps us to resolve puzzles like Parfit’s teletransportation paradox, then we must argue without these.

The second methodological principle is to take a broadly information-theoretic approach. On the one hand, this follows from our first principle: once we drop the assumption of a fundamental external world, it is only the informational structure of the first-person perspective which survives as the theory’s elementary building block. On the other hand, modern physics itself gives us plenty of evidence that the notion of information will probably be an important primitive ingredient of any truly fundamental physical theory. The last few decades have seen an explosion of the use of information theory in physics: the black hole information paradox [12–15], Jacobson’s interpretation of the Einstein equation as an equation of state [16, 17], or holographic duality [18], to name just a few examples, have all played a pivotal role in advancing fundamental physical science. Arguably, these recent successes are a symptom of information theory’s potential to allow us pursue a goal that was already shared by both Bohr and Einstein: “[...] to reduce fundamental assumptions to the simplest set by means of pruning claims to the truth of excess metaphysical assumptions” [19].

This approach of “dropping ontological excess baggage” [20] is sometimes seen as a departure from traditional ways of thinking that would typically be associated with realism. It is perhaps most clearly expressed in Wheeler’s “It From Bit” doctrine [21], and in interpretations of Bell’s theorem [22, 23] as showing us that unperformed experiments as in (1), or holographic duality [18], to name just a few examples, have all played a pivotal role in advancing fundamental physical science. Arguably, these recent successes are a symptom of information theory’s potential to allow us pursue a goal that was already shared by both Bohr and Einstein: “[...] to reduce fundamental assumptions to the simplest set by means of pruning claims to the truth of excess metaphysical assumptions” [19].

This approach of “dropping ontological excess baggage” [20] is sometimes seen as a departure from traditional ways of thinking that would typically be associated with realism. It is perhaps most clearly expressing in Wheeler’s “It From Bit” doctrine [21], and in interpretations of Bell’s theorem [22, 23] as showing us that unperformed experiments have no results [5]. Seeing this as a sort of methodology with which to approach quantum theory, the development and success of quantum information theory [24, 25] is clear evidence that this way of thinking is at least fruitful. In fact, it has been shown by several authors that the Hilbert space formalism of quantum theory can be fully reconstructed from simple information-theoretic principles [26–35], suggesting that quantum theory should be understood as a “principle theory of information” [36–39].

Quantum theory therefore provides us with an independent strong motivation for the approach taken in this paper, namely, to drop the assumption of a fundamentally objectively existing external world in favor of notions like information, observation, and probability, relative to an agent or observer. Clearly, the notion of an objective external world is in many cases an indispensable tool to organize our experience, and we will show in Section 8 that our theory predicts the emergence of such a thing as an excellent approximation. Nevertheless, I would argue that we learn from quantum theory that a truly fundamental approach to physics must do without it — and we can use quantum theory for an educated guess by what it should be replaced. Namely, all predictions of quantum theory are probabilistic — in more detail, they are in the form of conditional probabilities: given that we choose to measure a certain observable A, after having a preparation procedure characterized by quantum state ρ, the possible outcomes a_i (eigenvalues of A) have probabilities Prob(a_i|ρ, A) = tr(ρΠ_i), with Π_i the projector onto the a_i-eigenspace. The corresponding probabilities associated to other observables do not fit into a joint unconditional probability distribution, which is a consequence of contextuality [41]. The approach of this paper will analogously be based on conditional probabilities of the form

\[ P(\text{next observer state} | \text{previous observer state(s)}) \]  

The idea is that any observer, at any given moment, is in some state. Intuitively, this state encompasses all that she currently observes, experiences, and remembers — naively, in the case of a human observer, think of a complete scan of that human’s brain. Observer states will be expressed as (encoded into) finite sequences of zeros and ones — binary strings. An observer state is meant to be an information-theoretic expression for a certain “state of being”: there is a string that describes what it is like to be you, the reader, right now (which technically encompasses the letters that you are now reading, the emotions that you are having, and all of your memory), there is another string that describes “what it is like to be a (particular) bat” [42] in a particular moment of its life, and infinitely many other strings that describe completely incomprehensible “ways of being” that have nothing to do with biology whatsoever. This sounds certainly questionable and raises all kinds of questions (why binary strings? how is the encoding chosen? what do the bits mean? etc.) Many of these questions will be partially answered in the course of construction of the theory, while some others will be disregarded as irrelevant for our purpose.

To see how one can build a predictive theory on this notion of observer state, consider the problem of brain emulation (cf. Table 1). Suppose that an observer’s current state encodes extensive memories of her life on earth, emotions and similar content that we can disregard for now, and, crucially, an encoding of hearing her son promise on her deathbed to emulate her brain after she will pass away, in a simulated of a paradise-like world. Will the promise be fulfilled, and will her actual next observer state correspond to experiencing this fantastic simulated world? The theory of this paper claims that, from her perspective, the answer to this question is probabilistic. To estimate its probability P as in (1), we do not need to determine what it “feels like” to be in that woman’s state or to wake up in the simulation. Instead, we have to estimate the information-theoretic content of these

---

4 I am not from the onset excluding the possibility that other “possibilist” notions of chance instead of probability measures might be relevant, e.g. notions like “plausibility measures” [40], but the theory in this paper will actually turn out to assign probabilities in the usual sense in most cases (with some notable exceptions, see Section 12).

5 In some sense, the binary digits will turn out to have a similar status as coordinates in general relativity: they do not in themselves have a direct interpretation. It is rather the computability structure on the set of all strings that ultimately leads to concrete predictions.
states: how much information do we have to encode, in principle, to describe the hypothetical future observer state conditional on the previous state?

Thus, as we will motivate in more detail below, \( \mathbf{P} \) is related to description length: the more compressible the conceivable future state (given the previous states), the more likely. Thus, in the theory of this paper, answering the brain emulation question boils down to questions of (Kolmogorov) complexity and minimal description lengths. In fact, we will look at this problem in detail in Section 13, and see that the answer will very much depend on whether the simulation is open or closed (i.e. with or without intervention).

The theory in this paper does not assume that the probabilities in (1) arise from some incomplete knowledge of an objectively existing external world (or for some other reason), but considers them as fundamental, i.e. as expressing an irreducible notion of propensity or chance [43]. It instead regards the physical world as a consequence of those probabilities, and postulates that \( \mathbf{P} \) equals conditional algorithmic probability. Three different routes of argumentation motivate this postulate (cf. Section 6). Not only speculative situations like brain emulation can in principle be expressed in terms of \( \mathbf{P} \), but also more mundane situations like the observation of physics experiments. Thus, we indeed obtain a theory of the kind envisaged further above: a rigorous theory that allows one, at least in principle, to make predictions in the empirical and speculative realm in a unified way.

The theory is introduced in three successive steps (which are distinguished by their color shading):

I. Heuristic discussion and thought experiments

Sections 2 and 3.

II. Mathematical formulation

Sections 4 (algorithmic probability), 5 and 6.

III. Predictions of the theory

Sections 7–14.

While the second and third part are mathematically fully rigorous, the first part motivates the mathematical definitions and has some philosophical flavor. However, I do not claim to pursue serious philosophy here; the purpose of part I is merely to give plausible arguments from the overarching perspective of mathematical physics and computer science for the subsequent choice of mathematical formulation.

One of the most interesting aspects of this theory is the prediction of the emergence of an external world. In fact, it predicts that this world will be simple, computable, and probabilistic, which seems to be confirmed by physics as we know it. This prediction turns out to be the reversal of a phenomenon that is well-known in artificial intelligence: namely, Solomonoff induction [44]. Solomonoff induction is a method of universal prediction that works as follows: If you are an agent in an unknown computable probabilistic world, use algorithmic probability for induction. This will asymptotically yield correct predictions, and do so faster if the world is algorithmically simple. Here it is the other way around: If you are an agent for which algorithmic probability determines what you see, then with high probability this will in the long run look as if it came from an “external world” — a simple, computable process which contains you as a random variable, together with other stuff. The simpler the conceivable world, the more probable that it will actually emerge in this way.

According to this phenomenon, every observer state will apriori be part of its own “private” (simple, computable, probabilistic) universe. This theory does not assume from the outset that these states (or, intuitively, the different observers that we associate with them) are part of “the same” process in some sense, i.e. “fit into the same world”. However, Section 9 shows that the theory predicts an emergent notion of objective reality. To this end, consider the case that an observer \( A \) (Abby the guinea pig) identifies another string-valued random variable in her world — for example, the content of another guinea pig’s (Bambi’s) brain. Let us denote this random variable (and its time evolution in Abby’s world) by Bambi\(_{3rd} \) — the “third-person perspective”, i.e. what Abby will call “Bambi” (namely, “that other thing” and its brain states). At any given fixed time step indexed by \( i \), this is just a sequence of zeros and ones like \( x_i = 01001 \ldots \), and as such, we can identify it as an observer state. Let us call this observer state (represented by a binary string) Bambi\(_{1st} \) — the “first-person perspective”, i.e. the “actual mode of being in that state” at that moment.

Irrespective of the details of how to interpret or understand this, we can clearly associate two different probability distributions to this random variable and its change over time. Let us call the different brain states that Bambi\(_{3rd} \) has gone through in Abby’s world by \( x_1, x_2, \ldots, x_n \), with \( x_n \) its current state (every \( x_i \) is a binary string). Since Abby’s world is itself some sort of probabilistic process (more on this in Section 7), there is a well-defined notion of “probability of Bambi\(_{3rd} \)’s next state \( y \)" which we can denote \( \mathbf{P}_{3rd}(y|x_1, \ldots, x_n) \). This is the actual chance that Abby has, in accordance with the laws of physics in her (emergent) world, to observe that Bambi\(_{3rd} \)'s brain state random variable changes to \( y \) next.

However, there is a different probability distribution which, according to the theory’s postulates, determines what Bambi\(_{1st} \) will actually experience: namely, \( \mathbf{P}_{1st}(y|x_1, \ldots, x_n) = \mathbf{P}(y|x_1, \ldots, x_n) \), which is conditional algorithmic probability. Apriori we have \( \mathbf{P}_{1st} \neq \mathbf{P}_{3rd} \), which is a quite puzzling and counterintuitive aspect of the theory in this paper. However, I prove in Section 9 that, under some natural assumptions, \( \mathbf{P}_{1st} \) and \( \mathbf{P}_{3rd} \) are very close to each other; in particular, they converge to each other in the limit of \( n \to \infty \). In this case, for example, if Abby has a chance of close to 100% of seeing the sun rise tomorrow, and thus has a chance of about 100% of seeing Bambi\(_{3rd} \) see the sun rise tomorrow, then Bambi\(_{1st} \) will indeed have a chance of about 100% to see the sun rise tomorrow. In this sense, Abby\(_{1st} \) and Bambi\(_{1st} \) will be “part of a common world”. This is a form of emergent objective reality or “consistency” pretty much in the sense of [46] (not to be confused with

---

6 This phenomenon has a certain analogy to a class of representation theorems in mathematics. For example, the set of real or complex functions on some space would intuitively be considered as “supervening” on that space: we start with the space, and once we have it, we can define the functions on it. However, the Gelfand representation theorem [45] reverses this perspective: it tells us how to reconstitute the underlying space from the abstract C*-algebraic properties of the algebra of functions. Here we do something similar for probability: we start with a notion of “irreducible chance” that acts on the level of observations, and derive a notion of external reality from it for which this probability can be interpreted to encode incomplete knowledge.
Bayesian coherence) which follows from the mathematics of Solomonoff induction. That is, the same mathematical theorems that guarantee the correctness of induction algorithms in artificial intelligence [44] imply the emergence of objective reality in our theory.

Nevertheless, there are situations for which it is predicted that \( P_{1\text{st}} \neq P_{3\text{rd}} \), and this includes in particular exotic situations like some personal identity thought experiments mentioned in Table 1. That is, in some of these situations, studying Bamb\(k_{3\text{rd}}\) can tell Abby literally nothing about what subjectively actually happens to Bamb\(i_{1\text{st}}\). Since this is reminiscent of Wittgenstein’s notion of “zombies” [47], I will talk about “Bambi being a probabilistic zombie for Abby”. Indeed, as I will explore in later sections of this paper, some computer simulations, Boltzmann brains, or “observers that are too simple” are predicted to be probabilistic zombies.

While quantum theory is a major motivation for the approach of this paper, note that it is not the main goal of this work to provide a novel interpretation of quantum mechanics, or to give concrete (mechanistic or other) explanations of quantum phenomena. Nevertheless, in Section 12 I show that two characteristic features of quantum theory (the violation of Bell inequalities and the simultaneous validity of the no-signalling principle) can be understood quite naturally as consequences of information-theoretic properties of observer states. The details of this explanation notwithstanding, the main message of Section 12 will rather be that the search for “explanations” of quantum theory are misplaced, and should be replaced by questions about the relation between algorithms, causality and natural computational models.

This paper is somewhat lengthy, but readers who are not interested in the (philosophically anyway not particularly ambitious) conceptual motivation are invited to skip Section 2 and to jump to Definition 4.1 on page 12. Note also that some mathematical details do not need to be understood in all detail to follow the general argumentation. A self-contained summary of this work will be provided in Ref. [49].

2. ON EXISTENCE, OBSERVERS, AND INDUCTION

It will turn out to be useful for what follows to discuss some basic notions in more detail than is usually done in the context of theoretical physics, in particular the concept of “existence”. At first, this may seem like an inappropriate detour into the realm of metaphysics: why bother with a difficult philosophical question when the main goal of this paper is to put forward a concrete physical theory? But every formal theory rests on some informal motivating ideas, which will in our case be mainly expressed in terms of (unusual) thought experiments. These thought experiments may raise all kinds of metaphysical questions regarding what we mean when we say that “something exists”. The goal of this section is to clarify in a pragmatic way how these questions will be dealt with in the rest of the paper.

More concretely, I will lay down some terminology that is intended to precisely avoid such metaphysical discussion in the following. I will give a pragmatic but (hopefully) clear informal definition of “existence”, without claiming to answer any deep philosophical or metaphysical questions. This pragmatic definition will not only be helpful to understand the motivating thought experiments, but it will also be useful for the interpretation of the theory after its mathematical construction.

How can we find such a definition? Careful analysis of the use of this concept suggests that it makes sense to distinguish two different notions of existence. One of the two concepts is straightforward to introduce — it comes from our strategy to use mathematics in the course of scientific reasoning. Mathematics is based on axiomatic systems, containing statements about “mathematical objects” such as numbers, sets, or maps. It is clear what it means that an object like this exists in the mathematical sense:

Informal definition 2.1 (M-existence). We say that a mathematical object \( x \) M-exists if and only if the statement “\( x \) exists” is true in the axiomatic system which was used to define \( x \).

For example, there is an axiomatic system that introduces the real numbers \( \mathbb{R} \) as an ordered field which is Dedekind-complete. Using this axiomatic system and possibly some derived shortcuts for representing real numbers by equations, we can easily prove that there is exactly one real number \( x \) with the properties \( x > 0 \) and \( x \cdot x = 2 \). Thus, this mathematical object \( x = \sqrt{2} \) M-exists⁷.

Note that we will not discuss the question whether a mathematical object that M-exists is “real” in some particular sense — this is a philosophical question which is irrelevant for the purpose of this paper.

The concept of M-existence is a rather abstract one. When we say that the sun, a tree, or a rock exists, we mean something very different — we mean that “something is really out there”, and we can interact with it by experience. However, I will now argue that a precise definition of this other kind of “existence” has an unappreciated property: it is a relation rather than a predicate. To illustrate this point of view, it is helpful to draw an analogy with the physical notion (and our perception) of velocity.

From every-day experience, we are used to encounter things that move (such as trains) and others that are at rest (such as our house) and we have no problems to distinguish between the two. But we know from classical mechanics that this point of view is ultimately an illusion: motion depends on the reference frame. For every-day life, this relativity of motion is often irrelevant (and unnoticed) since we automatically use a standard reference frame which is locally determined by the earth’s surface (and the direction of its magnetic field). But careful analysis of the physical situation reveals this implicit choice of standard reference frame and the underlying fundamental relativity.

We should be similarly cautious when we talk about physical existence. Operationally, many physicists would say that something exists if it can in principle be observed — that is, if we can somehow interact with it, may it be directly or indirectly. This criterion distinguishes an invisible dragon in the garage from a small asteroid hovering around the sun, emitting a tiny bit of light that reaches us via our telescopes.

⁷ Note that we do not demand that mathematical objects can be “constructed” in any specific way [50], only that they are well-defined.
Now consider this: suppose your colleague claims that there is this asteroid out there, on collision course with earth, and it really exists because it has been observed by an invisible dragon that lives in his garage.

This would be highly dubious. In order to accept the existence of the asteroid, it would better be observable by us. But here we go: on careful analysis, what we mean by physical existence is in fact a relation. It describes that there is interaction between the thing on the one hand, and us observers on the other. In order to be really cautious, let us therefore try this as our working definition: physical existence is a relation between two things\(^8\) (such as an object and an observer) which describes potential mutual influence\(^9\). Note that a “thing” does not need to correspond to an object in the strict sense (physical, mathematical or otherwise), but simply something that we can talk about (e.g. a random variable).

**Informal definition 2.2** (P-existence). Given two things \(A\) and \(B\), we say that they \(P\)-exist for each other if and only if, under suitable auxiliary conditions, modifying the state of \(A\) will affect the state of \(B\), and vice versa.

In other words: if we wiggle \(A\) (resp. \(B\)) then \(B\) (resp. \(A\)) will wiggle too, at least sometimes (e.g. if we do not put a big wall between \(A\) and \(B\), which is what we call “auxiliary conditions” in the informal definition).

Clearly, all things in our universe (such as planets, rocks, or molecules) mutually P-exist for each other. It is evident that P-existence is usually an equivalence relation, except for very pathological cases. This is because if \(A\) and \(B\) are objects that (potentially) interact, and so are \(B\) and \(C\), then usually \(A\) and \(C\) interact as well (at least indirectly, in a way that is mediated by \(B\)). As an example for a possible exception of this rule, think of three very distant galaxies in our expanding universe, with \(A\) and \(B\) (and also \(B\) and \(C\)) departing from each other with a velocity that is close to the speed of light, such that the future lightcones of \(A\) and \(C\) do not overlap. However, in the following discussion, we can ignore situations like this and use the following pragmatic terminology.

**Informal definition 2.3** (World). An equivalence class with respect to P-existence will be called a world.

This means that a “world” is a collection of things that mutually P-exist for each other. Every thing is part of exactly one world\(^10\) (namely its equivalence class). As mentioned above, the notion of a “thing” will not be particularly relevant in the rest of the paper; instead, we will have “worlds” that are defined as closed, irreducible computational processes, and the “things” are stable identifiable patterns within those processes.

To illustrate our use of terminology, consider Conway’s cellular automaton “Game of Life”\(^{54}\). We have a square grid, with squares that can be either black or white, evolving in discrete time steps according to some simple rules (the details of these rules are not relevant for the discussion).

![FIG. 1. A configuration in Game of Life, emitting “gliders”.

Time evolution in Conway’s Game of Life shows all kinds of surprisingly complex behavior and emergent patterns. Some patterns remain unchanged over time, some oscillate or move at constant speed (such as “gliders”), and others evolve in complicated ways, such as the “glider gun” in Figure 1 (it emits a continuous stream of gliders).

When gliders meet at the same position of the grid (i.e. when they collide), some unexpected reaction occurs, often eliminating the gliders or changing them into some oscillating structure. That is, the properties of one glider (e.g. its position) can affect other gliders. Thus, gliders \(P\)-exist for each other if they live on the same grid following evolution on the same initial configuration. Gliders also M-exist (if suitably defined), but they do not P-exist with respect to rocks or trees in our universe. Thus, any particular history (starting from a fixed configuration) of Conway’s Game of Life — if we describe it as a collection of things, which often seems a useful approximation — is a world according to Informal definition 2.3.

We usually regard our universe (an instance of a world) as “real” and other hypothetical worlds, such as Game of Life, as “not real”. But the argumentation above intends to show that these notions may not be useful in the context considered here. Thus, I will avoid to use any notion of “reality” in the rest of this paper, and instead restrict myself to the terminology of M- and P-existence.

Regarding our universe for the time being as one instance in an infinite family of (M-existing) worlds\(^11\), it is interesting to identify whether it is in any sense distinguished from other “typical” worlds. One atypical property, as I will argue now, is the observation that it is described — at least to

\(^8\) Construing existence in relational terms is not a new idea. In fact, the argument that (P-)existence is not a predicate has been used by some philosophers (including Kant \([51]\) and Frege) as a basis for rejections of the ontological argument for the existence of god \([52]\).

\(^9\) A somewhat similar definition of “existence” has been given by Elis \([53]\), but with a different goal: he uses it as an argument along the lines of “if we take for granted that \(B\) exist, then we must also take seriously that \(A\) exists”. He thus does not think of (P-)existence as a relation.

\(^10\) This obviously assumes that we are talking about things to which we can apply Informal definition 2.2, i.e. things whose definition contains the specification of other things that they can interact with.

\(^11\) Some readers may worry that this statement claims implicitly that our universe “is” a mathematical structure (by definition of M-existence), and thus makes us commit to some form of idealism \([55]\). But it is not necessary to adopt this position for the approach of this paper; the actual postulates and the predictions of the theory constructed here will admit a multitude of interpretations. More detailed questions of substance and identity are irrelevant for our discussion.
a good approximation and in a specific sense — by simple, computable laws of physics.

Given data on initial conditions of some physical system, we can in principle write a computer program that simulates the laws of physics as we know them and produces predictions for all observations that we may perform on the system at later times. While these predictions will in general be probabilistic (as dictated by quantum theory), the statistical inferences that we draw from them are in great agreement with our actual observations. It is a remarkable empirical finding that the notion of “universal computation”, based on the Turing machine [56, 57], seems to capture every kind of process in our universe that can be subjected to this kind of controlled empirical analysis.12

This observation and its extrapolation to all physical experiments that we may perform in the future — sometimes called the “physical version” of the Church-Turing thesis — is supported by experience and a variety of arguments. All theoretical attempts to construct reasonable mathematical models of computation, especially under the constraint to be realizable in our physical world, have so far turned out to be equivalent to the Turing machine model. This includes quantum computers, which can compute exactly the same class of functions as classical ones (the fact that they may be superpolynomially faster at some tasks [24] does not invalidate the formulation of the thesis that we are considering here since we ignore questions of efficiency). Despite some claims in the opposite, no physical system performing “hypercomputation” has ever been identified [63].

If we imagine for a moment the multitude of all mathematically well-defined worlds, then almost none of them have the computability property of our universe as sketched above. This follows from the simple fact that there M-exist an uncountable number of different worlds, but there is only a countable number of algorithms that can be run on Turing machines. Then why does the notion of a simple computing machine seem to capture all processes in our universe?

The computability of the laws of physics, at least in the approximate form as we know them, is a remarkable fact. What is even more remarkable is the fact that these laws are in addition very simple: the basic postulates of general relativity or quantum theory, for example, can be stated in terms of a few concise mathematical definitions and equations. Even though it is difficult to give a precise account of what we mean by “simple” (we will come back to this problem later), the fact that there exist simple physical laws, at least in some intuitive sense [64], which describe a large variety of different phenomena in physics, is arguably a highly surprising and far-reaching discovery of science.

This insight brings us into trouble once we consider our role as observers. Within the terminology of this section, all “things” are organized in different worlds; every logically consistent world M-exists, and the objects inside any given world P-exist for each other. In some sense, we as human observers find ourselves to be part of one of those worlds, called our “universe”, and from what we have discussed above it seems that there is no hope to explain “why” we end up in this world and not another one.

This multiverse picture has no explanatory power. Despite attempts to resort to the anthropic principle (which I do not find convincing), there is not much that we can gain from this worldview. It even seems to contradict our observations: if our universe was an arbitrary instance of all M-existing worlds, then we should expect it to have generic properties. But as discussed above, it doesn’t: in particular, it has the atypical property of evolving according to simple computable laws, if some version of the physical Church-Turing thesis is true. In this sense, we live in a very special kind of world, and the question is how we can understand this fact.

We can rephrase this puzzle in a slightly different language. The unreasonableness of the computability of our world is closely related to Hume’s problem of induction [69]: “on what grounds do we come to our beliefs about the unobserved on the basis of inductive inferences?” The physical Church-Turing thesis holds the promise that patterns which we observe today will still remain valid tomorrow, since otherwise our world could not be described by a (simple) algorithm. The problem of induction is precisely the question of why we should trust in such a kind of stability (of patterns that we use for prediction).

In other words, even if our world does behave as claimed by the physical Church-Turing thesis, then how can we be sure that it does? At first sight the sparse metaphysics of this section suggests that we cannot, due to the following simple observation.14

Observation 2.4 (Self-locating uncertainty). It is impossible for any observer to deduce with certainty on the basis of her observations and memory which world she is a part of. That is, there are always many different worlds for which being contained in them is compatible with everything she knows, but which imply different predictions for future observations.

So if we assume that observers are simply “things” of a kind to which Informal definition 2.2 can be applied (i.e. some kind of objects that dynamically interact with other things inside a well-defined world), then this observation emphasizes that observers might well be part of a chaotic, non-computable world that does not allow any useful induction whatsoever.15 In fact, as argued above, this would be a reasonable expectation, given properties of a “typical” world.

12 This is a statement of principle and not of practice. For all practical purposes, it may e.g. remain forever impossible to produce an accurate simulate of all of planet Earth in any detail (as described by quantum theory or any future theory), even though the physical Church-Turing thesis claims that a corresponding (extremely inefficient) algorithm exists in principle.

13 While the original Church-Turing thesis does directly relate to physics, several different versions of this thesis have been formulated over the decades. The version that we refer to here resembles, for example, Wolfram’s [58] “principle of computational equivalence”. It has been analyzed in more detail by Gandy [59], who calls (something very similar to it) “Thesis M”, and in the quantum context by Arrighi and Dowek [60]. For an overview and discussion of different versions of the Church-Turing thesis, see e.g. [61, 62].

14 Cosmologists have also started to explore the consequences of self-locating uncertainty, see e.g. [67, 68].

15 Or they may at least expect to be part of a world where induction is just enough to allow for them to survive, but not to draw any reliable conclusions about anything else.
Something must be wrong — when we think about observers and their properties, and in particular think of their (information-theoretic) “first-person perspective” (like you, the reader, now have when you look at these letters through the window of your eyes), should we really think of “things” in the usual sense, dynamically interacting with other things within some well-defined world? In the next section, I will discuss some thought experiments that suggest that the answer will ultimately be “no”. My claim is that this will finally resolve the puzzle above, and give us some kind of satisfactory resolution of Hume’s problem.

3. OBSERVER STATES AND INDETERMINISM

To this end, let me introduce a series of conceptual arguments and a thought experiment. None of these arguments will be completely new, and they are not intended to yield any particularly profound insights, except for motivating some mathematical definitions. They all deal with our prototype of observer — the guinea pig.

Imagine a world in the distant future, where the guinea pigs have finally become intelligent, and the civilization of guinea pigs has conquered the world. Guinea pigs have modern technology — in fact, technology that is much further advanced than the best technology that is available to humans today. Our thought experiment will involve one particular guinea pig called Abby who experiences a very strange situation, namely a teleporter malfunction. The goal of this thought experiment will be to address the question of the first-person perspective: what exactly is it that makes Abby experience a notion of “herself” in the form of a temporal sequence of observations?

At first sight, this sounds more like a question of neuroscience or the philosophy of mind rather than physics; and this would be true if we were asking for the detailed mechanism in a guinea pig brain that is correlated with her observations, or for more advanced questions of consciousness and the quality of experience. But here we ask for much less: the question will be what the minimal abstract information-theoretic requirements are for modelling a temporal sequence of observations. We are thus looking for an answer that is basic and general enough to allow for a formal mathematical definition which abstracts from the notion of a guinea pig and all further philosophical questions (which will be Definition 4.1 below).

This is somewhat comparable to the famous thought experiment of the scientist in the elevator in general relativity [70]. Clearly, the details of how the scientist perceives acceleration by equilibrioception in a medical or biological sense is irrelevant for the conclusion of the thought experiment — namely, that the scientist cannot distinguish between being at rest in a static gravitational field or being accelerated with the elevator in free space. While the following considerations emphasize the first-person perspective more than in the elevator case (which may seem worrisome at first), they should analogously still be understood in an abstract formal sense.

So let us turn to the civilization of guinea pigs. From a “third-person perspective”, guinea pigs usually take the viewpoint that the other’s personal identity is linked to their body. Imagine one guinea pig, called Bambi, watching another guinea pig, called Abby. When Bambi watches Abby walking over to the hay deli shop, she can just follow Abby’s trajectory and be sure that the guinea pig arriving at the shop is still “the same” Abby as at the start. This third-person perspective seems to agree with the “first-person perspective”, in which Abby herself is actually experiencing to walk over to the hay deli shop, subjectively being convinced to be “the same” guinea pig as before. When Bambi and Abby talk to each other afterwards, they will both agree on what happened.

Due to this every-day experience, most guinea pigs draw one particular conclusion: namely, that the material body itself is the “container” of the first-person perspective. Let me phrase this differently. Abby experiences a sequence of observations which seem to persist in time in a way that allows her some kind of self-identification. She may now ask (and so may we) why this is the case, or, in other words, whether one can point to some “thing in the world” that is the “cause” of this experience. For the reasons just mentioned, the standard answer — unconsciously believed by the vast majority of guinea pigs — is that the material body itself is this thing.

But a moment’s thought shows that this view has severe problems. Obviously, a guinea pig’s body is simply not persistent in time in any way which is consistent enough to serve as a principal mechanism for something as elementary as the first-person perspective: not only is the guinea pig continuously aging, but it is even the case that the material of its body is almost completely exchanged in the course of time. Guinea pigs eat, breathe, cut their hair and kill brain cells when they get drunk; sometimes they even loose parts of their brain during cancer surgeries. Even these drastic changes usually do not raise any doubt about the remaining integrity of the guinea pig’s first-person perspective [16].

It seems that it is not so much the material body itself, but the kind of information processing in a guinea pig’s brain that is important here. In fact, the hypothesis of substrate independence of the first-person perspective is widely accepted in the philosophy of mind [8]. Here I adopt this point of view as a working hypothesis, and assume that the crucial correlate of the first-person perspective is in the “software”, not the “hardware”. That is, what makes a guinea pig experience a temporal sequence of observations is simply a property of the information that is processed in her brain: Abby remains Abby because she remembers having been Abby before [17].

This intuitive formulation can be very misleading; let us therefore clarify this in some more detail. An obvious objection is that there are crazy guinea pigs who believe that they are a reborn version of Napoleon Bonaparte (or rather his guinea pig counterpart). Thus, it cannot be “conscious memory” in the sense of “believing” which is meant by “remembering” in the previous statement. Instead, we should think of an abstract information-theoretic property of the 16

16 This stability is also the reason why I find it extremely plausible that only a finite amount of information in the brain is ultimately relevant. If so, this information can be modelled in principle as a finite binary string that changes in discrete time steps.

17 Similar views have been expressed by John Locke and David Hume, as summarized in [71, Sec. 5].
current content of Abby’s brain which links it to its earlier information content.

As a technological analogy, consider an ordinary computer. Suppose that the Linux operating system has been running for a long time on some machine. The operating system accepts inputs by an external user; if there is no input, it simply keeps on working its predefined cycles. At any given time step, the operating system is in some state (corresponding to the current content of the memory and hard disc). Time is passing in integer steps; denote by \( S(n) \) the state of the machine at time step \( n \in \mathbb{N} \). We can encode the states in finite binary strings, such as 1011 or 11110 (only much longer). Given that we know the state \( S(n) \) at some time \( n \), not all binary strings are possible predecessor states — there are some restrictions on what \( S(n-1) \) could have been. For example, if the current state contains the command to close a certain file, it must have been open in the time step before. This means that \( S(n) \) contains some information on \( S(n-1) \), even though it might not determine it uniquely.

For Abby the guinea pig, something similar should be true: the current state of Abby’s brain contains some information on its earlier state. We can say that the current state matches the state an instant before, because both describe possible snapshots of the brain’s information content, snapshots that are consistent with the algorithm that is actually processed in the brain. It seems plausible that it is this kind of consistency which correlates with the first-person perspective of experiencing a (consistent) sequence of observations. This motivates the following informal definition.

**Informal definition 3.1 (Guinea pig successor state).** The state of a guinea pig at a certain time is the information that is presently stored and processed in her brain. Some state \( y \) is a successor state of some state \( x \), if \( x \) and \( y \) “match” in the sense described above — that is, if they are compatible successive states of one guinea pig.

A sequence \( x = (x_1, \ldots, x_n) \) of states is a guinea pig history if every \( x_{i+1} \) is a successor state of \( x_i \).

The conclusion of this section can now be stated as follows: guinea pigs experience a sequence of successor states. The first-person perspective is correlated with the encoding of successor states, and not necessarily with the guinea pig’s body. At this point, the notion of a successor state is kept vague on purpose; it will be replaced by a mathematical definition further below. In the end, we will see that we can drop this notion altogether, but it will help us to motivate and get an intuition on what is happening in the next sections.

Referring to Informal definition 3.1, it is clear that every guinea pig state \( X \) has many (possible) successor states \( Y \), arguably infinitely many. As a colorful example, think about Abby the guinea pig’s state when she is sitting in a café, drinking water and thinking about the weather. One possible successor state describes her experience while still sitting in the café a moment later, still drinking water, and asking herself whether she has enough winter coat for the predicted cold snap next week. Another possible successor state describes Abby, terribly frightened because she suddenly sees all chairs and tables in the café fall upwards — maybe because the law of gravity has suddenly been reversed. In both cases, Abby will perceive continuity in a way that respects her personal identity, even though the second possibility does not conform with the laws of physics as guinea pigs expect. That is, to qualify as a possible successor state in this informal definition does not imply that this experience is possible according to laws of nature as we (or guinea pigs) know them.

If we identify a guinea pig’s “self” with the state of her body or brain (according to the “material container” perspective that we have described and abandoned above), then there will always be exactly one successor state that actually becomes realized. However, there are conceivable situations in physics with more than one actual successor state, for example in a thought experiment that has been described in similar form by Parfit [10]. It relies on the guinea pig technology of teleporters.

A teleporter is understood as a hypothetical device that is currently beyond our technological abilities, but that does not contradict known physical laws. We can imagine a teleporter as consisting of two devices, a “scanner”, and a “replicator”. Suppose Abby the guinea pig wants to travel long distance, say from Earth to Mars. On Earth she enters the scanner which scans her body and brain cells in great detail at an instant of time, down to all molecular details that are functionally relevant. At the same time, her body is instantly destroyed, and the scanned data is sent to the replicator station located at the journey’s target. There, the replicator instantly builds a perfect copy of Abby’s body and brain, based on the transmitted data.

Clearly the material body is destroyed (and rebuilt) in this process, which leads to instant feelings of uncanniness that most guinea pigs or humans who think about this scenario. However, if the guinea pigs accept the conclusion from the previous section (and so will we for the rest of this paper), then there is no need to worry: Abby’s information content is replicated perfectly. The state of the replicated brain on Mars will be a successor state of Abby’s state on Earth in the sense of Informal definition 3.1. Hence Abby’s first-person perspective of temporal experience will persist.

Nevertheless, a more interesting situations occurs in the following case.

**Thought experiment 3.2 (Teleporter malfunction).**

Like every morning, Abby the guinea pig uses a teleporter to travel to her workplace at a hay farm on Mars. The teleporter scans her body and brain cells in great detail at an instant of time, down to all molecular details that are functionally relevant. Instantly her body is destroyed, and the scanned data is sent to Mars. The receiving part of the teleporter instantly builds a perfect copy of her body and brain.

However, this one morning, a malfunction disturbs the daily routine: a malicious admirer of Abby hacks into the transmitter’s computer system and causes the teleporter to create two perfectly identical copies of Abby at exactly the same local time on Mars, at two different places.

How does Abby perceive this situation? What should be her bet on future observations the moment before she enters the teleporter?

---

18 Successor states are very similar to Parfit’s “Relation R” [10], and several arguments in this section are, at least in spirit, comparable to Parfit’s.
Directly after the replication, there will be two identical twins — let us call them Abby-1 and Abby-2. An instant later, due to diverging experiences, Abby-1 and Abby-2 will differ in the information contents of their brains. So how will Abby subjectively experience this situation? This seems like a tricky question, even in terms of our terminology of successor states. According to the previous section, we must conclude that Abby will (after the malfunction) experience a successor state. But now, there are two successor states in the world: that of Abby-1 and that of Abby-2. Thus Abby will end up as Abby-1 or Abby-2, but which one of them? And what about the other twin?

If we disregard all speculative esoteric resolutions of the dilemma, Abby-1 and Abby-2 will both behave as if they were legitimate successors of pre-teleportation Abby. For other guinea pigs, both will be indistinguishable from the old Abby, at least initially (until the twins start making different experiences), and both will probably vehemently claim to be the “correct” Abby. It seems to be the only possibility to attribute a valid first-person perspective to both. In other words, Abby-1 and Abby-2 will both believe they are Abby.

However, they will both only experience themselves, and not the other one. That is, Abby-1 will experience herself as a person that is different from Abby-2, and vice versa. The only possible conclusion seems to be that, after the teleportation, Abby will subjectively perceive to be one of the two, and of course not both at the same time in any strange way.

So before the teleportation, should Abby prepare to become Abby-1 or Abby-2? Without further assumptions, there is no way for Abby to predict which one of the two options will be realized in her subjective experience. Vice versa, due to the symmetry between Abby-1 and Abby-2, there will be no way for any of the two copies to retrospectively understand “why” they ended up as one Abby and not the other. Furthermore, none of the two Abdys can be distinguished as the “real” Abby. In summary, before entering the teleporter, Abby should expect to randomly experience to become either Abby-1 or Abby-2. This randomness is not arising from an epistemic restriction, but is irreducible.

Why have I given this strange thought experiment? Except for science-fiction scenarios, something like Abby’s teleportation malfunction does never seem to happen in reality. And what should it tell us about physics? In fact, I will argue below that a situation like this is not an exceptional case, but instead happens continuously at all times, and this ultimately undermines the idea that observers are “things” inside well-defined worlds.

Recall Observation 2.4: we concluded that an observer can never know with certainty in which world she is located. Consider, for example, Abby’s state at an arbitrary point in time. As discussed in Observation 2.4, there are many worlds (arguably infinitely many) which are possible worlds containing Abby. Let us denote them by $W_1, W_2, W_3, \ldots$ and so on.

All those worlds $W_i$ have the property to contain (at a certain time step) a thing (a possible “Abby”) in exactly the same state. As we have seen above, it is this information content (not the material body) which identifies her “self”. But then, all the “copies” contained in the different $W_i$ may claim on equal footing to be Abby — in other words, from her first-person perspective, Abby should be regarded as being contained in all the worlds $W_i$ at once.

Since the worlds are assumed to be different, many of them predict different observations for Abby in the subsequent time step. The different $W_i$ define different possible successor states of Abby — this is very similar to Thought experiment 3.2, where we had two different successor states within one world. But then, relying on the conclusion of that thought experiment, we have to conclude again that Abby should, from her perspective, describe the situation as attaining one of the possible successor states at random. In other worlds, the first-person perspective of any observer is not “confined” to any single world.

Here is a rather idealized and colorful example. One Sunday morning, Abby takes breakfast in her favorite café. She eats cabbage and drinks some carrot juice while thinking about her coming work week. At some point, Abby starts to read the newspaper.

Consider our universe as a world, and call it $W_1$ (in fact, it is the fictitious guinea pig universe). Let $W_2$ be a copy of this universe with a single small modification: due to some differences in the quantum fluctuations shortly after the Big Bang, a certain constellation of stars in a very distant galaxy develops differently from $W_1$. Apart from this, we assume that $W_1$ and $W_2$ are perfect copies of each other, at least as seen from the viewpoint of an observer on Earth at present time. Hence $W_1$ and $W_2$ both contain identical “Abbys” who are sitting in the café and eating cabbage.

When Abby opens the newspaper, she comes across an article on the guinea pigs’ space administration’s newest telescope, showing a photograph that the telescope has taken recently: it is a photograph of the farthest galaxy that has ever been discovered. In fact, it is the galaxy that we have just mentioned above. At this point, Abby will see one of two possible different photographs, depending on whether she (or rather the object carrying her information content) is located in $W_1$ or $W_2$.

Then we have the situation described above. The moment that Abby looks at the article is analogous to the moment after the teleportation in Thought experiment 3.2: two possible successor states are equally accessible. The only possible conclusion is that Abby will perceive one of the two possibilities at random\(^{20}\).

---

\(^{19}\) This scenario has been briefly discussed under the name “mechanical indeterminism” in [72]. A very similar discussion appears in the many-worlds interpretation of quantum mechanics, where the multiplication of observers in branches is interpreted as an origin of the appearance of probabilities, cf. e.g. [73]. Note that this does not in itself mean that the theory of this paper supports the Everettian interpretation of quantum mechanics; more on this in Section 12.

\(^{20}\) Some of these thoughts can be found in somewhat different formulations in the cosmology literature. For example, [74] and [68] recognize that “self-locating uncertainty” is a source of indeterminism or randomness. On the other hand, some authors (e.g. [1] and [67]) claim that taking this uncertainty seriously allows to derive the Born rule if one assumes the validity of quantum mechanics and an Everettian interpretation of the “quantum state of the universe”. However, none of them takes this thought to the extreme as is done in this paper, where I claim that all irreducible notions of chance whatsoever, and
But is world $W_2$ as “real” as $W_1$? It was one of the main concerns of this paper in Section 2 to defy such questions by introducing the notions of M- and P-existence. Both $W_1$ and $W_2$ M-exist (and so do the other possible worlds $W_i$), and all things inside a common world P-exist for each other. As explained in Section 2, I take the methodology to disregard all further questions of metaphysics, at least at this stage.\(^{21}\)

Thus, we arrive at a remarkable conclusion that we can summarize as follows:

**Observation 3.3** (From observers to observer states). According to the arguments and terminology of this section, regarding observers (like Abby the guinea pig, or the reader of these lines) as “things” (interacting with other things in well-defined worlds, cf. Informal definition 2.2) is inconsistent. We should drop the notion of “observer” in favor of a notion of “observer state” similarly as in Informal definition 3.1. Instead of dynamical time evolution of a thing in a world, we should model the experience of observers as probabilistic transitions from a state to a successor state.

In particular, Thought experiment 3.2 shows that observers can be “split” in some sense (arguably they can similarly get “fused”), which contradicts (or at least confuses) our usual idea of a “thing”. But then, the notion of a “world” in the sense of Informal definition 2.3 becomes irrelevant: being an observer is a quite bad synonym for “being in an observer state”, and observer states are not “things” in some “world”. Certainly, if they are not, this raises the question of why to us, as human observers (or rather as beings in human observer states), it looks so much as if there was some kind of world around us — and, indeed, one with the remarkable properties of simplicity and computability as we have described above. We will get back to this question, and in fact suggest an answer for it, in Section 8.

But to get there, we have to cast our informal insights of above into formal mathematical definitions. This will be done in the next section, and the main mathematical notion will turn out to be algorithmic probability.

### 4. ALGORITHMIC PROBABILITY

There are two main notions identified in Informal definition 3.1 above: that of the state of an observer, and that of a successor state. Our first goal will be to model both of these notions mathematically. Note that some of the following definitions will later on be simplified (using insights from the following sections); see in particular amended Postulates 14.1. We will begin by stipulating that observer states shall be modelled by the finite binary strings:\(^{22}\)

$$\{0, 1\}^* = \{\varepsilon, 0, 1, 00, 01, 10, 11, 000, \ldots\}$$

As explained and motivated on page 3, we will claim that every possible observer state corresponds to a binary string; and, vice versa, to every binary string there is a corresponding observer state, i.e. “state of being” of a conceivable observer. Now what would, for example, the string 01101 correspond to? What would it mean to “be in that observer state”? Would do the ones and zeros mean? This question would be similar to asking the question of “what does it mean to have the spacetime point $x = (0, 0.3, -0.14, 1.25)$?” in General Relativity. One would answer that a single spacetime point derives its meaning only from its relation to other spacetime points, and its actual coordinates are irrelevant artefacts of the choice of coordinate system. Similarly, as we will discuss in more detail below (in particular in Subsection 4.3), we should think of the binary strings as attaining their meaning from the computability relation to other strings, and we will also have a “choice of encoding” (similar to the choice of coordinate system) that renders the individual zeros and ones irrelevant. Moreover, we will see that we could have chosen any other countable set, for example the natural numbers $\mathbb{N}$, as describing the observer states, as long as there is a natural computable one-to-one correspondence with the finite binary strings.

Now, given any observer state $x \in \{0, 1\}^*$, what are the possible successor states? Here we arrive at a certain freedom of how to construct our theory; indeed, we will see later that we can abandon the notion of “successor state” altogether for reasons to be made clear in the next few sections, cf. Postulates 14.1. Yet, there are certain advantages in keeping this notion in the theory for now (in particular, backwards compatibility with earlier work in algorithmic information theory), so let us now define a notion of successor state. What this is supposed to mean is explained in Informal definition 3.1, but the description given there is of course far away from the stringency of a mathematical definition. Therefore, we will use a more abstract approach, and just say that to each observer (like Abby), there exists a corresponding map $A$ that, for every state $x$, gives the set $A(x)$ of all possible successor states of $x$. That is, we do not try to characterize the set of successor states; we just say that there exists a map $A$ which gives the set of successor states.

In our mathematical definition, the states will be described by finite binary strings:\(^{23}\)

$$\{0, 1\}^* = \{\varepsilon, 0, 1, 00, 01, 10, 11, 000, \ldots\}$$

More in detail, for Abby (and for every other observer) there is a subset $V$ of the binary strings that describes the

\(^{21}\) Philosophers might feel tempted to compare this viewpoint to David Lewis’ “modal realism” [73]: possible worlds are considered as real as the “actual” world. But this comparison is not quite accurate: here I am not making any claims about “reality” of worlds, but dismiss the use of this terminology altogether. All we are using is the fact that possible worlds M-exist, and we assume that all further philosophical questions along these lines are irrelevant for the purpose of this paper.

\(^{22}\) This set of binary strings will be used frequently in the remainder of the paper, so we use the opportunity to fix some notation. The length of a string $x \in \{0, 1\}^*$ will be denoted $\ell(x)$, for example $\ell(11) = 2$. The symbol $\varepsilon$ denotes the empty string of length zero.

\(^{23}\) This set of binary strings will be used frequently in the remainder of the paper, so we use the opportunity to fix some notation. The length of a string $x \in \{0, 1\}^*$ will be denoted $\ell(x)$, for example $\ell(11) = 2$. The symbol $\varepsilon$ denotes the empty string of length zero.
set of all states that this observer can possibly be in. Given two strings \( x \) and \( y \) from this set, it is either true that \( y \) is a successor state of \( x \) or not. Hence we can equivalently specify the observer by giving the set \( E \) of pairs \((x, y)\) with the property that \( y \) is a successor state of \( x \). But then, the pair \((V, E)\) is formally a directed graph that we also call \( A \). We call this graph an observer graph. This graph encodes the set of all conceivable state transitions that the corresponding observer can possibly undergo. This leads us to the following definition.

**Definition 4.1** (Observer graphs and histories). A computable directed rooted graph \( A = (V, E, \Lambda) \), where the set of vertices \( V \subset \{0, 1\}^* \) is a subset of the binary strings, \( E \subset V \times V \) is any set of edges, and the root is given by an arbitrary string \( \Lambda \in V \), is called an observer graph.

We write \( x \rightarrow_A y \) if \((x, y)\) is an edge of \( A \), i.e. if \((x, y)\) \( \in E \), and say that \( y \) is an \( A \)-successor state of \( x \). It will be convenient to denote the set of all \( A \)-successor states of \( x \) by \( A(x) \). A sequence \( x = (x_1, \ldots, x_n) \) of binary strings with \( x_1 = \Lambda \) is an \( A \)-history if \( x_i \rightarrow_A x_{i+1} \) for all \( i \).

The strings in an \( A \)-history can be interpreted as the temporal succession of an observer’s internal states, while the observer graph \( A \) determines what “links” later states to earlier states, that is, which later states describe “the same observer” as the earlier ones. The root \( \Lambda \) can be understood as some kind of “initial empty state”, preceding all observations. We will see below that it is necessary to have a root for measure-theoretic reasons. A generic example of an observer graph is illustrated in Figure 2.

![FIG. 2. Example of an arbitrary observer graph \( A = (V, E, \Lambda) \).](image)

The root \( \Lambda \) can be understood as some kind of “initial empty state”, preceding all observations. We will see below that it is necessary to have a root for measure-theoretic reasons. A generic example of an observer graph is illustrated in Figure 2.

![FIG. 2. Example of an arbitrary observer graph \( A = (V, E, \Lambda) \).](image)

The “computability” of the graph \( A \) is meant in the sense of theoretical computer science [76, 77]; we will come back later to the details of what this means. In Subsection 4.1, we will see why computability is necessary: we are going to consider drawing mathematical objects “at random”, and computability is necessary to stay in the realm of axiomatic systems. Intuitively, computability guarantees that an observer graph has some structure beyond total arbitrariness of assigning edges.

To illustrate the basic idea of this definition in more detail, let me discuss two examples. First, suppose that an unmanned spaceship has been sent to a planet orbiting a distant solar system; once it has arrived there, an autonomous robot, similar to NASA’s mars robot “Spirit", is marooned on the rocky surface of that planet. The robot starts with some large, empty memory (say, a hard disc with a capacity of a few terabytes) and then starts taking pictures and performing chemical analyses, maybe with the goal to detect potential life on the planet. Depending on its measurements, the robot is able to autonomously decide where to go and what experiments to perform next.

Suppose that at any time step, the robot’s internal memory (a finite binary string) consists of encodings of the previously taken pictures and a list of the previously performed measurements and their outcomes. Let the corresponding binary strings be called “robot memory states”. Moreover, suppose that an internal computer program decides deterministically at each time step what to do next, depending on the previous actions and measurement outcomes. Then we have an example of an observer graph \( A \) according to Definition 4.1: we define \( x \rightarrow_A y \) for robot memory states \( x, y \in \{0, 1\}^* \) if and only if \( x \) and \( y \) are possible consecutive robot memory states. The initial empty state will be identified with the root \( \Lambda \).

For example, suppose that \( x \) is a valid robot memory state such that the internal computer program decides, on the basis of the measurement outcomes recorded in \( x \), to analyze the water content in a previously picked sample of soil (and to record the outcome in its memory). If \( y \) describes any possible robot memory state which contains, in addition to \( x \), the record of any possible outcome of such an experiment, then \( y \) is a successor state of \( x \), i.e. \( x \rightarrow_A y \). Notice that

- the map \( A \) itself depends only on the robot’s internal computer program, not on the (unknown) properties of the planet, and
- for every valid robot memory state \( x \), there are several (possible) successor states \( y \), i.e. there is more than one string \( y \in \{0, 1\}^* \) such that \( x \rightarrow_A y \).

The sequence of robot memory states that are actually realized if we perform this experiment and see what happens is then an \( A \)-history, where the letter \( A \) refers to the robot’s observer graph \( A \). Every \( A \)-history describes a potential history of the robot’s sequential “experiences”.

As a second, more mathematically concrete example, define an observer graph \( A_P \) (\( P \) is for “prefix”) by \( x \rightarrow_A y \) if and only if \( x \) is a prefix of \( y \) with length \( \ell(x) + 1 = \ell(y) \); i.e.

\[
A_P(x) = \{x0, x1\};
\]

\[\text{e.g. } A_P(11) = \{110, 111\}.\]

Choose the empty string as the root: \( \Lambda := \varepsilon \). Then the following sequence is an \( A_P \)-history:

\[ (\varepsilon, 0, 0, 0, 010, 0101, 01011, 010111, \ldots). \]

We may interpret this as the internal states of some observer that, at each time step, acquires one new bit of information while fully remembering all its past observations.

---

24 In Definition 4.1, we will add a root \( \Lambda \), such that observer graphs are triplets \((V, E, \Lambda)\). The reason for this will be explained below.
We have argued above that the subsequent states of a guinea pig constitute a *guinea pig history*, which, in the terminology above, is simply an $A$-history $x = (x_1, \ldots, x_n)$ for some observer graph $A$. But what is the probability distribution $P$ on those histories that we have already announced in eq. (1)? The answer to this question is a crucial part of our theory, since it uniquely determines the “physics” that observers will experience.

It turns out that there are several different routes of argumentation that all lead to essentially the same probability distribution, namely algorithmic probability. Three of these routes will be described in detail in Section 6. Here we will focus on one of those possibilities, which motivates the choice with an intuition of “naturalness” (which, despite the wording, is not at all related to arguments that go under this name in particle physics). We will ask: is there a “natural” choice of probability distribution on the $A$-histories? This should ultimately be understood as a structural question, asking whether there is a “canonical aleatory structure” on the binary strings. The next subsection will argue that the answer to this question is yes.

### 4.1. Apriori probability from scratch

If an observer is in some state $x$, and the set of strings $A(x) \subset \{0, 1\}^*$ that are (possible) successor states has more than one element, then we would like to state that “the next string is chosen according to its natural apriori probability”.

How can we mathematically make sense of this idea? Is there some sort of probability distribution that we can infer from the heuristic notion of naturalness? If there was a finite set of (successor) states, then the equidistribution (all transitions equally probable) would be an obvious candidate. But the set of states (that is, of strings $\{0, 1\}^*$) is countably-infinite.

So what can we do? Let us step back for a moment and compare our situation to a very basic thought experiment on probability. When students start to learn probability theory at school, the first example they discuss is often that of a mathematical object from the “urn” of all mathematical objects. Mathematics itself represents the analog of the urn, or, say, the axiomatic system. In a mathematical formal system, we can “draw” a mathematical object by describing it. That is, we can write down a definition, based on the axioms of our formal system, and thereby selecting a mathematical object from the “urn” of all mathematical objects.

Thus, our random experiment might be performed by a mathematician, equipped with paper and pencil, who draws finite binary strings by describing them. Some strings are much easier to describe than others, even if they contain more bits. For example, the binary string

$$x := (0000\ldots 0)$$

is easy to describe — in fact, we have just described it (and it remains easily describable even if we demand a more formally sound way, say, a definition according to the rules of a fixed formal system). Similarly, it is easy to describe the string

$$x_{\pi} := 001000100001111101\ldots$$

containing the first $10^6$ binary digits of $\pi$. Some strings are much more difficult to describe, like

$$x_c := 010010100010000011110\ldots$$

which is a structureless string of 1000 bits, generated by a thousand tosses of a fair coin. The simplest way to describe the string by mathematical means seems to be to write it down bitwise, which arguably needs more effort (and more paper space) than the previous two strings.

So the strings $x$ and $x_{\pi}$ seem to be easier to describe, and, according to our urn metaphor, easier to “draw” than $x_c$, for example. Hence they should have larger probability with respect to the distribution that we are looking for.

But how can we formalize this idea? How can we “describe a string at random” and get a meaningful probability distribution? The idea of a mathematician, randomly writing down definitions on a piece of paper, is clearly not formal enough to determine a well-defined distribution.

It turns out that there is a precise formal definition of this very idea, which is known as *algorithmic probability*. The main insight is as follows: every step of formal manipulation performed by the mathematician can also be done by a universal computing machine. Thus, instead of asking how easy

---

25 This is also very intuitive in the context of the guinea pig thought experiments of Section 3: for any given state of a guinea pig, for example, we can always imagine an unbounded number of possible next states if we think of very wild and unexpected experiences.

26 What I write here has only motivational value; I do not claim to say anything profound about the foundations of probability theory.
it is for a mathematician to write down a definition of a binary string, we can ask how easy it is to program a universal computer to output the corresponding string.

I will now give a brief introduction to algorithmic information theory and probability which is mainly based on the book by Hutter [44]. I will be concise and focus only on those aspects that are relevant for the present paper, assuming that the reader is familiar with some basic notions of theoretical computer science (e.g., the Turing machine, the halting problem, and computability). A more detailed and pedagogical introduction can be found in the book by Li and Vitányi [78], see also [79]. As explained earlier, we denote the set of finite binary strings by \( \{0,1\}^* \), and the length of a string \( x \) is denoted \( \ell(x) \). The set \( \{0,1\}^* \) also contains a unique empty string \( \varepsilon \) of length \( \ell(\varepsilon) = 0 \).

One of the basic models of computation is the Turing machine [80], consisting of several (input, work and output) tapes carrying some data given by bits, a finite state machine [80], consisting of several (input, work and output) tapes, and a head that reads all of \( T \) but no more).

Now we distinguish two different possible events: first, the Turing machine \( T \) might halt and output a fixed, finite binary string \( x \in \{0,1\}^* \). Second, the Turing machine \( T \) might compute a possibly infinite bit string without ever halting; in this case, we may still observe that the output string starts with a finite bit sequence \( x \in \{0,1\}^* \). This is due to the fact that the output tape is assumed to be unidirectional. We use the definition given in [44]:

**Monotone TM.** We say \( T \) outputs/computes a string starting with \( x \in \{0,1\}^* \) on input \( p \in \{0,1\}^* \), and write \( T(p) = x^* \) if \( p \) is to the left of the input head when the last bit of \( x \) is output (\( T \) reads all of \( p \) but no more). \( T \) may continue operation and need not halt. For given \( x \), the set of such \( p \) forms a prefix code. We call such codes \( p \) minimal programs.

Now we are ready to define the crucial concepts of Kolmogorov complexity and algorithmic probability:

**Definition 4.2 (Algorithmic probability and complexity).** Let \( T \) be any monotone Turing machine. The monotone complexity or (monotone) Kolmogorov complexity of a string \( x \in \{0,1\}^* \) with respect to \( T \) is given by

\[
Km_T(x) := \min \{ \ell(p) \mid T(p) = x^* \}
\]

or by \( \infty \) if no such program \( p \) exists. Moreover, define the algorithmic probability that \( T \) outputs some string that starts with \( x \in \{0,1\}^* \) by

\[
M_T(x) := \sum_{p \mid T(p) = x^*} 2^{-\ell(p)}.
\]

Since the set of programs \( p \) such that \( T(p) = x^* \) is prefix-free, it follows from the Kraft inequality that \( M_T(x) \leq 1 \) for all \( x \). This expression can be interpreted as the probability that \( T \) outputs a string that starts with \( x \) if the input is chosen by tossing a fair coin. In more detail, \( M_T(x) \) is a semimeasure in the sense of the following definition:

**Definition 4.3 (Semimeasures [44]).** A function \( m : \{0,1\}^* \to \mathbb{R}_0^+ \) is called a semimeasure if \( m(\varepsilon) \leq 1 \) and \( m(x) \geq m(x0) + m(x1) \), and a probability measure if equality holds in both cases.

One of the most important facts in computer science is the existence of “universal computers” that are capable of simulating every other computer. That is, if \( U \) is a universal computer and \( T \) an arbitrary computer, then every program for \( T \) can easily be “translated” into a program for \( U \) which generates the same output:

**Theorem 4.4 (Universal Turing machine [44]).** There exists a universal monotone Turing machine \( U \) which simulates every monotone Turing machine \( T \) in the following sense: to every \( T \), there is a finite binary string \( x_T \in \{0,1\}^* \) such that

\[
T(p) = U(x_T p),
\]

where \( x_T p \) denotes the binary string obtained by concatenating \( x_T \) and \( p \).

Since a universal Turing machine \( U \) can simulate every other machine, its monotone complexity measure \( Km_U \) is “optimal” in the sense that \( Km_U(x) \leq Km_T(x) + c_T \) for every Turing machine \( T \), where \( c_T \in \mathbb{N} \) is a constant that does not depend on \( x \). A similar inequality holds for algorithmic probability: we have

\[
M_U(x) \geq c'_T \cdot M_T(x),
\]

where \( c'_T > 0 \) is another constant not depending on \( x \). In algorithmic information theory, these optimality inequalities are then used as a motivation to choose an arbitrary universal Turing machine \( U \), and to define all the relevant quantities with respect to that machine:

**Definition 4.5.** Fix any universal monotone Turing machine \( U \), and set \( Km(x) := Km_U(x) \) and \( M(x) := M_U(x) \).
below by a single computer program (computing $\Phi$), without necessarily knowing how close the approximation will be to the true value $f(x)$. In this case $f$ is called *enumerable*. If additionally $(-f)$ is enumerable as well, then we can estimate the error of approximation for finite $n$ by computably determining a finite interval that contains $f(x)$. If this is the case, $f$ is called *computable*.

**Theorem 4.6 (Universality of $M$ [44]).** $M$ is a “universal enumerable semimeasure”, i.e. an enumerable semimeasure which multiplicatively dominates all enumerable semimeasures $m$. That is, for every such $m$ there is $c_m > 0$ with

$$M(x) \geq c_m \cdot m(x);$$

we can choose $c_m = c \cdot 2^{-K(m)}$ with $c > 0$ some fixed constant. The semimeasure $M$ is enumerable, but not computable.

*The Kolmogorov complexity of a function like $m$ [i.e. $K(m)$] is defined as the length of the shortest self-delimiting code of a Turing machine computing this function. Up to a multiplicative constant, $M$ assigns higher probability to all $x$ than any other computable probability distribution [44].*

After this excursion to the general theory of algorithmic probability, let us return to our original problem: given any observer graph $A$, what is the apriori probability that any $A$-history containing string $x$ will have followed by string $y$? It will turn out to be useful to start with a simple example, which is the prefix observer graph $A_P$ as defined in Section 3: set $\Lambda := \varepsilon$, and for $x \in \{0,1\}^*$, let $A_P(x)$ be the set of all strings $y$ with length $\ell(y) = \ell(x) + 1$ such that $x$ is a prefix of $y$. For example,

$$A_P(101) = \{1010, 1011\}. $$

For this particular observer graph, the probability distribution that we are looking for can be described in a simple way: suppose we have an $A_P$-history $x_0 \rightarrow x_1 \rightarrow x_2 \rightarrow \ldots$ which starts with $x_0 = \varepsilon$ (i.e. the empty string) and that is continued indefinitely. Then $x_i = x_{i-1} b_i$, where $b_i \in \{0,1\}$ is some bit; we can describe the $A_P$-history equivalently by the (possibly infinite) sequence of bits $b := b_1 b_2 b_3 \ldots$ that are subsequently concatenated.

Hence, to define the probability of a transition $x \rightarrow y$ for $y = xb$ and $b \in \{0,1\}$ (denoted $P(y|x; A_P)$), we ask for the apriori probability that *any* (possibly infinite) sequence of bits that starts with the segment $x$ continues with the bit $b$. If we say that this probability is given by the corresponding behavior of a universal Turing machine, this means that we ask for the probability that a universal monotone Turing machine outputs bit $b$ as the next bit, assuming that it has already output the string $x$. Up to normalization, this equals by definition $M(xb)$; including normalization, we have motivated to define the transition probability as

$$P(xb|x; A_P) := \frac{M(xb)}{M(x0) + M(x1)}, \quad \text{(4)}$$

In other words, we can interpret the bits that appear on the output tape of a monotone Turing machine as an $A_P$-history. The semimeasure $M(y)$ is then interpreted as the apriori probability that an $A_P$ history encounters the string $y$. This leads directly to (4), which can also be written

$$P(xb|x; A_P) = \frac{M(b|x)}{M(0|x) + M(1|x)}, \quad \text{(5)}$$

where $M(b|x) := M(xb)/M(x)$ denotes the conditional probability [78] that the next bit is $b$ if $x$ has been output. That is, our transition probability is simply a normalized version (the “Solomonoff normalization” [78]) of $M(b|x)$.

So far so good, but we have so far ignored an important problem: there are infinitely many different universal monotone Turing machines $U$, and we have simply chosen one of them arbitrarily in Definition 4.5. But a different choice of universal machine will in general yield a different semimeasure $M$. These semimeasures are within a multiplicative constant of each other, as discussed above. For many applications in information theory, in particular those which are concerned with asymptotic statements on long sequences of bits, this kind of similarity is “good enough”. However, this is not true any more for the theory of this paper, where $M$ is supposed to describe physics: a supernova happening tomorrow with probability 1/2 represents a very different situation from a supernova happening tomorrow with probability $c\cdot1/2$ for $c = 10^{-20}$, for example. So which choice of $U$ is the “right” one?

There is currently no satisfactory answer to this question [81, 82], and one can make a general argument why it must be impossible to find a natural “machine-independent” definition [83]. Perhaps surprisingly, we will show in Subsection 4.3 that there is a way out of this problem by replacing the idea of machine-independence by a weaker notion of “covariance”. But for now, let us simply assume that the reference monotone machine $U$ is chosen arbitrarily among the universal machines.

Deferring this problem to the next subsection, let us first address a different question that will turn out to be closely related: how can we generalize the notion of a “monotone machine” to observer graphs $A$ which are different from the prefix observer graph $A_P$?

### 4.2. Graph machines: measures on histories

To define transition probabilities for other observer graphs $A \neq A_P$, we will now give a Turing machine model that generalizes the monotone Turing machine. Consider any monotone Turing machine $X$, but imagine that its output tape $O$ is replaced by an infinite sequence of output tapes $O_1, O_2, \ldots$ which are all initially blank. We will call the resulting machine $\tilde{X}$. This modified machine is supposed to perform exactly the same internal calculations (and the same reading operations on its input) as the original machine $X$. The only difference is that it writes the output in a different way: whenever $X$ would write the bits $b_1 b_2 b_3 \ldots$ on its output tape, $\tilde{X}$ will instead write the $A_P$-history

$$(\varepsilon, b_1, b_1 b_2, b_1 b_2 b_3, \ldots)$$

onto its output tapes. That is, $\tilde{X}$ writes the empty string $\varepsilon$ on tape $O_1$, the one-bit string $b_1$ on $O_2$, the two-bit string $b_1 b_2$ on $O_3$, and so on. Clearly, the modified machine $\tilde{X}$ is
is a straightforward generalization of the corresponding definition analogous to the one below Definition 4.5. Note that an enumerable $A$-measure is automatically computable, that is, it can also be computably estimated from above.

Note that the existence of $A$-measures is closely related to a graph-theoretic property of $A$:

**Lemma 4.10.** Call an observer graph $A = (V, E, \Lambda)$ dead-end free if for every $x \in V$ that can be reached from $\Lambda$, there exists some $y \in V$ such that $x \rightarrow y$.

For any observer graph $A$, there exists a positive $A$-measure (i.e., an $A$-measure $m$ such that for every $x \in V$ that can be reached from $\Lambda$, there exists an $A$-history $x = (\Lambda, \ldots, x)$ with $m(x; A) > 0$) if and only if $A$ is dead-end free. This is also equivalent to the existence of a strictly positive $A$-measure, i.e., an $A$-measure $m$ with $m(x; A) > 0$ for all $A$-histories $x$. 

Definition 4.9 (Semimeasure on histories). Let $A = (V, E, \Lambda)$ be any observer graph. A map $m$ which assigns to every finite $A$-history $x = (x_1, \ldots, x_n), n \in \mathbb{N}$, a non-negative real number $m(x; A)$ is called an $A$-semimeasure if it satisfies the following conditions:

$$1 \geq m(\Lambda; A),$$

$$m(x_1, \ldots, x_n; A) \geq \sum_{x_{n+1} \in \mathcal{A}(x_n)} m(x_1, \ldots, x_n, x_{n+1}; A).$$

If all inequalities “$\geq$” are equalities, $m$ is called an $A$-measure. If $x$ is not an $A$-history, we will by convention set $m(x; A) := 0$.

If $m$ is an $A$-semimeasure, we define a conditional version for $y = (y_1, \ldots, y_m)$ and $A$-histories $x = (x_1, \ldots, x_n)$ as

$$m(y|x; A) := \frac{m(x, y; A)}{m(x; A)}$$

whenever the denominator is not zero, where $x, y$ denotes the history obtained from concatenating histories $x$ and $y$.

In analogy to the standard case of monotone Turing machines in Subsection 4.1, an $A$-semimeasure will be called enumerable if it is computable from below, with a formal definition analogous to the one below Definition 4.5.
4. Algorithmic probability

The proof is simple: on order to have equality in the second inequality of Definition 4.9, there must exist at least one string \( x_{n+1} \in A(x_n) = A(x) \) to obtain a non-zero sum.

It is now straightforward to define a generalization of the semimeasure \( M \) from Definition 4.2:

**Definition 4.11** (Graph machine semimeasure). Let \( X \) be any graph machine, and let \( A = (V,E,\Lambda) \) be any observer graph. For every finite \( A \)-history \((x_1,x_2,\ldots,x_n)\), set

\[
M_X(x_1,\ldots,x_n) := \sum_{p:X(p,A) = (x_1,\ldots,x_n)} 2^{-\ell(p)},
\]

(sum over all minimal programs), that is, the probability that \( X \) computes an \( A \)-history that starts with \((x_1,\ldots,x_n)\). This is a semimeasure in the sense of Definition 4.9.

Furthermore, suppose that \( A \) is dead-end free, and that \( X \) is a graph machine with \( M_X(z|A) > 0 \) for all finite \( A \)-histories \( z \) (this is true in particular if \( X \) is \( A \)-universal in the sense of Definition 4.12 below). Then we define the normalized graph machine measure \( P_X \) recursively as

\[
P_X(x_1,\ldots,x_{n+1};A) := \mathcal{M}_X(x_1,\ldots,x_n,x_{n+1};A) / \sum_{y \in A(x_n)} \mathcal{M}_X(x_1,\ldots,x_n,y;A).
\]

The proof that \( M_X \) is a semimeasure is deferred to page 68 in the appendix. It is easy to check that \( P_X \) is an \( A \)-measure, and that the probability ratios of \( M \) and \( P \) agree:

\[
\frac{P_X(x_1,\ldots,x_n,x_{n+1};A)}{M_X(x_1,\ldots,x_n,x_{n+1};A)} \geq \frac{M_X(x_1,\ldots,x_n,x_{n+1};A)}{M_X(x_1,\ldots,x_n,x_{n+1};A)}.
\]

Indeed, this property uniquely characterizes the measure \( P_X \). We also have \( P_X(x;A) \geq M_X(x;A) \) and

\[
P_X(y|x;A) \geq M_X(y|x;A).
\]

The measure \( P_X \) is basically the Solomonoff normalization of the semimeasure \( M_X \), cf. [78, Sec. 4.5.3].

The next step is to show the existence of a universal graph machine, generalizing Theorem 4.4.

**Definition 4.12** (Universal graph machine). Let \( A \) be any observer graph. A graph machine \( U \) is called \( A \)-universal, if for every graph machine \( X \), there exists a string \( p_{X,A} \in \{0,1\}^* \) such that

\[
X(x,A) = U(p_{X,A}x,A) \quad \text{for all} \ x \in \{0,1\}^*. \tag{6}
\]

\( U \) is called universal if it is \( A \)-universal for every observer graph \( A \).
Equation (6) implies in particular that $X(x, A)$ is undefined if and only if $U(p_{X,A}, x, A)$ is undefined; if $X(x, A)$ attains several values at once (as described above), the same values shall be attained by $U(p_{X,A}, x, A)$. Note also that $U$ cannot produce any output if its input is a proper prefix of $p_{X,A}$ unless $X$ is a machine that never outputs anything. This is because $U(p, A) = (\Lambda, \ast)$ implies that $U(p_{X,A}, x, A) \neq (\Lambda, \ast)$ for all $x$, and so $X$ never produces any output.

A universal graph machine is able to simulate every other graph machine. Note that the string $p_{X,A}$ which achieves the simulation may depend on $A$. Another notion of universality would be that for every machine $X$, there is a string $p_{X} \in \{0,1\}^*$ not depending on $A$ such that $X(x, A) = U(p_{X}, x, A)$ for all strings $x \in \{0,1\}^*$ and all observer graphs $A$. In Lemma A.2 in the appendix, we prove that graph machines with this stronger notion of universality exist. But they will only be used as a proof tool and not be important for the following discussion.

Universal graph machines yield universal enumerable semimeasures in analogy to Theorem 4.6:

**Theorem 4.13 (Universal enumerable semimeasure).** If $A$ is an observer graph and $X$ is a graph machine, then $M_X(\cdot; A)$ is an enumerable $A$-semimeasure. Vice versa, for every enumerable $A$-semimeasure $m$, there exists a graph machine $X$ with $M_X(\cdot; A) = m(\cdot; A)$.

Moreover, if $X$ is $A$-universal, then $M_X(\cdot; A)$ is a universal enumerable $A$-semimeasure; that is, for every enumerable $A$-semimeasure $m$, it holds

$$M_X(x; A) \geq 2^{-K_X(m; A)}m(x; A)$$

for all finite $A$-histories $x$, where $K_X(m; A)$ denotes the length of the shortest binary string that makes $X$ emulate any graph machine which has $m$ as its $A$-semimeasure, i.e.

$$K_X(m; A) = \min\{\ell(p) \mid \forall x : X(px, A) = Y(x, A) \text{ and } \forall x : M_Y(x; A) = m(x; A)\}.$$

**Proof.** The value $M_X(x; A)$ can be computed from below by enumerating all input strings $p \in \{0,1\}^*$ with the property that $X(p, A) = (x, \ast)$. In Lemma A.4 in the appendix, we prove that for every enumerable $A$-semimeasure $m$ there exists a graph machine $Y$ such that $M_Y(x; A) = m(x; A)$ for all $x$. The proof of this statement is analogous to the proof of a corresponding statement for monotone Turing machines. If $X$ is $A$-universal, then there exists some string $p \in \{0,1\}^*$ such that $X(px, A) = Y(x, A)$ for all $x \in \{0,1\}^*$, hence

$$M_X(x; A) \geq 2^{-\ell(p)}M_Y(x; A) = 2^{-\ell(p)}m(x; A).$$

The claimed inequality follows from choosing the string $p$ with minimal length $\ell(p)$. \qed

In the special case of the prefix observer graph $A_P$ defined in eq. (2), we can interpret every monotone Turing machine $T$ as a graph machine, if we identify every\footnote{The fact that $x = \varepsilon$ is special is also reflected in [84, Lemma 1].} output string $x \in \{0,1\}^* \setminus \{\varepsilon\}$ of $T$ of length $n \in \mathbb{N}$ with the $A_P$-history $x := (\varepsilon, x_1, x_2, x_3, \ldots, x_n)$, where $x_i$ denotes the string consisting of the first $k$ bits of $x$. In particular, $M_T(x; A_P) = M_T(x)$ for all $x \neq \varepsilon$, and the transition probability $P_T(xb|x; A_P)$ for bits $b \in \{0,1\}$ is the Solomonoff normalization of conditional algorithmic probability,

$$P_T(xb|x; A_P) = \frac{M_T(b|x)}{M_T(0|x) + M_T(1|x)},$$

which agrees with our earlier guess, eq. (5).

### 4.3. Syntax, semantics, and covariance

So far, all our definitions and results are in complete analogy to the well-established theory of monotone Turing machines. Now we depart from this path by introducing a novel notion which is the *covariant graph machine*. Covariant graph machines have the property that they can simulate every universal graph machine in a particularly strong way: on the same inputs, they yield the same outputs up to a computable permutation and corresponding redefinition of the observer graph.

**Definition 4.14 (Covariance and computomorphisms).** A computable injective map $\varphi : V \to \{0,1\}^*$, where $V \subset \{0,1\}^*$ is a computable subset, will be called a *computomorphism* if its inverse $\varphi^{-1}$ is computable, too (equivalently, if its image in $\varphi$ is computable).

A graph machine $C$ is called *covariant* if for every observer graph $A = (V, E, A)$ and for every $A$-universal graph machine $X$ there exists a computomorphism $\varphi : V \to \{0,1\}^*$ such that

$$\varphi(X(p, A)) = C(p, \varphi \circ A \circ \varphi^{-1})$$

for all $p \in \{0,1\}^*$, where the left-hand side means that $\varphi$ shall be applied to all entries of the sequence of strings $X(p, A)$.

We will discuss the meaning of covariance in detail further below. To understand the notation, recall that every observer graph $A = (V, E, A)$ induces a corresponding map: $y \in A(x)$ iff $(x, y) \in E$. Consider the map $A' := \varphi \circ A \circ \varphi^{-1}$; this is the map which corresponds to the observer graph $A' = (V', E', A')$ with $A' = \varphi(A), V' = \varphi(V)$ and $(x', y') \in E'$ if and only if $(\varphi^{-1}(x'), \varphi^{-1}(y')) \in E$. That is, the observer graphs $A$ and $A'$ are identical up to “renaming the strings” according to the computomorphism $\varphi$.

The following theorem is of fundamental importance; its proof is technically involved and thus deferred to page 68.
in the appendix (there we also show that covariant graph machines need not be universal in general):

**Theorem 4.15.** There exists a universal covariant graph machine.

This machine is not unique; there certainly exist infinitely many universal graph machines. For us, the crucial property of covariant graph machines is that they attain exactly the same transition probabilities as any other universal graph machine:

**Lemma 4.16.** Let \( X \) be a covariant graph machine. Then, for every observer graph \( A = (V, E, \Lambda) \) and for every \( A \)-universal graph machine \( Y \), there exists a computomorphism \( \varphi : V \to \{0, 1\}^* \) such that

\[
M_Y(x; A) = M_X(\varphi(x); \varphi \circ A \circ \varphi^{-1})
\]

for all finite \( A \)-histories \( x \), and thus

\[
P_Y(y|x; A) = P_X(\varphi(y)|\varphi(x); \varphi \circ A \circ \varphi^{-1}) \tag{7}
\]

for all finite \( A \)-histories \((x, y)\).

Note that \( P \) can be undefined, as specified in Definition 4.11. However, the left-hand side of (7) is well-defined if and only if the right-hand side is well-defined.

**Proof.** This is a direct consequence of Definition 4.14: we have the equivalence

\[
\begin{align*}
Y(p, A) &= (x_1, x_2, \ldots, x_n, *) \\
\iff \varphi(Y(p, A)) &= (\varphi(x_1), \varphi(x_2), \ldots, \varphi(x_n), *) \\
\iff X(p, \varphi \circ A \circ \varphi^{-1}) &= (\varphi(x_1), \varphi(x_2), \ldots, \varphi(x_n), *) .
\end{align*}
\]

Thus, we get

\[
M_Y(x; A) = \sum_{p: Y(p, A) = (x, *)} 2^{-\ell(p)} = \sum_{p: X(p, \varphi \circ A \circ \varphi^{-1}) = (\varphi(x), *)} 2^{-\ell(p)}
\]

\[
= M_X(\varphi(x); \varphi \circ A \circ \varphi^{-1}) .
\]

The corresponding statement for \( P_Y \) follows easily from this, for example by using the equation

\[
P_Y(y|x; A) = \prod_{i=1}^{m} \frac{M_Y(x, y_1, \ldots, y_i; A)}{\sum_{y_i} M_Y(x, y_1, \ldots, y_{i-1}, y'_i; A)}
\]

if \( y = (y_1, \ldots, y_m) \).

Why have we introduced the notion of covariance? Recall the problem of choice of the universal reference machine that we first encountered in Subsection 4.1: when we postulate that observers experience transitions in their observer graph \( A \) according to probabilities \( P_U(y|x; A) \), then which universal machine \( U \) should we choose as reference machine? It is clear that different choices of \( U \) yield different probabilities \( P_U \) in general. At first sight, this seems to render our theory incomplete.

However, the notion of covariant machines solves this problem in a surprising way: our theory will be independent of the choice of reference machine, as long as we choose any universal covariant graph machine as our reference. Explaining why this is the case needs a bit of discussion.

First, suppose that \( X \) and \( Y \) are two different universal covariant graph machines. According to Lemma 4.16, if \( A = (V, E, \Lambda) \) is any observer graph, then there exists a computomorphism \( \varphi : V \to \{0, 1\}^* \) such that (7) holds. That is, \( X \) predicts exactly the same transition probabilities as \( Y \), except that the strings \( x \in V \) have to be replaced by \( \varphi(x) \), and the map \( A \) has to be replaced by \( \varphi \circ A \circ \varphi^{-1} \). This can be understood as follows: the binary strings \( x \) themselves are not actually the state of a corresponding observer at a certain time step, but they describe that state. That is, the state itself is some kind of abstract information content which is encoded in some string \( x \). This encoding is not unique; different encodings correspond to different universal covariant graph machines. However, the transition probabilities do not depend on the encoding.

In other words: if we choose reference machine \( X \) instead of \( Y \), then the set of possible observers (and their transition probabilities) described by our theory are exactly the same as before; the only difference is that the new choice of machine corresponds to a different encoding of the observer’s abstract information content into binary strings. The structure of the observer graph (including its computability structure), however, is preserved.

This graph machine notion of “covariance” is similar to an ubiquitous notion of covariance in physics (hence the name): whenever we have physical objects (for example space-time points) that are encoded in some coordinate system, there is a class of encodings that lead to equivalent descriptions of the same physics, in the sense that the physical laws preserve their form. In classical mechanics, these are the inertial frames, whereas in general relativity, it is a larger class of coordinate systems related by diffeomorphisms.

The area of mathematics that describes this behavior is
differential geometry [85]. Figure 4 shows the basic situation of introducing coordinates on a manifold. Two different coordinate maps \((\xi, \eta)\) are depicted.

The smooth map \(\varphi := \eta \circ \xi^{-1}\) is a coordinate transformation; it describes how to change from one coordinate system to the other without talking about the manifold itself anymore.

Suppose there is a random process happening in the manifold: a particle, initially located at some point \(p\), moves randomly to one of three points \(q_1, q_2,\) or \(q_3\). This is only a snapshot in time concerning a single “hop”; in the case that the process iterates, it may be useful to introduce a map \(B\) such that for points \(x\) in the manifold, the term \(B(x)\) describes the set of all possible points where the particle is allowed to move. For the single step that we are interested in, this means that \(B(p) = (q_1, q_2, q_3)\). The corresponding transition probability can be denoted \(P(q|p; B)\).

Now consider the description of this process in the coordinate system given by \(\xi\). Let \(x := \xi(p)\) and \(y_i := \xi(q_i)\) for \(i = 1, 2, 3\), then in this coordinate system, the particle starts at \(x\) and moves to one of the points \(y_1, y_2, y_3\) randomly. With the notation \(A(x) := (y_1, y_2, y_3)\), the transition probabilities for \(y \in A(x)\) can be written

\[
P_{\xi}(y|x; A).	ag{8}
\]

Looking at the process in the coordinate system given by \(\eta\), we can use the identities \(\eta(p) = \eta(\xi^{-1}(x)) = \varphi(x)\) and \(\eta(q_i) = \eta(\xi^{-1}(y_i)) = \varphi(y_i)\), and the observation

\[
A(x) = (y_1, y_2, y_3) \iff \varphi \circ A \circ \varphi^{-1} (\varphi(x)) = (\varphi(y_1), \varphi(y_2), \varphi(y_3))
\]

to write the transition probabilities for \(y \in A(x)\) as

\[
P_{\eta}(\varphi(y)|\varphi(x); \varphi \circ A \circ \varphi^{-1}).	ag{9}
\]

By definition, (8) and (9) have to be equal to describe the same random process. This equality is guaranteed by the fact that (8) and (9) are just different coordinate expressions of the same scalar function \(q \rightarrow P(q|p; B)\) defined on the manifold. Vice versa, if we only know the coordinate representations of the random process (the bottom part of Figure 4), but have no concept of the manifold in the first place (the top part of that figure), then equality of (8) and (9) is a necessary condition to deduce that there is a unique process going on which is only represented in two different ways.

According to Lemma 4.16, the transition probabilities \(P_U(y|x; A)\) on the observer graph satisfy the same equations as the probabilities on the manifold that we discussed above. Comparing the equations shows that each differential geometric notion has an analogue in our theory context:

<table>
<thead>
<tr>
<th>differential geometry</th>
<th>information theory</th>
</tr>
</thead>
<tbody>
<tr>
<td>actual point (p) on physical manifold</td>
<td>abstract information content (semantics)</td>
</tr>
<tr>
<td>coordinate space (\mathbb{R}^n)</td>
<td>set of binary strings ((0,1)^n)</td>
</tr>
<tr>
<td>coordinates of point (p)</td>
<td>description as a binary string (syntax)</td>
</tr>
<tr>
<td>choice of coordinate system (via (\xi) or (\eta))</td>
<td>choice of covariant graph machine ((X, E))</td>

<tr>
<td>coordinate transformation diffeomorphism (\varphi)</td>
<td>computomorphism (\varphi ) from Lemma 4.16</td>
</tr>
<tr>
<td>smooth function</td>
<td>computable function</td>
</tr>
<tr>
<td>coordinate maps (\xi, \eta)</td>
<td>encoding of abstract information into strings</td>
</tr>
</tbody>
</table>

Thus, Lemma 4.16 suggests the following interpretation: the choice of the reference graph machine (as long as it is universal covariant) corresponds to an arbitrary choice of encoding of abstract information into strings. The transition probabilities themselves do not depend on the encoding, similarly as physical predictions in General Relativity do not depend on the choice of the coordinate system. The mathematical equations transforming from one encoding to the other are the same as the differential geometric formulas describing coordinate transformations.

The notion of covariance can also be motivated from an alternative starting point. Namely, it is conceptually somewhat questionable to say that a guinea pig’s subjective experience equals a binary string; instead, it seems more plausible to say that the binary string describes the guinea pig’s experience. Hence our theory should allow to encode this experience (whatever it is) in different ways into binary strings; say, via two different maps \(\xi\) resp. \(\eta\). Then Figure 4 will still accurately represent the maps that appear in this situation, and there will be a computomorphism \(\varphi\) that maps one encoding to the other. This is the map \(\varphi\) that features in the definition of covariance.

In fact, every choice of pair of encodings, and thus of computomorphism \(\varphi\), can be described by a change of universal covariant graph machine. This is the content of the following lemma, which is proved on page 72 in the appendix:

**Lemma 4.17.** Let \(X\) be a covariant universal graph machine and \(\varphi : \{0,1\}^* \rightarrow \{0,1\}^*\) a computomorphism. Then the map

\[
Y(p, A) := \varphi^{-1}(X(p, \varphi \circ A \circ \varphi^{-1}))
\]

is a covariant universal graph machine, too. Moreover,

\[
M_Y(x; A) = M_X(\varphi(x); \varphi \circ A \circ \varphi^{-1})
\]

for all observer graphs \(A = (V, E, \Lambda)\) and \(A\)-histories \(x\), and

\[
P_Y(y|x; A) = P_X(\varphi(y)|\varphi(x); \varphi \circ A \circ \varphi^{-1})
\]

for all \(A\)-histories \((x, y)\).

The notion of covariant graph machines thus solves the problem of machine-dependence of \(P_U\) by promoting it from a problem to a feature: it reminds us that an observer’s experiences do not themselves equal binary strings, but are described by them. Therefore, similarly as in many other situations in physics, there must be a freedom of choice of encoding, which we have shown to be equivalent to a freedom of choice of universal covariant graph machine. Since transition probabilities are independent of the choice of machine, this allows us to show that our theory is, too.

Our definition of covariance should be regarded as a first attempt; there may be other possible definitions, and it would be interesting to explore them all. For example, note that there is a subtle asymmetry between Definition 4.14 and Lemma 4.17: in the former case, the computomorphism \(\varphi\) is allowed to depend on the observer graph \(A\), while in the latter case it is independent of \(A\). As a consequence, when we have two observer graphs \(A = (V_A, E_A, \Lambda_A)\) and \(B = (V_B, E_B, \Lambda_B)\), and they have one state \(x \in V_A \cap V_B\) in common, then a change of universal covariant graph
machine will in general change the corresponding maps to $\varphi_A \circ A \circ \varphi_A^{-1}$ and $\varphi_B \circ B \circ \varphi_B^{-1}$, respectively, and thus map $x$ to $\varphi_A(x) \neq \varphi_B(x)$. In this sense, there is no robust notion of “different observers being in the same state”.

Thus, a natural question is, for example, whether Definition 4.14 can be modified such that the computomorphism $\varphi$ depends only on the pair of machines $X$ and $C$, and not on the observer graph $A$. While it is easy to prove existence of graph machines with this stronger notion of covariance, it is however not clear whether those machines can be universal\(^{29}\), i.e. satisfy an analog of Theorem 4.15. Note that these questions may be interesting in more general contexts (such as artificial intelligence) beyond the scope of this paper.

While covariant graph machines allow us to formulate our theory in a well-defined and machine-independent way, it is clear that they do not solve all conceptual or practical problems related to the choice of reference machine. For example, given any fixed choice of universal covariant machine $U$, how would a given observer decide in practice what observer graph $A$ she corresponds to? This problem gets almost solved later on, when we amend our postulates in Section 14 by demanding that all observer graphs must be complete graphs (i.e. all transitions must be in principle allowed); it only leaves the choice of the root of this graph open. But a more severe problem is this: how should an observer actually predict concrete probabilities of future observations, given that she assumes that the theory in this paper is correct? We will certainly learn more about this question in the later sections (when we consider predictions of the theory), but we will not be able to answer it completely and conclusively.

While this problem appears particularly obvious and pressing in the context of our theory, it is actually present to some extent in other physical theories as well: the predictions of every mathematical theory have to be matched with the real world; from a possibly large set of solutions, we have to pick the one that applies to our specific situation. In general, it is far from trivial to find this correspondence\(^{30}\), and it always involves a fair amount of guesswork and previous data. For example, when we compute a solution to Einstein’s equations (say, a Schwarzschild solution), then there still remains the task to physically interpret the variables that appear in the equations (such as $r$, $\varphi$, and $\theta$). That is, one still has to extract concrete predictions for clicks of detectors, or for colored pixels on a CCD image sensor (taking pictures of planets orbiting in the gravitational field), from the equations.

This task can only be accomplished after a fair amount of effort has been spent on exploration, calibration, building and testing of devices. Viewing physics as induction, we may regard the results of all these efforts as additional data on which we condition our future predictions. If we have a theory that is probabilistic (like quantum mechanics, or the theory in this paper), then there appears the additional difficulty of devising statistical tests, and of setting practical thresholds of statistical significance that are deemed acceptable (such as the “5 sigma” standard in particle physics). In fact, Solomonoff himself argues for a strong conceptual relation between this kind of “statistical subjectivity” and the choice of universal computer in algorithmic probability\(^{87}\).

One should not be surprised to find these difficulties in the theory of this paper, too. Similarly as probabilistic predictions become perfectly testable only in the ideal case of an unbounded number of repetitions of a random experiment, most of our theory’s predictions will be formulated in the ideal “asymptotic” case of an observer making (and remembering) an unbounded number of observations. We will return to this discussion in Section 14.

5. THE POSTULATES OF THE THEORY

With the mathematical results of the previous section at hand, we are ready to state our main postulates — that is, the basic claims of our theory. As in every theory, the postulates themselves cannot be proven, but only (hopefully) be falsified if their predictions disagree with our observations. It was the goal of Sections 1–3 to motivate these postulates. Here they are.

Postulates 5.1 (Postulates of the theory).

1. Every observer is characterized by an observer graph $A = (V, E, A)$ in the sense of Definition 4.1. Being in some observer state $x \in V$ now, the observer will be in some observer state $y$ next, where $(x, y) \in E$.

2. The probability (chance) of the next state $y$ is $P(y|x; A)$, i.e. conditional algorithmic probability from Definition 4.11, where $x = (x_1, \ldots, x_n)$ is the sequence of all the previous states of the observer, and $x_1 = A$.

Remark. These postulates will be further simplified in Section 14, where we will argue that $A$ must always be the complete graph on all strings (with some root $A$). This will mostly remove the question of the “correct choice” of observer graph $A$.

This is the complete set of postulates. We do not assume any more; in particular, the theory does not assume any given external world or “universe” that contains the observer. There is only an implicit notion of an observer’s subjective time, counted in integer steps, which labels the sequence of observations. All other familiar properties of physics are assumed to emerge from those postulates, including the possibility to negotiate with other observers in comparing observations about an emergent external world.

While Postulate 2 involves the probabilities $P(y|x; A) = P_U(y|x; A)$ which depend on the choice of universal covariant graph machine $U$, the resulting theory is independent of the choice of reference machine, as we have discussed in detail in Subsection 4.3. Thus, the formulation of our two postulates is consistent in this sense (see however the discussion of drawbacks at the end of that subsection). As we have also shown in Subsection 4.3, there is a “freedom of choice

\(^{29}\) This problem seems to be related to the question whether the set of universal graph machines is enumerable, or whether one should use an alternative definition of universality in the first place. However, it is easy to see that covariance is not compatible, for example, with the strong notion of universality of Lemma A.2.

\(^{30}\) This difficulty has been acknowledged by philosophers, see e.g. [86], and the arguments following “So I suggest that the principal difficulty is not that of how to leave the theory outside the laboratory door, but that of how to get the laboratory inside the theory.”
of encoding” of an observer’s actual experience into binary strings, which is reflected by the mathematical properties of covariant graph machines.

If we accept these postulates, then also guinea pig (and human) observers should be described by an observer graph $A$ — but by which one? We will be able to say more about this question in later stages of this paper; in fact, we will argue in Section 14 that $A$ must always correspond to the complete graph that allows all transitions. However, it will only be possible to understand why this makes sense and is well-motivated after we have explored the consequences of the present formulation, which allows different choices of observer graphs and thus encodes more directly the intuition of Section 3. Moreover, allowing different observer graphs $A$ allows us to include earlier results from algorithmic information theory as a special case, where the choice $A = A_P$ (the prefix observer from eq. (2)) corresponds to graph machines that are equivalent to standard monotone Turing machines.

What kind of predictions can we hope to extract from the postulates above? Since the postulates are inherently probabilistic, it follows immediately that some aspects of what observers see will be contingent. But this is true for every non-deterministic theory of physics: a quantum theory of gravity, for example, will never be able to explain the exact distribution of every single pixel in a Hubble space telescope photograph of some region of the early universe. As long as a standard statistical interpretation of quantum theory is retained, at least some of the pixels will correspond to fundamentally random outcomes.

As in every probabilistic theory, the most reliable predictions can be made for asymptotic situations where the number of subsequent observations becomes large (basically due to variants of the law of large numbers). It is also this case where the choice of universal reference machine $U$ becomes irrelevant due to standard arguments from algorithmic information theory. Most of the following sections of this paper will therefore be concerned with this situation, with some notable exceptions (e.g. Observation 10.1). We will see that the postulates have interesting consequences, predicting many aspects of the physical world as we know it as well as some novel phenomena (as announced in the introduction).

However, the postulates also predict their own limitation: they seem to say that large aspects of what we call “laws of nature” are merely contingent (cf. Section 7). They predict some basic properties of these laws (for example, being algorithmically simple, and resembling some characteristics of quantum theory), but not their exact form. As such, there is a fundamental limitation to the predictive power of the postulates, and the resulting theory does not represent some kind of “theory of everything”; it will have to be silent on most things and useless for most fields of physics, including of course quantum gravity and particle physics. Its main benefit lies in the realm of the questions listed in Table 1.

6. THREE ROADS TO ONE THEORY

Before exploring the consequences of Postulates 5.1, it is instructive to recapitulate the motivation that has led us to formulate these postulates in the first place. In a nutshell, we can give three different lines of argumentation that all separately lead to the theory encapsulated in these two postulates, or at least to something close to it. They will be described below. While (i) and (ii) have been employed to some extent in conjunction above, (iii) is a completely separate argument in favor of our theory.

(i) Fundamental self-locating uncertainty. As described in Observation 2.4, it is in principle impossible for any given observer to determine in which M-existing world she is located, since there are always infinitely many M-existing worlds that are compatible with her observations. As I have argued in detail in Sections 2 and 2, it is dubious to consider one of those worlds as “really existing” and all others as merely “hypothetical”; similarly, there is no reason to pick one of those worlds, and claim that our specific observer “is really located in this world, and not in any other world”. In other words, the question of which is “the correct” world does simply not have an answer, since there is no matter of fact out there that would decide this question.

Thus, if one starts with an ontology of “worlds”, then one is forced to give up the idea of observers being part of one specific world. Rather, one will have to assign probabilities to the different worlds that are compatible with an observer’s experience, and argue that the observer should bet on future observations with respect to this probability distribution. Moreover, this probability should not be interpreted as arising from a lack of knowledge — it is not only unknown in which world the observer is located, it is in fact undetermined. In some sense, every given observer is “delocalized” over an ensemble of worlds. The probability distribution over future observations (conditioned on past observations) would somehow count “how many” of the possible worlds give rise to some specific future observations, and assign higher weight to observations that are more common in the space of possible worlds.

It turns out that this is exactly the main idea of algorithmic probability, if we understand “worlds” as “computable worlds” (more on the motivation of this identification in (ii) below). In fact, Observation A.1 in the appendix shows that this identification can be made exact: our theory can be interpreted as assigning probabilities to observations that correspond to statistics over ensembles of deterministic worlds.

Note, however, that the fundamental postulates of our theory (Postulates 5.1) do not mention the notion of “world” at all any more; there are only probabilities of observations. It is only later on (see Section 8) that we will show how the notion of an “external world” (but now in another sense) reappears in our theory as a consequence of the postulates.

It seems very likely that this is a generic outcome of any approach that takes the ideas above seriously: as soon as we talk about an observer experiencing a statistical mixture of some given class of possible worlds, this observer’s experiences will be described by statistics that does not any more correspond to one of the worlds in this class. In other words, it leads us to give up the standard ontology of “one objectively evolving universe, and the observer being part of it”, which brings us close to something like our theory.

But what about the choice of probability distribution over worlds? At first sight it seems like there is a large amount of freedom in choosing this distribution, but a moment’s thought tells us that we get some aspects of algorithmic probability automatically. If the class of worlds that we
consider relevant is countable, then we have to distribute unit probability measure to the infinitely many worlds. To this end, we must enumerate the worlds (possibly with repetition), and assign probability $p_1$ to the first world, $p_2$ to the second, and so on. To do this, $p_n$ must tend to zero, and we must have an effective method of enumeration. Our probability measure will then favor worlds that appear earlier in the enumeration, which can be interpreted as being somehow “simpler” or “more natural” to appear than others. These properties are certainly characteristic features of algorithmic probability, even though they do not ensure that we obtain algorithmic probability exactly.

(ii) Algorithmic probability as a natural propensity structure. The relevance of algorithmic probability can be motivated in terms of a certain structural argument which is ubiquitous in theoretical physics, but is rarely spelled out explicitly. Let us first discuss how this argument has played out in physics previously, before we analyze how it applies in the context of this paper. It will involve a way of thinking that is somewhat related, but not identical to, some ideas along the lines of (ontic) structural realism [88].

The main starting point is the architecture of modern mathematics. The axiomatic method has led to a way of thinking that emphasizes the presence or absence of natural structures as the main characteristics of mathematical “objects” that are used in mathematical reasoning. For example, if one is given a vector space $V$ (say, $\mathbb{R}^2$), then there is a distinguished, natural notion of adding two vectors $v, w \in V$ to obtain another vector $v + w$. Clearly, the “+” here is not the only way to add vectors; we could, for example, choose any homeomorphism $f : R^2 \rightarrow V$ and define $v \oplus w := f^{-1}(f(v) + f(w))$, which has similarly nice properties as “+”. The point is, however, that among these infinitely many possible ways to add vectors, one of them is considered natural, or distinguished (sometimes called “canonical”) once a vector space structure has been specified.

Once we have a vector space, we might also be interested in determining the length of a vector. Again, there are infinitely many ways to define this notion; in order to pick one, we can introduce an inner product $\langle \cdot, \cdot \rangle$ and define $\|v\| := \sqrt{\langle v, v \rangle}$. The resulting inner product structure might describe aspects of a world as experienced by an observer. Ordinary space is in fact to good approximation a Euclidean vector space $\mathbb{R}^3$. Now suppose that a (primitive) observer has discovered that her world is very well described by an inner product space of this form, and the resulting notion of “length” describes very accurately her measurements when she is using rulers to determine distances. One day, our observer discovers something new: namely, that she can build protractors to measure angles. After doing so for a while, she is amazed to discover that the following formula describes her measurements very accurately:

$$\angle(v, w) = \arccos \frac{\|v + w\|^2 - \|v - w\|^2}{4\|v\| \|w\|}.$$  

Should she be surprised? Arguably, no, she shouldn’t. The point is that vectors and lengths (coming from an inner product) are sufficient to determine a unique, natural notion of “angle”. The formal expression $\angle(v, w)$ has all the properties that one would expect an angle to have. Therefore, it is not surprising that an observer who is immersed in a world that admits distinguished notions of vectors and lengths will, one day or another, stumble across properties of her world that resemble this abstract notion. The observer will then give this property a name (“angle”), and will find that the already existing mathematics accurately describes it. In other words, the mere existence of this natural, “canonical” mathematical structure automatically manifests itself as a characteristic empirical property of the observer’s experience.

This way of thinking is particularly pronounced (though usually only implicit) in modern theories of physics, for example General Relativity (GR). In GR, spacetime is described by a dynamical semi-Riemannian manifold, carrying a metric field $g_{\mu\nu}$ which introduces a Lorentzian inner product structure on the tangent spaces [85]. In order to relate different tangent spaces, for example for allowing parallel transport of vectors along curves, one needs a notion of connection. Now the point is that the metric field itself already determines a unique, distinguished notion of connection (characterized by properties like torsion-freedom), the Levi-Civita connection. Therefore, it comes as no surprise that this is indeed the connection that determines many aspects of gravitational physics, featuring prominently in many of GR’s equations. Again, this reinforces the insight that if we search for the description of a structure in the empirical world (say, a connection), and if there is a natural, distinguished mathematical structure of this kind that arises from the mathematics that we are already using, then we should pick this particular structure and expect that it accurately describes what we are looking for.

Now how is all this related to algorithmic probability? To see this, let us apply the above prescription to the notion of physics itself, reduced to its most basic form. Arguably, the most basic requirement on any physical theory is that it allows us to predict future observations, given past observations. For example, if I lift a stone above my head and let it drop, then mechanics tells me to expect to see it fall downwards, not upwards. It may not always be possible to predict with certainty, but any reasonable theory should at least sometimes give us reasons to regard one possible future observation as more likely than another one. After all, this is what we are using when we test a physical theory empirically. But instead of talking about theories, we can interpret this as an insight about physics itself: physics, or “the external world”, is nothing but a structure that makes some possible future experiences more likely than others, or, in other words, that determines the chances of future observations. In this sense, we can view physics as an “aleatory structure” or “propensity structure”.

But then, clearly, the above idea of “natural structures”

---

31 More accurately, it is an affine space, since there is no distinguished notion of origin $(0,0,0)$. But this distinction is irrelevant for the present discussion. For the sake of the argument, we are also ignoring the possibility to define a norm that does not come from an inner product, leading to the notion of Banach spaces.

32 There may certainly be further benefits that one might hope to get from a physical theory, such as certain notions of “understanding what’s going on” that go beyond the mere possibility of prediction. But this point is irrelevant for the present discussion.

33 To be clear on this point, the word “physics” in this sentence does
tells us to look for a natural propensity structure that is already there, as part of the mathematics that we are already using, and to expect this structure to correspond to our experienced propensity structure, namely physics. In this case, the “mathematics that we are already using” is not as obviously characterized as in the case of GR, where we had a notion of a semi-Riemannian manifold. Here, we have not picked any such mathematical object. Nevertheless, there is some kind of mathematical structure that we are committing ourselves to, merely by definition of the notion of mathematics: this is the world of axiomatic systems, and thus of provability or computability. As soon as we are attempting to do empirical science, we have to organize and reason about our observations, which presumes logic and thus mathematics. Steps of inference or argumentation are computable; the correspondence between axiomatic systems and computability is deep and well-known [89]. Thus, I suggest that the computability structure over the finite binary strings (or, equivalently, natural numbers or any other countable set) represents the “mathematics that we are already using”, because we cannot avoid its use in the first place.

As soon as we are at this point, we are in fact given a natural propensity structure, namely algorithmic probability.34 Its formal definition leads to a natural notion of $P(y|x;A)$ (defined up to a choice of universal computer) which has all the properties of a conditional probability distribution. In other words, it has all the mathematical properties that we would expect from a “propensity of future observations, given past observations” to satisfy (we can derive our expectations on such a mathematical structure e.g. from arguments like Dutch book coherence [90]). Therefore, we should expect that this probability distribution manifests itself somehow in the experience of observers as a propensity — it is the natural candidate for physics.

(iii) Extrapolating Solomonoff induction. The postulates of our theory can also be understood in a more pragmatic way, namely as the result of extrapolating a successful method of prediction to a larger and more general domain.35

Let us first consider the realm of ordinary laboratory physics, where we set up experiments and record the outcomes. This regime of experience turns out to be described to excellent accuracy by computable probabilistic “laws of nature”, as we have discussed in detail in Section 2. But then, it follows automatically that observers in this regime can in principle successfully apply Solomonoff induction to predict their future experiences (disregarding practical problems of implementation). This is the reason why Solomonoff induction finds applications in artificial intelligence, where it is seen as an (albeit practically only partially implementable) “gold standard” for inductive inference of agents in computable environments [44].

It is a very simple and at the same time quite surprising insight to understand what this means: Solomonoff induction gives at least as good predictions as our best current physical theories, assuming that the agent in question has made enough previous observations. This is because Solomonoff induction will automatically discover the probabilistic laws of nature that we already have (such as quantum theory), based only on the statistics of previous observations. Moreover, it will also discover those laws that we do not yet know (if there are any, and if they apply in the agent’s regime of experience). In some sense, Solomonoff induction can thus be seen as a formalization of the scientific method itself.

One of the major motivations of this paper is the insight that there are regimes of experience that we are currently entering which go beyond the standard domain of physics, cf. Table 1: for example, we are interested in the experience of observers in extremely large universes (cosmology and the Boltzmann brain problem), or we would like to understand the experience of an agent if her brain is simulated on a computer (philosophy of mind). The problem is that physics as we currently know it is not designed to address these questions, at least not directly, as heralded by the controversial discussions that surround these topics. It is at this point where the insight above is quite suggestive: Solomonoff induction agrees perfectly with our best physical theories in the usual regime of physics, but it can also be applied in more general domains. But then, there is an obvious approach that we can take: Go ahead and apply Solomonoff induction to these new regimes of experience!

Applying Solomonoff induction means nothing but predicting the future according to conditional algorithmic probability. But this is exactly what Postulates 5.1 are claiming: namely, that we should bet on future experiences via conditional algorithmic probability. In this sense, our postulates can be seen as simply formalizing the prescription that we have derived above — namely, to apply Solomonoff induction to all regimes of experience.36 Therefore, while this paper for the most part takes the interpretation that Postulates 5.1 are fundamental, one does not have to take this perspective. One can instead interpret these postulates as “rules of thumb” that arise from the extrapolation of a successful method of prediction to a more general domain.

In the rest of the paper, we are indeed going to apply these “rules of thumb” to novel regimes of experience. For example, we will use them to exorcise the Boltzmann brains in Section 11, and we will derive predictions on brain emulation in Section 13.

Before we go there, however, we need to address a more basic question. The description above may make Solomonoff induction seem almost “magical”, by somehow agreeing with our best physical theories by fiat. But all the above really says, at least up to this point, is that agents who have made observations in agreement with our physical theories in the past should bet on the validity of those theories in the future. Clearly, our theory should say more than that to be

---

34 Not refer to physics as a science, but to “physics” in the sense of “the external world” — that is, our basic experience of constraints that seem to be external to us, and that make, in a way that we often cannot control but that seems to be governed by regularities, some possible observations more likely than others.

35 However, there are different versions of algorithmic probability, and this argument does not in itself directly tell us which of these versions we should use in our theory. We will come back to this question in Section 14.

36 This method of inference, “Solomonoff induction”, will be explained in more detail in Section 7. For the rest of this section, I assume that the reader has some basic familiarity with Solomonoff induction. The book by Li and Vitányi [78] gives a good introduction.

36 Note that there are certain subtleties to this claim, for example in the context of “predictivity” as we will discuss in Sections 7 and 14.
considered successful as a physical theory: it should explain why these past observations, indicating the presence of simple computable laws within an external world with certain properties, are to be expected in the first place. This is what we are going to address next.

7. SIMPLE PROBABILISTIC LAWS OF PHYSICS

“The only thing harder to understand than a law of statistical origin would be a law that is not of statistical origin, for then there would be no way for it [...] to come into being. On the other hand, when we view each of the laws of physics [...] as at bottom statistical in character, then we are at last able to forego the idea of a law that endures from everlasting to everlasting.” (John A. Wheeler, “Law Without Law” [48]).

Now we are ready to prove the first consequence of our postulates: our theory implies that observers will, with high probability, see simple probabilistic laws of physics (that is, laws that assign probabilities to observations and which have a short description), but the form of these laws will itself be contingent (that is, the result of a random process). This will be shown in detail in Theorems 7.3 and 7.8 below; we start with a preliminary instance of this phenomenon which rests on the notion of the complexity of a history:

Definition 7.1 (Graph machine complexity). For any graph machine $X$, observer graph $A$, and finite $A$-history $x$, set

$$Km_X(x; A) := \min\{\ell(p) \mid X(p, A) = (x, *)\}$$

or as $\infty$ if there is no such program $p$.

That is, the graph machine complexity of an $A$-history is the length of the shortest program that produces this history on the reference graph machine. This generalizes the notion of monotone complexity $Km$ as used in the theory of monotone Turing machines [78].

Suppose that an observer $A$ has experienced history $x = (x_1, \ldots, x_n)$. According to our postulates, her next observation will be described by a string $y \in A(x_n)$ with probability

$$P(y|x; A) = \frac{P(x, y; A)}{P(x; A)} \geq \frac{M(x, y; A)}{P(x; A)} \geq \frac{2^{-Km(x, y; A)}}{P(x; A)},$$

where all expressions are denoted with respect to the choice of universal covariant reference graph machine $U$.

This inequality tells us that transitions to those $y$ tend to be preferred which “fit more naturally” to the previous observations $x$. That is, if $(x, y)$ has a short description, i.e. if $Km(x, y; A)$ is small, then the corresponding $y$ tends to occur with higher probability than other possible successor states $y'$. Thus, simplicity in the sense of compressibility is favored. Intuitively, highly compressible histories (or strings) are those that contain regularities which can be used to generate shorter descriptions.

How can we define the notion of “regularities” and prove that they are somehow favored by algorithmic probability $P$? It turns out that an abstract approach is the most simple and powerful one: namely, defining a “regularity” of a history $x$ as some property for which a computer program can check in finite time whether or not it is present:

Definition 7.2 (Computable tests). A computable function $f$ that maps finite $A$-histories $x$ to single bits $f(x) \in \{0, 1\}$ is called a computable $A$-test (we drop the “$A$” if the observer graph is clear from the context). A computable $A$-test is called open if it can yield both 0 or 1 (interpreted as “yes” and “no”) for future observations — that is, if for every non-empty $A$-history $x = (x_1, \ldots, x_n)$ there exist $x_{n+1}, x'_{n+1} \in A(x_n)$ such that $f(x, x_{n+1}) = 0$ and $f(x, x'_{n+1}) = 1$.

Open computable $A$-tests only exist for observer graphs $A = (V, E, A)$ for which every vertex $x \in V$ that can be reached from $A$ has at least two outgoing edges. This will be true in most cases of interest, since most relevant observer graphs will have infinitely many outgoing edges for every vertex (see in particular Postulates 14.1).

Imagine an observer that has experienced $A$-history $x = (x_1, \ldots, x_n)$, and suppose that there is a computable $A$-test $f$ such that $f(x_1, x_2) = f(x_1, x_2, x_3) = \ldots = f(x_1, \ldots, x_n) = 1$. This describes a regularity: all previous observations had the property that the test $f$ yielded the outcome “yes”. In this case, the observer may believe that this regularity will also hold in the future. The following theorem shows that this will typically be correct due to the properties of algorithmic probability. We will first give the formal result and subsequently discuss its interpretation. We use the notation $x_1^k := (x_1, x_2, \ldots, x_k)$ if $x = (x_1, \ldots, x_n)$ and $k \leq n$.

Theorem 7.3 (Persistence of regularities). Let $A$ be a dead-end free observer graph, and $f$ an open computable $A$-test. For bits $a_1, \ldots, a_n, b \in \{0, 1\}$, define the measure $p$ as

$$p(b|a_1a_2\ldots a_n) := P\{f(x_1^{n+2}) = b \mid f(x_2^n) = a_1, \ldots, f(x_1^{n+1}) = a_n\},$$

and similarly define the semimeasure $m$ with $P$ replaced by $M$. Then we have\footnote{Note that $x_1 = \Lambda$ by definition, hence $f(x_1) = f(x_1)$ does not tell us anything interesting about the history, and we can drop it.} $m(0|1^n) \leq 2^{-K(n) + O(1)}$, and for the measure $p$ we have the slightly less explicit statement

$$p(1|1^n) \xrightarrow{n \to \infty} 1,$$

but the convergence is rapid since $\sum_{n=0}^{\infty} p(0|1^n) < \infty$. Moreover, the probability that $f(x_1^{n+1}) = 1$ for all $n \in \mathbb{N}$ is non-zero.

This theorem is proven on page 75 in the appendix. As a simple example, suppose that an observer $A$, after making observations $x = (x_1, \ldots, x_n)$, discovers some regularity in those observations. For example, this regularity might say that every $x_1$ starts with the bit 1, not with a 0 (possibly except for the first observation, which corresponds to $x_1 = A$). In the notation of Theorem 7.3, this would mean that $f(x_1^2) = \ldots = f(x_1^1) = 1$, where

$$f(x_1, \ldots, x_k) := \begin{cases} 1 & \text{if } x_k \text{ starts with a } '1' \\ 0 & \text{otherwise.} \end{cases}$$
Theorem 7.3 says that the probability \( p(1|1^n) \) of seeing that \( x_{n+2} \) starts with a ‘1’, given that all previous observations \( x_2, \ldots, x_{n+1} \) have started with a ‘1’, approaches unity asymptotically. In other words, the postulates of our theory say that it is rational for \( A \) to bet on the persistence of the regularity “observations starting with a ‘1’ ” if she has observed this regularity for long enough in the past.

Note that the assumption of openness of the computable test \( f \) is not only necessary for technical reasons, but also excludes some pathological situations. Imagine, for example, that the observer graph \( A \) is constructed in such a way that all finite A-histories \( \mathbf{x} = (x_1, \ldots, x_k) \) of length, say, \( k \leq 10^{100} \) have the property that \( f(\mathbf{x}) = 1 \), but all longer histories \( \mathbf{y} \) have the property that \( f(\mathbf{y}) = 0 \). An observer graph of this form might seem unnatural, but we can definitely construct one in a computable way. (We will discuss, and in fact resolve, the question of the choice of observer graph in Section 14.) In this case, the observer would be misled in extrapolating the regularity into the future. But this situation is excluded in the premises of the theorem, since such an \( f \) would not be an open \( A \)-test.

The regularities encoded in \( f \) do not need to depend on single observations only, but they can also refer to relations between previous observations, since \( f \) is a function of a full history \((x_1, \ldots, x_k)\). They can describe regularities that are far more elaborate than “starting with a 1”. For example, we can imagine a computable test of whether a given history \((x_1, \ldots, x_k)\) is the “typical” result of some given computable measure \( \mu \). As long as there are always “very surprising” next possible observations that are considered not \( \mu \)-typical (for example, that have \( \mu \)-probability zero), the premise of openness will be satisfied. We will consider this example in the context of Boltzmann brains in Section 11.

All in all, we can interpret Theorem 7.3 in terms of the following phenomenological principle:

**Observation 7.4 (Principle of persistent regularities).** Computable regularities that were holding in the past tend to persist in the future.

This principle is arguably an important principle of science (though “computability” is rarely explicitly involved); whenever we extrapolate past measurement results to the future, we are assuming it in one way or the other. It is interesting that it becomes a provable consequence of our theory’s fundamental postulates, suggesting a possible answer to the question of “why” this principle holds true in the first place.

However, if we compare the situation with physics as we know it, we find that there is more to understand. Namely, regularities in physics are often on the level of the statistics rather than in the actual results. In particular in the context of quantum theory, when we talk about “simple laws of physics”, we have simplicity in a peculiar form: often the probabilistic laws themselves seem to be simple, but the individual measurement outcomes turn out to be complex.

As an example, consider a single quantum spin-\( \frac{1}{2} \)-particle (a qubit) and the following experimental setup: the spin is first measured in Z-direction, then in X-direction, then in Z-direction again and so on — that is, Z- and X-direction are alternately measured on the single qubit; in total, there are \( n \) measurements. Assume for the sake of the argument that the particle starts in a quantum state where the spin points exactly in X-direction. Whenever the result is “spin-up”, it will be denoted by a one, and “spin-down” will be denoted by a zero. The result of the measurement is a binary string, consisting of \( n \) bits which encode the measurement outcomes.

Denote the eigenstates in Z-direction by \(|0\rangle \) and \(|1\rangle \), and those in X-direction by \(|+\rangle = (|0\rangle + |1\rangle)/\sqrt{2} \) and \(|-\rangle = (|0\rangle - |1\rangle)/\sqrt{2} \). The particle starts in state \(|+\rangle \). Thus, the first measurement (which is in Z-direction) will yield outcome “spin-up” or “spin-down” with probability \( \frac{1}{2} \) each. After that measurement, by the projection postulate, the state of the system will be either \(|0\rangle \) or \(|1\rangle \). But then, the following measurement in X-direction will again yield spin up or down with probability \( \frac{1}{2} \) each, and so on. According to elementary quantum mechanics, the resulting string will be completely random (and there are good arguments that this randomness is irreducible and not just “apparent” in some sense [91, 92]).

In the end, the situation is equivalent to \( n \) tosses of a fair coin: the \( n \) bit values are independently and identically distributed. But a string \( x \in \{0, 1\}^n \) that is generated by such a process is incompressible with high probability [93, 94], i.e. its monotone complexity \( K_m \) is close to maximal, i.e. \( K_m(x) \approx n = f(x) \).

In this example, the rules of quantum mechanics (which yield the outcome probabilities) are very simple, but the outcomes themselves are arbitrarily complex. This is a typical situation in physics. In what follows we will show that this kind of behavior is predicted by the theory of this paper.

Similarly as in Section 4, it makes sense to start by restricting our attention to the simplest prototype of observer graph \( A \), which is the prefix graph \( A_\mu \) from (2). In this case, the transition probability can be written as in (4), that is,

\[
P(xb|x; A_\mu) = \frac{M(xb)}{M(x0) + M(x1)} \sim M(b|x)
\]

for all strings \( x \in \{0, 1\}^n \) and bits \( b \in \{0, 1\} \), where \( \sim \) denotes equality up to a normalization constant which is independent of \( b \). That is, the transition probability is essentially given by the well-known universal semimeasure \( M \), defined via monotone Turing machines (cf. Section 4). Hence we are in the realm of classical algorithmic complexity theory and may use well-known results from this field as a guideline.

In the following, we will be concerned with characterizing the behavior of \( M(b|x) \) for very long strings \( x \), i.e. after a very large number of observations has been made. It will be helpful for us that this has been studied in algorithmic information theory, albeit with a different goal, under the name of Solomonoff induction [44, 78]. Its essence is captured by the following theorem [78]:

**Lemma 7.5 (Ref. [78], Corollary 5.2.1).** Let \( \mu \) be a computable measure. Then there is a set \( S \subseteq \{0, 1\}^\infty \) of \( \mu \)-measure one, such that for every \( x \in S \) and every \( b \in \{0, 1\} \)

\[
M(b|x^n) \overset{n \rightarrow \infty}{\sim} \mu(b|x^n).
\]

The arrow is to indicate that the difference between left- and right-hand side turns to zero, not that both sides converge individually. In this equation, \( x = x_1x_2x_3 \ldots \) is an infinite binary string, and \( x^n = x_1x_2 \ldots x_n \) denotes the string of length \( n \) that consists of the first \( n \) bits of \( x \).
What does this mean? Consider a physicist who observes a certain random process which emits random bits $x_1, x_2, \ldots$. Suppose that the physicist has no idea what random process it is; all she knows is that there is some underlying probability measure $\mu$ that describes the process accurately, and that $\mu$ is computable. Despite the missing knowledge, she would like to predict the probability of future outcome bits.

This situation is in principle close to what scientists are doing when they try to uncover the hidden mechanisms of nature; it is a simple model of science. The lemma above now says that in the long run, i.e. for large $n$, the physicist may simply use the universal semimeasure $M$ to predict the probability of the next outcomes. This is Solomonoff induction: algorithmic probability is used as a tool for prediction.

A simple example is given in [78, 95]: suppose that the unknown process is actually deterministic and emits only 1’s, that is, $\mu(1^n) = 1$ for all $n \in \mathbb{N}$, where $1^n = 111 \ldots 1$ is the string of length $n$ consisting only of 1’s. Then the probability that Solomonoff induction predicts a 0 as the next bit is asymptotically $M(0|1^n) = 2^{-K(n)+O(1)}$, which is of the order $1/n$ for most $n$. In particular, this converges to the “correct” probability zero for large $n$.

Let us now generalize Solomonoff induction to the realm of graph machines, i.e. to the case where the observer graph $A$ is different from the prefix graph $A_P$. In Definition 4.9, we have introduced the notion of measures and semimeasures on $A$-histories for arbitrary observer graphs $A = (V, E, A)$. In the following, we use the notation $A^n$ for the set of $A$-histories of length $n$, and $A^\infty$ for one-way countably-infinite $A$-histories (that is, infinite sequences $x = (x_1, x_2, \ldots)$ such that $x_i = \bot$ and $x_{i+1} \in A(x_i)$ for all $i$). We also adopt a slightly more general measure-theoretic viewpoint introduced in [78] (see there), and interpret any $A$-measure $\mu$ as a measure on (the Borel sets of) $A^\infty$, such that $\mu(x;A)$ is the weight of all infinite sequences that start with the finite $A$-history $x$. This works for every dead-end free observer graph $A$; the measure-theoretic details are worked out around Lemma A.7 in the appendix.

Now we introduce some quantities that will be useful in the following. They are straightforward generalizations of the corresponding quantities that appear in the proof of classical Solomonoff induction [78]. In what follows, we choose an arbitrary covariant universal graph machine $U$ and define all quantities which appear with respect to $U$; in particular, $M := M_U$. Let $A = (V, E, A)$ be a dead-end free observer graph and $\mu(\cdot;A)$ an $A$-measure. For every $y \in V$, set

$$S_n(y; A) := \sum_{x \in A^{n-1}} \mu(x; A) \left( \sqrt{M(y|x; A)} - \sqrt{\mu(y|x; A)} \right)^2.$$ 

Moreover, define

$$S_n(A) := \sum_{y \in V} S_n(y; A),$$

$$D(\mu(\cdot; A)||\mathcal{M}(\cdot; A)) := \sum_{y \in V} \mu(y; A) \ln \frac{\mu(y|x; A)}{M(y|x; A)},$$

and

$$D_n(A) := \sum_{x \in A^{n-1}} \mu(x; A) D(\mu(\cdot; A)||\mathcal{M}(\cdot; A)).$$

All three quantities are non-negative, and it is clear that $S_n(y; A)$ is finite. However, $S_n(A)$ and $D(\mu(\cdot; A)||\mathcal{M}(\cdot; A))$ as well as $D_n(A)$ might possibly be infinite if $\#V = \infty$. Note that $D(\mu(\cdot; A)||\mathcal{M}(\cdot; A))$ denotes the relative entropy or Kullback-Leibler divergence between the probability measure $\mu(\cdot; A)$ and the semimeasure $\mathcal{M}(\cdot; A)$. Moreover,

$$S_n(A) = \sum_{x \in A^{n-1}} \mu(x; A) H(M(\cdot|\cdot; A), \mu(\cdot|\cdot; A)),$$

where $H(P, Q) := \sum_{y \in V} \left( \sqrt{P(y)} - \sqrt{Q(y)} \right)^2$ is the Hellinger distance between two semimeasures $P$ and $Q$ on $V$. Since $H(P, Q) \leq D(P||Q)$ if $P$ is a measure and $Q$ a semimeasure [78], we get

$$S_n(A) \leq D_n(A).$$

As a next step, we show that $D_n(A)$ is finite. In fact, we have a much stronger statement:

**Lemma 7.6.** It holds $\sum_{n=1}^\infty D_n(A) \leq K(\mu; A) \ln 2$, where $K(\mu; A)$ is defined in Theorem 4.13.

**Proof.** This is a matter of calculation:

$$D_n(A) = \sum_{y \in V} \sum_{x \in A^{n-1}} \mu(y|x; A) \mu(x; A) \ln \frac{\mu(y|x; A)}{M(y|x; A)}$$

$$= \sum_{x \in A^n} \mu(x; A) \ln \frac{\mu(x|x_1, \ldots, x_{n-1}; A)}{M(x|x_1, \ldots, x_{n-1}; A)}.$$ 

Now we use the fact that $\mu$ is an $A$-measure: according to Definition 4.9, we have for all $k \in \mathbb{N}_0$

$$\mu(z; A) = \sum_{y \in V^k} \mu(z, y; A),$$

where $\mu(z, y; A) = 0$ by definition if $(z, y)$ is not an $A$-history. Setting $m := n + k$, this shows that for all $m \geq n$,

$$D_n(A) = \sum_{x \in A^n} \mu(x; A) \ln \frac{\mu(x|x_1, \ldots, x_{n-1}; A)}{M(x|x_1, \ldots, x_{n-1}; A)}.$$ 

Summing over $n$, the sum becomes a product inside the logarithm, and

$$\sum_{n=1}^\infty D_n(A) = \sum_{x \in A^m} \mu(x; A) \ln \prod_{n=1}^m \frac{\mu(x|x_1, \ldots, x_{n-1}; A)}{M(x|x_1, \ldots, x_{n-1}; A)}.$$ 

It follows from the definition of conditional probability that

$$\prod_{n=1}^m \mu(x|x_1, \ldots, x_{n-1}; A) = \mu(x_1, \ldots, x_m; A)$$

and similarly for $M$. Thus,

$$\sum_{n=1}^m D_n(A) = \sum_{x \in A^m} \mu(x; A) \ln \frac{\mu(x_1, \ldots, x_m; A)}{M(x_1, \ldots, x_m; A)}.$$ 

But according to Theorem 4.13, $M$ is a universal enumerable $A$-semimeasure, hence

$$M(x_1, \ldots, x_m; A) \geq 2^{-K(\mu; A)} \mu(x_1, \ldots, x_m; A),$$

and

$$\sum_{n=1}^m D_n(A) \leq \sum_{x \in A^m} \mu(x; A) \ln \frac{M(x_1, \ldots, x_m; A)}{M(x_1, \ldots, x_m; A)}.$$
and we get
\[ \sum_{n=1}^{\infty} D_n(A) \leq \sum_{x \in A^n} \mu(x; A) \ln 2^{K(\mu; A)} = K(\mu; A) \ln 2. \]

The claim follows from taking the limit \( m \to \infty \).

Now we are ready to state the generalization of Solomonoff induction to graph machines. While it is formulated in terms of the asymptotic behavior for history length \( n \to \infty \), we will discuss some intuition on its finite-\( n \)-behavior in Section 10.

**Theorem 7.7** (Generalized Solomonoff induction). Let \( A = (V, E, A) \) be a dead-end free observer graph, and \( \mu \) a computable \( A \)-measure. Then there is a set \( S \subseteq A^\infty \) of \( \mu \)-measurable 1 such that for all \( x \in S \) and \( y \in V \)
\[ M(y|x_1, \ldots, x_n; A) \xrightarrow{n \to \infty} \mu(y|x_1, \ldots, x_n; A), \]
in the sense that the Hellinger distance between left- and right-hand side (treated as functions of \( y \)) tends to zero:
\[ \sum_{y \in V} \left( \sqrt{M(y|x_1, \ldots, x_n; A)} - \sqrt{\mu(y|x_1, \ldots, x_n; A)} \right)^2 \xrightarrow{n \to \infty} 0. \]
Moreover, for all \( x \in S \), we have asymptotic normalization:
\[ \sum_{y \in V} M(y|x_1, \ldots, x_n; A) \xrightarrow{n \to \infty} 1. \]

**Proof.** The proof uses Lemma A.9 in the appendix. Define the non-negative function \( f_{n-1} : A^{n-1} \to \mathbb{R} \) as
\[ f_{n-1}(x) := \sum_{y \in V} \left( \sqrt{M(y|x; A)} - \sqrt{\mu(y|x; A)} \right)^2. \]

With notation of Lemma A.9 and due to (12), we have
\[ F_{n-1} = \sum_{x \in A^{n-1}} \mu(x; A) f_{n-1}(x) = S_n(A) \leq D_n(A). \]
Thus, Lemma 7.6 proves that \( \sum_{n=1}^{\infty} F_n \) is finite. But then, Lemma A.9 shows that there is some subset \( S \subseteq A^\infty \) of \( \mu \)-measure 1 such that \( \lim_{n \to \infty} f_n(x_1, \ldots, x_n) = 0 \) for all \( x \in S \), proving that the Hellinger distance goes to zero as claimed.

In order to see asymptotic normalization, define \( r_y := \sqrt{M(y|x_1, \ldots, x_n; A)} \) and \( s_y := \sqrt{\mu(y|x_1, \ldots, x_n; A)} \) for \( y \in V \). This defines square-summable vectors \( r, s \in \ell^2(V) \). By definition, we have for the \( \ell^2 \)-norm
\[ \| r - s \|^2 = \sum_{y \in V} (r_y - s_y)^2 = f_n(x_1, \ldots, x_n) \xrightarrow{n \to \infty} 0. \]
On the other hand, it holds \( \| r - s \| \leq \| r - s \| \) by the triangle inequality, hence
\[ \| r - s \| = \left( \sum_{y \in V} M(y|x_1, \ldots, x_n; A) - 1 \right) \]
must tend to zero for \( n \to \infty \).

This generalized formulation of Solomonoff induction will become important in Section 9. For now, we are more interested in its consequences for the asymptotic behavior of \( \mathcal{P}(y|x_1, \ldots, x_n; A) \) for \( n \to \infty \). This will lead us to formulate the following theorem that we can interpret as stating the “emergence of simple laws of physics”, even though the reason for this interpretation will only become gradually clear in the following. We use the simplified notation \( \mathcal{P}(\bullet) := \mathcal{P}(\bullet; A) \) and \( \mu(\bullet) := \mu(\bullet; A) \).

**Theorem 7.8** (Emergence of simple laws of physics). Let \( A \) be a dead-end free observer graph, and \( \mu \) a computable \( A \)-measure. Then
\[ \mathcal{P}\left\{ \mathcal{P}(y|x_1, \ldots, x_n) \xrightarrow{n \to \infty} \mu(y|x_1, \ldots, x_n) \right\} \geq 2^{-K(\mu; A)}, \]
that is, with probability at least \( 2^{-K(\mu; A)} \) (which is large if and only if \( \mu \) is simple), the actual transition probability \( \mathcal{P} \) will in the long run converge\(^{39} \) to the computable measure \( \mu \) (in Hellinger distance).

Before turning to the proof, let us briefly discuss the interpretation. In some sense, the observer \( A \) will randomly “catch a bunch of physical laws”, similarly as catching a cold: with probability of at least \( 2^{-K(\mu; A)} \), the observer will see that the computable measure \( \mu \) governs her experiences in the long run. This probability is vastly larger for simple measures \( \mu \), i.e., for measures that have a shorter description and thus smaller Kolmogorov complexity \( K(\mu; A) \). This will be explained in more detail below.

**Proof.** Since \( \mathcal{P} \) is just a normalized version of \( M \), Theorem 7.7 and asymptotic normalization imply that there is a Borel set \( S \subseteq A^\infty \) with \( \mu(S; A) = 1 \) such that
\[ \sum_{y \in V} \left( \sqrt{\mathcal{P}(y|x_1, \ldots, x_n)} - \sqrt{\mu(y|x_1, \ldots, x_n)} \right)^2 \xrightarrow{n \to \infty} 0 \]
for all \( x \in S \). Now if \( x \) is any finite \( A \)-history, Theorem 4.13 shows that \( \mathcal{P}(x; A) \geq M(x; A) \geq 2^{-K(\mu; A)} \mu(x; A) \). According to Lemma A.8, this inequality must then also be true

\(^{39} \)Regarding the speed of convergence, it seems to be a generic phenomenon that the standard notion of limit (for every \( \delta > 0 \) there is some \( N \in \mathbb{N} \) such that the difference is smaller than \( \delta \) for all \( n \geq N \) does not yield the strongest or most relevant notion of convergence in this context. That is, one would expect that even for “most” \( n < N \), the difference is small already. This is a consequence of the irregular behavior of Kolmogorov complexity, and can be seen nicely in the example on page 27: we have \( M(0^{1^n}) = 2^{-K(n)+O(1)} \). This expression tends to zero, but does so extremely slowly, since there are always astronomically large \( n \) with exceptionally small complexity \( K(n) \). However, it is close to zero (or, in more detail, to \( 1/n \) for most \( n \), since most \( n \) have \( K(n) \approx \log n \). An observer experiencing a random process with transition probabilities \( M(\bullet^{1^n}) \) will thus typically not notice the exceptional values of \( n \), and see convergence much faster than in the formal \( \delta \)-criterion. This shows that Theorem 7.8 features a very strong form of convergence, and it might be more relevant to ask whether \( \mu \)-typicality of outcomes might be a “persistent regularity” (in the sense of Observation 7.4), for example.
for $S$, i.e. $P(S; A) \geq 2^{-K(\mu; A)}\mu(S; A)$, lower-bounding the probability of the stated event as claimed\footnote{It is tempting to conjecture an alternative proof of Theorem 7.8 in the following way. Let $p \in \{0, 1\}^*$ be a minimal program for $\mu$ in the sense of Theorem 4.13; in particular, $\ell(p) = K(\mu; A)$. Consider the set of infinite strings $T := \{pq \mid q \in \{0, 1\}^\infty \}$, $q$ is Martin-Löf random, and the corresponding set $S$ of infinite output histories that are generated by our universal reference machine $U$ if all strings of $T$ are chosen as inputs. Since almost all infinite strings are Martin-Löf random, we have $\mu(S) \geq 2^{-\ell(p)} = 2^{-K(\mu; A)}$, and these output strings should be "$\mu$-typical" since the strings in $T$ are, and thus satisfy the property stated in Theorem 7.8. However, Exercise 5.2.8 in [78] shows that the latter assertion is not quite true. Thus, one needs more refined arguments to make this proof idea work. See also the result of [96].}. If the event on Theorem 7.8 happens (for some small measure $\mu$), the situation will look to the observer as follows:

- "What I observe seems to be fundamentally non-deterministic; it seems that that there is irreducible randomness that governs my experience."

- "But it seems that this randomness is itself subject to simple laws, which I can write down in concise equations. I can feed these equations into a computer and use them to predict future observations quite successfully, even if only probabilistically."

At this point, we are only talking about probabilities of observations, or experience — there is not yet any notion of "physics", or of an "external world" that the observer finds herself immersed in. We will come to this in the next section. What we have found so far, however, is that an observer may, with high probability, find probabilistic "laws" that govern her experiences, and they are with high probability simple in the sense of having a short description. Recalling our discussion at the beginning of Section 2, this closes the circle by supplying an actual explanation for the remarkable fact that we see these highly non-generic features.

While we do not know whether the the event in Theorem 7.8 (i.e. convergence to some computable measure $\mu$) happens with total probability one, we can interpret it in a way that suggests that some possibly weaker form should always be true. Namely, it seems to say that all regularities which persist according to Theorem 7.3 will tend to "fit together" into a coherent overall lawlike behavior. That is, if the answers to several computable tests $f$ all remain "yes", then this can be interpreted as consequences of a single computable statistical law (namely $\mu$) which yields $\mu$-typical outcomes. Since $\mu$-typicality of the sequence of observations is a much weaker statement than the convergence of probabilities in Theorem 7.8, it might still hold in all cases even if that strong convergence does not happen with unit probability. We leave a more detailed analysis of this to future work.

In the following, we will often assume that the event of Theorem 7.8 actually happens and explore the consequences of this. Even if this "strong" convergence to some measure $\mu$ does not have unit probability, we will work under the hypothesis that some kind of weaker version of it will always apply. We hope that the insights we gain by analyzing this strong convergence situation will also remain valid in the more general case.

It is interesting to see how Theorems 7.3 and 7.8 as well as Observation 7.4 circumvent a problem called "Goodman’s new riddle of induction" [97]. In the notation of Theorem 7.3, consider the computable test $f$ in (11). Fix some very large number $N \in \mathbb{N}$ (say, one with large Kolmogorov complexity $K(N) \gg 1$), and define a modified test $f'$ by

$$f'(x_1, \ldots, x_k) := \begin{cases} 
  f(x_1, \ldots, x_k) & \text{if } k \leq N, \\
  1 - f(x_1, \ldots, x_k) & \text{if } k > N.
\end{cases}$$

The computable test $f$ seems as simple or "natural" as properties like "green" or "blue" (after all, it just asks whether the current string $x_k$ starts with a "1"), whereas $f'$ resembles Goodman’s properties "grue" or "bleen". Now if our observer has seen that $f(x_1^1) = \ldots = f(x_1^n) = 1$, but $n \leq N$, then Theorem 7.3 applies to both $f$ and $f'$. The apparent contradiction is resolved by noting that Theorem 7.3 gives only an asymptotic statement: it only says that if $n$ is large enough, then $f$ (resp. $f'$) will yield the answer "yes" (i.e. 1) with high probability in the future, if they did in the past. Intuitively, what happens is that the regularity $f = 1$ stabilizes itself much faster than the regularity $f' = 1$. In particular, if $k = N$, then the statement $f(x_1, \ldots, x_{k+1}) = 1$ will hold with much higher probability than $f'(x_1, \ldots, x_{k+1}) = 1$ since $f$ is a simpler computable test, and thus the corresponding regularity statement is preferred by algorithmic probability. This intuition is confirmed by Theorem 7.8, even if its mathematical formulation is somewhat different: it says that simple regularities have a higher probability of stabilizing themselves indefinitely than more complex regularities.

If the event of Theorem 7.8 happens, then a simple computable measure $\mu$ will determine the observer’s experiences: the probability of future observations $y$ given past observations $x$ will asymptotically be given by

$$\mu(y|x; A) \equiv \mu(y|x_1, \ldots, x_n; A).$$

However, all that the observer "knows" is her current state $x_n$. Therefore, there is no way for an observer to use these conditional probabilities directly to predict the future, because $x_1, \ldots, x_{n-1}$ are unavailable to her in principle.

Clearly, there are exceptions: for example, if $A$ is a tree, then for every vertex $x$, there is a unique $A$-history $x = (\Lambda, \ldots, x)$ that ends with $x$. In this case, $x_n$ determines $x = (x_1, \ldots, x_n)$ uniquely, and we can interpret $\mu(y|x; A) := \mu(y|x; A)$ as the probability of future observations $y$, given the present observation (or state) $x$.

A similar conclusion can be drawn if $A$ is not a tree itself, but if the measure $\mu$ effectively makes it a tree — that is, if $\mu$ assigns probability zero to all those transitions that violate the tree structure. This is formalized in more detail in the following definition, which introduces several properties of $A$-measures that are relevant in this context.

**Definition 7.9** (Types of measures). Let $A = (V, E, \Lambda)$ be an observer graph, and $\mu$ an $A$-measure. If for every $x \in V$ there is at most one finite $A$-history $x = (\Lambda, \ldots, x)$ ending with $x$ such that $\mu(x; A) > 0$, then $\mu$ is called tree-like. The $A$-measure $\mu$ is called Markovian if $\mu(y|x; A) = \mu(y|x'; A)$ for all finite $A$-histories $x = (\Lambda, \ldots, x)$ and $x' = (\Lambda, \ldots, x)$ of non-zero measure that end with the same string $x \in V$. Finally, $\mu$ is called acyclic if repetitions have probability zero, i.e. if $\mu(x, y, z; x; A) = 0$ for all $x, y, z$. 
Note that the graph structure of $A$ imposes constraints on the measure: if $A$ is itself a tree then $\mu$ is tree-like; if $A$ is a directed acyclic graph then $\mu$ is acyclic. Tree-like measures are Markovian; the set of acyclic $A$-measures is convex.

By definition, Markovian measures do not lead to the problem explained above: they allow for direct prediction. On the other hand, Markovianity is clearly not necessary for an $A$-measure $\mu$ to allow an observer $A$ that experiences $\mu$ to make meaningful predictions. All we need is the following:\footnote{Predictive measures can be interpreted as those that always admit an implementation of what David Lewis [98] called the “Principal Principle”: namely, that subjective degrees of belief should be determined by objective chance if there is a notion of the latter.}

\section{Informal definition 7.10 (Predictivity).} Given any observer graph $A = (V,E,\Lambda)$, an $A$-measure $\mu$ is called \textit{predictive} if for all $x \in V$ that have non-zero probability to be reached from $\Lambda$, the measure uniquely induces a notion of conditional probability $\mu(y|x;A)$ for all $y = (y_1, \ldots, y_n), n \in \mathbb{N}$, such that $y_i \xrightarrow{A} y_{i+1}$.

In order to obtain a formal measure-theoretic definition, we have to specify what exactly we mean by this, which will be done in Section 12. For now, let us simply explore this informal definition intuitively, and defer the formal proofs to Section 12 and the appendix. Clearly, Markovian measures are predictive: the notion of conditional probability is

$$\mu(y|x;A) \equiv \mu(y|x;A),$$

where $x = (\Lambda, \ldots, x)$ is any $A$-history that ends with $x$. Thus, we have shown the first part of the following lemma:

\section{Lemma 7.11.} Markovian measures are predictive, and so are acyclic measures.

\textit{Proof.} If $\mu$ is acyclic, we have to recall some measure-theoretic aspects as detailed right before Lemma A.8 in the appendix. Finite $A$-histories which contain the string $x$ \textit{more than once} have $\mu$-probability zero. Therefore, the following events are well-defined:

$$X := \{x = (x_1, x_2, x_3, \ldots) \in A^\infty \mid \exists k : x_k = x\},$$

$$Y := \{x \in X \mid x \text{ is followed by } y\}.$$

In other words, if we know that $x \in X$, then there is a unique index $k \in \mathbb{N}$ such that $x_k = x$, and we can ask whether the sequence of strings $(x_{k+1}, \ldots, x_{k+n})$ equals $y \equiv (y_1, \ldots, y_n)$. With $\mu$ treated as a measure on $A^\infty$, the expression $\mu(Y|X) = \mu(X \cap Y)/\mu(X) = \mu(Y)/\mu(X)$ is the natural candidate for $\mu(y|x;A)$. This yields

$$\mu(y|x;A) \equiv \frac{\sum_{x=(\Lambda, \ldots, x)} \mu(x,y;A)}{\sum_{x=(\Lambda, \ldots, x)} \mu(x;A)}.$$ 

One can prove directly that both sums converge: the numerator is upper-bounded by the denominator, which in turn can be written $\sum_{x\in\mathcal{H}} \mu(x;A)$, where

$$\mathcal{H} = \{x = (\Lambda, \ldots, x) \mid \mu(x;A) > 0\}.$$

Since $\mu$ is acyclic, this is a \textit{prefix-free set}: $x \in \mathcal{H}$ implies that $(x,y) \notin \mathcal{H}$, for any $y = (y_1, \ldots, y_n), n \in \mathbb{N}$. Similarly as in the classical theory of bit strings, we have a generalized \textit{Kraft inequality}, Lemma A.10 in the appendix, which guarantees that the sum must then be upper-bounded by 1, and, in particular, must converge.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig5.png}
\caption{Sets of computable $A$-measures; ‘M’ is for Markovian, ‘A’ is for acyclic, and ‘T’ is for tree-like. Tree-like measures are acyclic and Markovian; acyclic measures and Markovian measures are predictive. Some (but not all) acyclic measures are Markovian, and vice versa. There exist predictive measures which are neither Markovian nor acyclic, and there exist non-predictive computable measures. Note that if an observer graph $A$ is a DAG (a tree) then every $A$-measure is acyclic (tree-like).
\end{figure}

The situation is schematically depicted in Figure 5. Note that there is a countably-infinite set of computable $A$-measures $\mu$, and they all appear with positive probability of (at least) $2^{-K(\mu:A)}$ in Theorem 7.8. Therefore, for any property that we have specified (such as predictivity or Markovianity), there is a strictly positive probability that an observer will experience a measure with this property in the long run.

This is true even though these properties may seem “fine-tuned” at first sight. For example, in order to be Markovian, an $A$-measure $\mu$ must satisfy a large set of strict equalities, expressing that transition probabilities only depend on the final observation and not on the previous ones. Clearly, among all $A$-measures (not just the computable ones), the set of Markovian measures is a null set, for any natural way of counting (unless $A$ itself is a tree). However, this is not true for the set of \textit{computable} $A$-measures — as long as there are Markovian measures which are simple to describe, observers need not be surprised to find one of them determine their observations. The naive notion of fine-tuning does not apply in this situation.

In the following sections, we will analyze in detail what observers see if the event in Theorem 7.8 actually happens; that is, if there is a simple computable measure $\mu$ that determines their observations asymptotically. Regarding the properties of $\mu$, it will turn out that the most important further distinction lies in the question of whether $\mu$ is acyclic or not. In Section 12 (when we discuss the relation to quantum theory), we will see that particularly interesting and counterintuitive effects emerge from cycles in histories, and predictivity will play an important role.
The discussion above exposes a particular conceptual subtlety that motivates a final comment. The discussion in Section 3 concluded that we have to specify probabilities for transitions $x \rightarrow y$ in order to have a meaningful physical theory. Implicitly, the way this was described suggested that this probability should depend only on $x$ and $y$, meaning that we have Markovian transition probabilities. As we have just seen, $P$ is not in general Markovian, and any measure $\mu$ that an observer “sees” in the long run need not be either. This does not contradict any of the discussion in Section 3, but we will see later on that it leads to some undesirable conceptual consequences. We will come back to this in detail in Section 14. In a nutshell, in that section we will argue that there should be a fully Markovian reformulation of our theory, but such a formulation faces formidable mathematical challenges. We will thus stick to the current formulation, which will turn out to give us a fully rigorous theory with fascinating predictions that are compatible with empirical observations, and we postpone the discussion of the aforementioned problem and its possible solution to Section 14.

8. AN EXTERNAL WORLD THAT CONTAINS THE OBSERVER

In Section 7, we have seen two ways in which our theory predicts that observers will, with high probability, make observations that are described by simple, probabilistic “laws of physics”. Namely, Theorem 7.8 states that these observations will asymptotically, with high probability, be governed by simple, probabilistic “laws of physics”. As we have just seen, $P$ is not in general Markovian, and any measure $\mu$ that an observer “sees” in the long run need not be either. This does not contradict any of the discussion in Section 3, but we will see later on that it leads to some undesirable conceptual consequences. We will come back to this in detail in Section 14. In a nutshell, in that section we will argue that there should be a fully Markovian reformulation of our theory, but such a formulation faces formidable mathematical challenges. We will thus stick to the current formulation, which will turn out to give us a fully rigorous theory with fascinating predictions that are compatible with empirical observations, and we postpone the discussion of the aforementioned problem and its possible solution to Section 14.

In Section 7, we have seen two ways in which our theory predicts that observers will, with high probability, make observations that are described by simple, probabilistic “laws of physics”. Namely, Theorem 7.8 states that these observations will asymptotically, with high probability, be governed by a simple computable measure $\mu$. While we do not know whether this will happen with probability one, Theorem 7.3 proves unconditionally that regularities that were holding in the past (say, due to mere chance) will with high probability persist in the future.

In this section, we will explore the consequences of these findings in more detail. In order to do so, we assume that the event of Theorem 7.8 actually happens — that is, a simple computable measure $\mu$ determines our observer’s experiences asymptotically. We will then argue that the lessons that we learn from this assumption should hold even if this assumption is not strictly satisfied (see also the discussion in the previous section).

In particular, we will see that our theory predicts (under the assumption just mentioned) that observers should indeed expect to see two facts which are features of our physics as we know it: first, the fact that the observer seems to be part of an external world that evolves in time (a “universe”), and second, that this external world seems to have had an absolute beginning in the past (the “Big Bang”).

Let us start by taking these two features as empirically confirmed facts about our physical world, and look at the “informational” consequences of these facts in the context of algorithmic complexity. A possible analysis (assuming a certain view on the quantum state that we do not need to share) has been performed by Tegmark [64] in a paper with the title “Does the universe in fact contain almost no information?”

In this paper, Tegmark argues that the universe’s quantum state at (or shortly after) the Big Bang has been very simple, in the sense that it had in principle a very short description. Furthermore, there seem to be algorithmically simple laws of nature determining the state’s time evolution. Thus, there should in principle exist a concise complete description of the current quantum state of the universe: simply append a description of the physical laws and a description (in some coordinate system) of the time that has passed since the Big Bang to a description of this initial quantum state. From this, a computationally immensely complex but algorithmically very simple computer program will be able to extract the present quantum state of the universe.

If we continue to accept Tegmark’s Everettian interpretation of quantum mechanics for the sake of the argument, then we can argue as follows. If, instead of the full quantum state, we restrict our attention to observations in specific branches of the wavefunction, then these observations will nevertheless look very complex, i.e. have large Kolmogorov complexity. The reason is very similar to, say a classical coin tossing process. While the process itself has a very short description, the actual sequence of outcomes of, say, $10^9$ coin tosses will typically have very high Kolmogorov complexity (namely, about $10^9$).

We can thus reformulate the two empirical facts about our universe in informational terms: observers make observations that are typically complex, but that are nevertheless described by an algorithmically simple evolution of an external world. This external world has the property that its evolution will in general only allow probabilistic predictions of future observations.

Let us now see how these observations can be understood as consequences of Theorem 7.8. If the event that is described in this theorem happens, then the transition probability $P$ will converge to a simple computable measure $\mu$,

$$P(y|x_1, \ldots, x_n; A) \xrightarrow{n \to \infty} \mu(y|x_1, \ldots, x_n; A),$$

where $K(\mu; A)$ is small. According to the definition in Theorem 4.13 this means the following. Denote the reference covariant universal graph machine by $U$. Then there is a short computer program (a finite binary string) $q$ of length $\ell(q) = K(\mu; A)$ with the property that

$$\sum_{p: U^{(q,p,A)} = (x,*)} 2^{-\ell(p)} = \mu(x; A)$$

for all finite $A$-histories $x = (x_1, \ldots, x_n)$. That is, he computer program $q$ causes the universal graph machine $U$ to operate in the following manner:

- after having read the prefix $q$ from its input, the graph machine enters a particular mode of computation. In this mode, it sequentially reads bits from the input tape (the finite sequence of these bits that has previously been read, at any given time step, is called $p$).
- The machine does (possibly very complex) computations in its working memory, and
- sometimes produces a new output $x_i$ on its output tape, building up an $A$-history $x_1, x_2, x_3, \ldots$.

Attaching the weights $2^{-\ell(p)}$ to the input strings $p$ can be interpreted as supplying independent, identically distributed random bits to the graph machine $U$ as input. These bits are read by the machine, and processed in a computation
which produces outputs from time to time. The outputs are distributed according to \( \mu \).

The outputs \( x_1, x_2, x_3, \ldots \) constitute the observer \( A \)'s (Abby’s) subjectively experienced history. However, if Abby herself — or an imaginary bystander — would like to predict future outputs (that is, future observations), she would better take the whole graph machine \( U \) into account. After all, this machine works according to a simple algorithm and contains a large internal memory whose content will have impact on the probability of future outputs.

In other words: Abby’s experience is shaped by the fact that she is only a small part of a “bigger” stochastic process, which is the graph machine \( U \) and its computational history. If Abby is smart enough, she may actually discover this, and call the graph machine her “external world”, and its computation the time evolution of this world. This time evolution will necessarily have a simple structure in the sense that it is governed by a short computer program.

![FIG. 6. As explained in the main text, we can abstract from the concrete graph machine model. It is irrelevant that we have used a colorful model with tapes, internal memory etc. in our definition; all that counts is the resulting abstract notion of computational processes. An observer’s subjectively experienced history corresponds to the outputs of a graph machine that generates the asymptotic measure \( \mu \). We can obtain the observer’s history by simply reading off the outputs from the output tapes, which defines a function \( f_A \) as sketched on the left-hand side. In the picture of the abstract computational process, this corresponds to a computable function \( f_A \) that reads off the output (that is, the current history) from wherever it appears in that process, with \( g(t) \) the complete state of this process at computational time \( t \). This is the formulation that we will use later in this paper. An observer will regard this computational process as her “external world”, and \( f_A \) can be interpreted as a “locator function”.](image)

One should not think too naively about this computation: this insight does not suggest that Abby should see actual tapes, binary digital memory or other specific aspects of a graph machine’s hardware in her external world. As every theoretical computer scientist knows, a computation in the mathematical sense is a process that is abstracted from the underlying machine model. For example, in order to define the universal apriori probability \( M(x) \) as in Definition 4.5, one starts by introducing a very concrete and colorful model of a “monotone Turing machine”, and then defines \( M(x) := M_U(x) \) for a universal machine \( U \) of this kind. But the actually resulting measures \( M \) can be characterized in different ways, without direct reference to a monotone Turing machine, for example as \emph{(universal) enumerable semimeasures} similarly to Theorem 4.6. The same is true for the generalization of \( M \) to graph machines that we are using in this paper.

This demonstrates that we would obtain the same theory (and set of measures) if we started with a very different machine model — say, a model where computation is not carried out on tapes, but in a way which more closely resembles a cellular automaton. The choice of model of computation is completely arbitrary and can be extremely exotic, as long as it can in principle be simulated by a graph machine, and (in the universal case) is in principle able to simulate every graph machine\( ^{42} \). All we need is a notion of sequentiality in reading the input (in order to define a semimeasure \( M \) in the first place), and a distinguished way to “read off” the machine’s output during the computation; all else can simply be regarded as an abstract computational process. This is explained in more detail in Figure 6, which also shows how we will use these abstract notions later in this paper.

While Abby should not expect to see binary digits or output tapes directly in her external world, there are some properties that are common to \emph{all} computational processes. One of them is the fact that computations initially start in a simple state (at least if the computer program has small algorithmic complexity, which is the case here), and tend to become more and more complex during the computation. This complexity comes from the unfolding of logical depth and computational complexity over many time steps, and in our case also from the random input bits.

Since the computer program has small algorithmic complexity, the computation itself will correspond to a simple algorithm. In principle, Abby may be able to determine a description of this algorithm or of some of its properties, and predict future time evolution according to these “laws of nature”. Likewise, Abby can use her knowledge of these laws to “calculate backwards”, and to retrodict the graph machine’s past states, given her knowledge about its current state. This may include internal machine times that have been before the machine has produced any output; in this sense, before what she might be tempted to call her “birth”.

If she continues computing backwards to retrodict earlier and earlier states of her universe, she will typically find simpler and more “compact” states, with measures of entropy or algorithmic complexity decreasing — simply because she is looking at earlier and earlier stages of an unfolding computation\( ^{43} \). At some point, Abby will necessarily arrive at the state that corresponds to the initial state of the graph machine’s computation (right after the machine \( U \) has read the prefix \( q \)), where simplicity and compactness are maximal. At this point, two cases are possible: either Abby’s method of computing backwards will cease to work; or Abby will retrodict a fictitious sequence of “states before the initial state”, typically with increasing complexity backwards

\( ^{42} \)In particular, there is no need to postulate that input bits are distributed independently identically at random, as (14) seems to suggest at first sight [99].

\( ^{43} \)For more details on this, in particular on the relation between complexity and entropy, see Section 11.
in time [100]. The latter scenario is only possible if there exist graph machine states which would be transformed by the computer program’s time evolution to the actual initial state of the computation.

In both cases, Abby will identify a singular state in the past, where the universe was particularly “small” and “simple” in the algorithmic sense. If Abby reconstructs the previous history of her universe (the computational process giving rise to her asymptotic measure $\mu$), she will see that complexity unfolded after this stage in a way that resembles an abstract computation according to simple probabilistic laws. Thus, she may call this initial state the “Big Bang”, and hypothesizes that time had its beginning in this moment. This is a striking consistency with our actual physical observations. We will discuss further details of this in Section 11.

Clearly, the description of this computational process is not unique. The fact that we can describe computations in many completely different ways (which however give equivalent algorithmic probabilities) must have a counterpart in Abby’s freedom of choosing among different descriptions of her external world which make equivalent empirical predictions. But this is a phenomenon which is well-known in many fields of physics. For example, we can choose different coordinate systems to describe spacetime, or we can prefer to add unobservable “pilot waves” to our description of quantum mechanics. The nontrivial prediction is that there exists some simple description in terms of concise laws of small algorithmic complexity, not that this description is unique. At the same time, our theory claims that this appearance of an external world is ultimately not fundamental: according to Postulates 5.1, what actually determines Abby’s future observations is conditional algorithmic probability. In particular, her observations do not fundamentally supervene on this “physical universe”; it is merely a useful tool to predict her future observations. Nonetheless, this universe will seem perfectly real to her, since its state is strongly correlated with her experiences. If the measure $\mu$ that is computed within her computational universe assigns probability close to one to the experience of hitting her head against a brick, then the corresponding experience of pain will probably render all abstract insights into the non-fundamental nature of that brick irrelevant.

For what follows, it will be useful to formulate our findings within a certain terminology that has first appeared in the context of the foundations of quantum mechanics: that of an ontological model [101, 102]. We will be using this word in a context that differs somewhat from its originally intended use. The starting point will be to talk about an operational theory [102]. In the context of quantum mechanics, this would be a theory that describes preparation procedures (represented, for example, by quantum states) and measurements. In our context, we can regard an observer $A$ that has experienced an $A$-history $x$ as being subject to a preparation procedure which leads to an operational state $\mu(y|x; A)$. The corresponding measurement procedure would be to wait for $m$ time steps to see what new observations $y = (y_1, \ldots, y_m)$ the observer actually makes next\(^{44}\). If we adopt this terminology, then the graph machine computation becomes an ontological model according to the following definition [102]:

“An ontological model is an attempt to offer an explanation of the success of an operational theory by assuming that there exist physical systems that are the subject of the experiment. These systems are presumed to have attributes regardless of whether they are being subjected to experimental test, and regardless of what anyone knows about them. These attributes describe the real state of affairs of the system. Thus, a specification of which instance of each attribute applies at a given time we call the ontic state of the system. If the ontic state is not completely specified after specifying the preparation procedure, then the additional variables required to specify it are called hidden variables. We shall denote the complete set of variables in an ontological model by $\lambda$, and the space of values of $\lambda$ by $\Omega$.”

We can apply this terminology to the graph machine computation (generating the measure $\mu$), and arrive at the following observation (we will get back to this in Section 12).

**Observation 8.1 (Computational ontological model).** Suppose that an event as described in Theorem 7.8 actually happens, i.e. that $P(y|x; A)$ converges to a (simple) computable measure $\mu(y|x; A)$ (which happens with probability at least $2^{-K(\mu;A)}$). If we regard the conditional probability $\mu(y|x; A)$ as an operational state preparation in the sense explained above, then the corresponding state of the computational process which generates the measure $\mu$ represents an ontological model of the corresponding operational theory. This “computational ontological model” has a set of states $\Omega$ that corresponds to the possible configurations of the computational process. Formulating this process in terms of a graph machine, preparation of $\mu(y|x; A)$ amounts to the preparation of a probability distribution over the configurations $\lambda \in \Omega$, including, for example, identically independently distributed bits on the unread part of the input tape. The “hidden variables” include those parts of the machine which cannot be inferred from the output alone. This ontological model is simple (in the sense that it is expected to have small Kolmogorov complexity $K(\mu; A)$), probabilistic, and evolves in time in a way that has once started in a particularly simple initial state (“Big Bang”). We can thus interpret it as an observer’s external world.

Is this “computational ontological model” unique? Even if we stick to graph machines and fix our universal reference machine $U$, there may be more than one graph machine program of length $K(\mu; A)$ which computes $\mu$. If those programs make the graph machine perform different computations (which however all lead to an output string statistics resembling $\mu$), then we have several equally simple computational ontological models\(^{45}\). However, we expect that there are not too many programs of length $K(\mu; A)$ that compute $\mu$. What we take as evidence for this conclusion is that there is a well-known analogous statement for standard Kolmogorov

---

\(^{44}\) It is usually considered crucial in the context of quantum theory that there is not only a single measurement, but a “choice of measure-

\(^{45}\) As we have seen around Figure 6, we have an additional notion of non-uniqueness coming from the fact that any given fixed computation can be represented abstractly in many different ways.
complexity, which says that the number of shortest programs of any object is bounded by a universal constant, cf. [78, Exercise 4.3.6]. We conjecture that the main mathematical argument carries over to graph machine complexity $K(\mu; A)$, in which case it would follow that the number of (simplest) computational ontological models of any computable $A$-measure $\mu$ is bounded by a universal constant.

Arguably, what we call “our universe” is essentially nothing but a (certain type of) ontological model of our observations, which is useful to us because it helps us predict future observations. The arguments above might suggest that what we call our “physical universe” corresponds exactly to this computational ontological model. As we will see in Section 12, this is almost a valid guess, but not quite: there will be additional complications due to the fact that observers generically do not have full information about the state of this computational ontological model. Observers may then decide to use a more compact “effective description” in terms of only the information that is in principle available to them, which will be responsible for certain probabilistic effects that resemble properties of quantum theory.

Therefore, our theory predicts some sort of effective pan-computationalism [103]: our (emergent external) world is in some sense a computation. Nevertheless, there is no naive correspondence between the structure of our world and the causal structure of the computational process as it is usually envisioned. Earlier proposals of that kind, including approaches by Zuse [104], Schmidhuber [105], ’t Hooft [106] and Lloyd [107], take a naive one-to-one mapping between modules of the model of computation (such as “gates” or “tape cells”) and space-time regions. The theory of this paper predicts that there is typically only a weak correspondence of this form, going beyond the naive proposals just mentioned, as will be discussed in more detail in Section 12.

9. EMERGENCE OF OBJECTIVE REALITY

“How come ‘one world’ out of many observer-participants?” (J. A. Wheeler [21]).

In the previous sections, we have seen that our theory predicts many aspects of physics as we know it: with high probability, observers see simple probabilistic “laws of nature”, and find themselves to be part of a larger external world that they may call “the universe”. However, there is one further crucial aspect of physics that is not trivially true in our theory: namely that different observers see the same physical world\(^{46}\).

In fact, demanding that all observers see the same is not necessary, and will turn out to be wrong. The weaker, but crucial empirical fact that has to be reproduced by our theory is that different observers that can communicate with one another will agree on seeing the same physics around the time of communication. Or, as Smérald and Rovelli put it in [108], “In fact, the very reason we can do science is because of the consistency we find in nature: if I see an elephant and I ask you what you see, I expect you to tell me that you too see an elephant. If not, something is wrong.”

We will now show that the mathematics of Solomonoff induction guarantees this to be the case within our theory. Suppose that Abby the guinea pig finds herself to be part of a probabilistic universe described by a simple computable measure $\mu$, as predicted by Theorem 7.8. As explained in Section 8, this means that there is a simple computational process (as illustrated in Figure 6) which generates her sequence of observer states according to the measure $\mu$. She can interpret this computation as an evolving “external world”, encompassing and processing additional information that is not directly accessible to her.

Suppose that Abby encounters another guinea pig, called Bambi\(_{3rd}\), in her (Abby’s) external world. The subscript indicates that this describes a “third-person perspective”: Abby points to something (an object, a pattern) in her world that she calls “Bambi”. Moreover, Abby can in principle consider the information that is stored and processed in Bambi\(_{3rd}\)’s brain, and reason about how this information changes in time. Even if it may be impossible for Abby (or unethical) to open Bambi\(_{3rd}\)’s brain and read out all this information in practice, Abby can still argue that this information content changes over time, in accordance with the evolution of Abby’s world. If this evolution is probabilistic, then there will be an induced probability distribution $P_{3rd}$ that describes the distribution of Bambi\(_{3rd}\)’s brain states one moment after the other.

But now, if this information content corresponds to a sequence of binary strings $x = (x_1, \ldots, x_n)$, then our theory forces us to regard these strings as observer states. In other words, we can think of the corresponding first-person perspective that describes “what it is like” to be in state $x_i$, and think of a corresponding abstract observer Bambi\(_{1st}\) — the actual “mode of being” in those states.

Typically, Abby will expect (and, if they are friends, probably hope) that Bambi\(_{3rd}\) and Bambi\(_{1st}\) are in some sense “identical”. In other words, when she observes Bambi\(_{3rd}\) expressing a feeling of happiness on seeing Abby (together with the corresponding neural correlates), she will assume that Bambi\(_{1st}\) really does have that feeling in some sense. But is this really true? Given that our theory allows that Bambi\(_{3rd}\) and Bambi\(_{1st}\) are in some sense different things, is such an identification possible and meaningful?

This is not a philosophical text, but a probabilistic mathematical theory, and so the corresponding formal question that we can ask (and that arguably addresses an important aspect of this question) is a matter of comparing probabilities: on the one hand, we have $P_{3rd}$, the probability induced by Abby’s world on Bambi\(_{3rd}\)’s fate; on the other hand, we have algorithmic probability, $P_{1st} := P$ that determines Bambi\(_{1st}\)’s actual fate. Is there any relation between the two?

To put these considerations into a more concrete form, consider the question whether the sun rises tomorrow. Suppose that Abby has gathered enough information about her external world, and about the physical measure $\mu$, to expect with probability close to one that she is going to see the sun rise tomorrow. She would thus also have close to 100% chance of seeing Bambi\(_{3rd}\) see the sun rise tomorrow.

\(^{46}\) Note that the main notion on which this work rests is that of an “observer state”, not of an “observer”, as noted in Observation 3.3. What we mean by an observer in this section will become clear from the context.
FIG. 7. Informal illustration of the setup that is considered in this section. We have an observer A (Abby) who finds herself to be part of a simple computational process which generates some A-measure $\mu$ (we know from Theorem 7.8 that this happens with high probability). This means that the computational process is what she may call her “external world” as explained in Section 8; her observer state history (here e.g. $(x_1, x_2, x_3, x_4)$) is a function $f_A$ of the process’ state (see also Figure 6). Suppose that there is another simple computable function $f_B$, acting on the states of this graph machine, which produces a B-history, where B is another observer graph. Then Abby can interpret this as “having another observer Bambi$_{3rd}$ in her world”, and she may predict what happens to Bambi$_{3rd}$ in her world in the future. However, Bambi’s first-person perspective, Bambi$_{3rd}$, is governed by algorithmic probability, $P_{3rd} \equiv P$; and these probabilities may a priori be completely unrelated. In other words, what Bambi$_{3rd}$ really sees next (symbolized by the grey speech bubble) may be very different from what Abby sees that Bambi$_{3rd}$ is seeing. But as we show in Theorem 9.2 below, asymptotically (i.e., for a large number of observations), the conditional probabilities $P_{3rd}$ and $P_{1st}$ will be very close to each other — in this sense, Abbi and Bambi will be “part of the same world”, and Bambi$_{3rd}$ will be a faithful representation of Bambi$_{1st}$. This is a probabilistic form of emergent objective reality.

But what is Bambi$_{1st}$’s actual chance of seeing the sun rise tomorrow, from her first-person perspective?

Let us go into a bit more formal detail. As in Figure 6, we have some computational process that generates Abby’s experiences (histories over an observer graph A), and a computable function $f_A$ which “reads out” Abby’s current history from the full computational process. But now, in addition, we have another computable map $f_B$ which reads out another history, corresponding to another observer graph B, as illustrated in Figure 7. That is, $f_B$ reads out the state of Bambi$_{3rd}$. We may have $A = B$ or $A \neq B$ for the observer graphs, and since those graphs are not very relevant for what follows, we will suppress them from most of the notation, e.g. simply write $P$ instead of $P(A)$. Since the computational process is probabilistic, the state of this computation (say, of the universal graph machine $U$) at some computational time $t$ is a random variable, $g(t)$. For every $t$, the function $f_A$ reads out the A-history $f_A(g(t))$ that Abby has experienced until that computational moment. (We will assume that this computational world retains a memory of all previous observations.) Similarly, $f_B(g(t))$ will yield a B-history. If $f_B$ is suitably chosen, then $f_B(g(t+1))$ will always be either equal to, or an extension of, $f_B(g(t))$. For $f_A$, this is automatically true due to the way that the output of a graph machine is defined, cf. Figure 6.

For example, $f_B$ can simply read out “the current information content of Bambi$_{3rd}$’s brain”, and infer the corresponding information content at all earlier times (if the computational process is reversible), patching all of them together to produce a history $f_B(g(t))$. But in general, $f_B$ can be completely arbitrary as long as it is computable.

Since $g(t)$ is a random variable (depending on the random input bits supplied to the graph machine), we thus have to distinguish the following two probability distributions:

1. The distribution $P_{3rd}$ on $f_B(g(t))$ (i.e., on the states of Bambi$_{3rd}$) that is induced by the probabilities of the different computational histories $g(t)$;

2. the distribution $P_{1st} \equiv P$ that is predicted by our theory (according to Postulates 5.1) to determine what actually happens to Bambi$_{1st}$. This is algorithmic probability.

In our example, if there is an almost 100% chance that Abby will see that Bambi$_{3rd}$ sees the sun rise tomorrow, then this is a probability assignment of $P_{3rd} \approx 1$. If we ask what Bambi$_{1st}$ will actually see, then this asks for the corresponding value of $P_{1st}$.

Apriori, both probabilities can take very different values. However, if they are in fact different, then we have a quite strange situation, reminiscent of Wittgenstein’s philosophical concept of a “zombie” [47]: Bambi$_{1st}$ would in fact not subjectively experience what Abby sees Bambi$_{3rd}$ experience, but would divert into her own “parallel world” with high probability. This does not mean that Abby will subsequently be confronted with a “soulless” Bambi$_{3rd}$ (since $f_B$ will still produce an observer state, associated with some first-person perspective); it would somehow, very roughly, correspond to some strange sort of “identity switch” as discussed in the main text around Observation 3.3. It is probably safe to say that we lack both intuition and terminology to describe
non-mathematically what that would mean\footnote{Note that this would be much stranger than the simple effect of having different “computational branches”, following different values that the random variable $g(t)$ can take. Similarly as in Everettian interpretations of quantum mechanics, a “many-worlds”-like picture suggests that we should imagine different “instances” of Abby and Bambi, following the different branches. Nevertheless, if Abby and Bambi meet in one branch of an Everettian world, they will both be subject to the same objective chances of joint future observations (like seeing the sun rise tomorrow). For “probabilistic zombies” as just described, this would not be the case.}.\footnote{Strictly speaking, this kind of consistency (as expressed in Theorem 9.2) would not have to hold necessarily to have a well-defined theory; physics would still make sense in a solipsistic world in which every observer is surrounded by probabilistic zombies. But such a world would be truly terrifying.} As we will soon see, the good news is that the properties of algorithmic probability imply that this strange situation will not typically happen in the regime of every-day life\footnote{Note that this does not mean that there is a distinguished global time foliation; the computational process can be of quite unfamiliar structure, as we discuss in more detail in Section 12 below.} but see also Section 10). Instead, $P_{\text{str}}$ and $P_{\text{erd}}$ will be very close to each other under natural circumstances. To prove this formally in Theorem 9.2, we have to carefully specify the assumptions that go into the proof.

**Assumption 9.1.** We assume that the event in Theorem 7.8 happens for Abby, who is described by a dead-end free observer graph $A$. As explained in Section 8, she will then find herself to be part of an “external world”, corresponding to a computational process which will be in some state $g(t)$ at every computational time\footnote{Note that this does not mean that there is a distinguished global time foliation; the computational process can be of quite unfamiliar structure, as we discuss in more detail in Section 12 below.} $t \in \mathbb{N}$.

Let $f_B$ be a computable map that assigns to each $g(t)$ (from some $t_0$ on) a $B$-history, where $B$ is another observer graph. We interpret $f_B$ as a “locator function” that reads out the state of Bambi$_{\text{erd}}$ as she appears in the computation. In this section, we make two assumptions on $f_B$:

- For every $t \in \mathbb{N}$, $f_B(g(t+1))$ is either equal to or an extension of $f_B(g(t))$ (otherwise there would be no consistent notion of “Bambi$_{\text{erd}}$’s observer state history” along a computational path);
- for every $t$, there will be some $t' > t$ with $f_B(g(t')) \neq f_B(g(t))$ with unit probability (otherwise Bambi$_{\text{erd}}$ would get “frozen”).

The map $f_B$ can be interpreted as an “observer localization” of Bambi$_{\text{erd}}$\footnote{Note that this would be much stranger than the simple effect of having different “computational branches”, following different values that the random variable $g(t)$ can take. Similarly as in Everettian interpretations of quantum mechanics, a “many-worlds”-like picture suggests that we should imagine different “instances” of Abby and Bambi, following the different branches. Nevertheless, if Abby and Bambi meet in one branch of an Everettian world, they will both be subject to the same objective chances of joint future observations (like seeing the sun rise tomorrow). For “probabilistic zombies” as just described, this would not be the case.} inside the computational world. The first assumption above can be interpreted as “Bambi$_{\text{erd}}$ surviving indefinitely”. For example, if $f_B(g(t)) = (y_1, y_2, y_3)$, then either $f_B(g(t+1)) = (y_1, y_2, y_3)$ (no new observation by Bambi$_{\text{erd}}$) or $f_B(g(t+1)) = (y_1, y_2, y_3, \ldots, y_n)$ (one or more new observations). If this condition was not satisfied, then Bambi$_{\text{erd}}$’s memory would be “wiped out” or “changed inconsistently” at some computational time.

Now suppose that there is some computational time $t$ such that Abby meets Bambi$_{\text{erd}}$ for the first time. Then $x := f_B(g(t))$ denotes the history of observations that this version of Bambi is supposed to have had in the past in this external world. After this first meeting, Abby and Bambi$_{\text{erd}}$ go their own way (they possibly interact from time to time or they don’t). During this time, Bambi$_{\text{erd}}$ will attain some new observer states $z_1, z_2, \ldots, z_k$. The distribution of the random variable $g(t)$ (that is, the probabilistic behavior of the computational process) determines the probabilities of these observations. Let us denote these probabilities by $P_{\text{erd}}(x, z_1, z_2, \ldots, z_k)$, which is a $B$-measure and which yields the probabilities of computational Bambi$_{\text{erd}}$’s future states after computational time $t$.

Finally, at some later computational time $t' > t$, Abby and Bambi$_{\text{erd}}$ meet again. Let us denote by $y$ a state of Bambi$_{\text{erd}}$ that includes “seeing the sun rise in the morning”. Abby will predict that Bambi$_{\text{erd}}$ is going to see the sun rise tomorrow morning with probability $P_{\text{erd}}(y|x, z_1, \ldots, z_k)$. However, Postulates 5.1 say that the instance of Bambi$_{\text{erd}}$ who has seen $(x, z_1, \ldots, z_k)$ is actually going to experience $y$ with probability $P(y|x, z_1, \ldots, z_k)$. These are the two different probability distributions mentioned above. How do the two compare to each other?

Our assumptions above imply that $P_{\text{erd}}$ is a computable $B$-measure. This has a compelling consequence: due to our generalized version of Solomonoff induction in Theorem 7.7, $P_{\text{erd}}$ and $M$ get asymptotically close to each other, i.e.

$$P_{\text{erd}}(y|x, z_1, \ldots, z_k) \xrightarrow{k \to \infty} M(y|x, z_1, \ldots, z_k)$$

with $P_{\text{erd}}$-probability one. Taking into account asymptotic normalization in Theorem 7.7 and $P_{\text{erd}} \equiv P$, we obtain

$$P_{\text{erd}}(y|x, z_1, \ldots, z_k) \xrightarrow{k \to \infty} P_{\text{str}}(y|x, z_1, \ldots, z_k)$$

with $P_{\text{erd}}$-probability one. That is, almost surely will the graph machine’s transition probabilities in the long run reproduce the probabilities that actually impact Bambi$_{\text{erd}}$. If the sun is going to rise for Abby tomorrow, such that Abby predicts that Bambi$_{\text{erd}}$ will see the sun rise, then the sun will indeed also rise for Bambi$_{\text{erd}}$.

**Theorem 9.2** (Emergence of objective reality). In the setting of Assumption 9.1, the probabilities $P_{\text{erd}}$ that determine the fate of Bambi$_{\text{erd}}$ as seen by Abby in her (Abby’s) external world are close to the actual chances $P \equiv P_{\text{str}}$ of Bambi$_{\text{str}}$’s first-person perspective, at least asymptotically. That is, with $P_{\text{erd}}$-probability one,

$$P_{\text{erd}}(y|x, z_1, \ldots, z_k) \xrightarrow{k \to \infty} P_{\text{str}}(y|x, z_1, \ldots, z_k),$$

where $k \in \mathbb{N}$ is the number of state changes that Bambi$_{\text{erd}}$ has undergone in Abby’s external world after some reference time ($k$ is related to Bambi’s “age”), and $y \in B(z_k)$ is Bambi’s next observation, following her previous observations $(x, z_1, \ldots, z_k)$.

In this sense, Abby and Bambi “inhabit the same world” asymptotically — the instance of Bambi that Abby encounters after a long time will subjectively experience the same probabilities that Abby thinks that she does. Note that this theorem is formulated “from Abby’s perspective”: convergence happening with $P_{\text{erd}}$-probability one means that Abby assigns unit probability to this convergence.

At first sight, this resembles the idea of Bayesian consistency\footnote{Note that this does not mean that there is a distinguished global time foliation; the computational process can be of quite unfamiliar structure, as we discuss in more detail in Section 12 below.} 110: if two agents start with different prior distributions, but receive the same data, their Bayesian posterior
distributions will in many cases converge towards each other. However, there is an important conceptual difference: in Bayesian consistency, it is usually assumed that both agents are part of the same “reality” (or world, in our terminology), and their posteriors converge to the actual, “true” distribution which is an objective property of that world. In the theory of this paper, however, no such assumption is made. Instead, each agent is part of their own “reality”. Asymptotically, it then turns out that their realities become compatible, in the sense that they fit naturally into a joint computational process, and we obtain an emergent notion of external world that contains both.

10. PROBABILISTIC ZOMBIES AND SUBJECTIVE IMMORTALITY

Theorem 9.2 shows in what way our theory predicts the emergence of objective reality: while the fundamental ontology is given by each observer’s first-person perspective, there is nevertheless a tendency for observers to agree that they see a specific objective “external world”, assuming that they “see each other” for long enough. Due to the properties of Solomonoff induction, this includes predictions that the observers make about the future behavior of their world.

While the existence of an objective reality is a background assumption of all other theories of physics, it is not a postulate but a theorem in our theory. But every theorem rests on some mathematical assumptions, and so does Theorem 9.2. Specifically, it relies on the following two assumptions:

• Bambi is “old enough”: the number \( k \in \mathbb{N} \) of time steps that Abby has seen Bambi experiencing is large. This assumption is necessary because Theorem 9.2 only gives an asymptotic statement for \( k \to \infty \).

• Bambi “survives forever”: That is, the locator function \( f_B \) that reads out Bambi’s state from the computational process (that is, from Abby’s world) will always yield a consistently growing history of observations, even in the very distant future. This is formalized in Assumptions 9.1.

While it seems plausible that both assumptions are satisfied approximately in typical interactions between guinea pigs, they will not always hold perfectly. In this section, we will thus have a closer look at what happens if we drop these two assumptions. Let us start by dropping the first of the two — namely that Bambi is “old”:

Observation 10.1 (Probabilistic zombies). In the notation of Theorem 9.2, the probabilities \( \mathbf{P}_{3rd} \) that determine the observations of Bambi_{3rd} in Abby’s world, and \( \mathbf{P}_{1st} = \mathbf{P} \) that determine Bambi_{1st}’s actual first-person experience, will in general be very different if the number of time steps \( k \in \mathbb{N} \) that Abby has seen Bambi_{3rd} experiencing is small.

If this is the case, we will say that Bambi_{3rd} is a “probabilistic zombie” for Abby. In particular, this will be the case if Bambi’s current history \( (\mathbf{x}, \mathbf{z}) = (x_1, \ldots, x_k) \) is simple in comparison to \( \mathbf{P}_{3rd} \), i.e. if \( K(\mathbf{x}, \mathbf{z}) \ll K(\mathbf{P}_{3rd}; \mathbf{B}) \).

Since \( K(\mathbf{x}, \mathbf{z}) \geq K(m + k) + O(1) \), where \( m \) denotes the number of entries in \( \mathbf{x} \), the complexity of \( \mathbf{z} \) tends to grow with \( k \), and thus \( K(\mathbf{x}, \mathbf{z}) \) being small can be interpreted roughly as “Bambi is still young”, or as “Bambi hasn’t yet had very complex experiences”. However, there is in general no simple monotonous relationship between age and complexity.

As explained in Section 9, this notion of “probabilistic zombie” vaguely resembles Wittgenstein’s notion of a zombie [47], but it is on the one hand more precise and on the other hand less intuitive. It means that the observer Bambi_{1st} is (with non-negligible probability) not really experiencing from a first-person perspective what Abby thinks she does: if Abby assigns probability close to one to some future event (e.g. seeing the sun rise tomorrow), then this does not imply that the actual chance of Bambi_{1st} to make this experience is close to one. While Abby will still see that the instance of Bambi_{3rd} in her world will actually make this experience (confirming her probability assignment), subjective Bambi_{1st} has a non-negligible probability of not making this experience. If Abby knew what was going on, then it would look, according to her perspective, as if Bambi_{1st} would “divert into a parallel world”. What remains, then, is another “instance” of Bambi that has made a rather improbable experience. Abby can then compare her future predictions to those of this novel instance of Bambi. If this happens \( k \) times, and \( k \) becomes large, then Theorem 9.2 implies that these two predictions will be very close to each other — the “old-age” instance of Bambi_{3rd} that Abby encounters will have lost zombie status. This is when “emergence of objective reality” kicks in.

We will not formally prove the quantitative statement of Observation 10.1 (thus its status as an “observation”), but we will justify it by a general, intuitive, though not fully rigorous argument. Furthermore, we will give a simple example for which it is easy to check that the statement holds.

Let us begin with some intuition why the conclusion of Theorem 9.2 is true if \( k \) is large. We have \( \mathbf{P}(y|x_1, \ldots, x_k; B) \approx \mathbf{M}(y|x_1, \ldots, x_k; B) \), which becomes asymptotically exact due to Theorem 7.7. The universal enumerable semimeasure \( \mathbf{M} \) dominates all enumerable semimeasures, i.e. is a mixture of all of them. This is expressed, for example, by the inequality of Theorem 4.13, which furthermore says that simpler semimeasures \( m \) contribute to \( \mathbf{M} \) with a higher weight of at least \( 2^{-K(m; B)} \).

In more detail, note that the set of enumerable \( B \)-semimeasures is itself enumerable. Given some computable enumeration (possibly with repetition; we will give some extra conditions on this enumeration below)

\[ m_1(\bullet; B), m_2(\bullet; B), m_3(\bullet; B), \ldots, \]

we can define a universal enumerable \( B \)-semimeasure \( \mathbf{M}' \) via

\[ \mathbf{M}'(w; B) := \sum_{j=1}^{\infty} 2^{-K(j)} m_j(w; B) \] (16)

for all finite \( B \)-histories \( w \). This is well-defined since \( \sum_j 2^{-K(j)} \leq 1 \) [78], and enumerable since \( K(j) \) can be computed.

---

50 It is quite amusing that the pop-cultural image of a zombie typically depicts features that would more easily be associated with “being extremely old”, whereas here it is the opposite.
putably estimated from above. Since \( \mathbf{M} \) is universal enumerable as well, there exist constants \( c' \geq c > 0 \) such that
\[
c \cdot \mathbf{M}(\mathbf{w}; B) \leq \mathbf{M}'(\mathbf{w}; B) \leq c' \cdot \mathbf{M}(\mathbf{w}; B)
\]
for all finite \( B \)-histories \( \mathbf{w} \). It follows that
\[
\frac{c}{c'} \mathbf{M}(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) \leq \mathbf{M}'(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) \leq \frac{c'}{c} \mathbf{M}(\mathbf{y}|\mathbf{x}, \mathbf{z}; B),
\]
using the notation from Theorem 9.2. If we are interested in the prediction of long sequences of observations \( \mathbf{y} = (y_1, \ldots, y_m) \), then the multiplicative factors \( c/c' \) resp. \( c'/c \) become irrelevant. We will therefore argue in terms of \( \mathbf{M}' \) instead of \( \mathbf{P} \).

We can rewrite (16) as
\[
\mathbf{M}'(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) = \sum_{j=1}^{\infty} 2^{-K(\mathbf{j})} m_j(\mathbf{x}, \mathbf{z}; B) m_j(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) (17)
\]
for all finite \( B \)-histories \( (\mathbf{x}, \mathbf{z}, \mathbf{y}) \).

Starting with this equation, Solomonoff induction can be interpreted intuitively (but not fully rigorously) as follows. There is an unknown given computable measure \( \mathbf{P}_{3rd} \), and an observer trying to infer \( \mathbf{P}_{3rd} \) from her previous observations. This observer assigns apriori probability \( 2^{-K(\mathbf{j})} \) to every enumerable semimeasure \( m_j \), resulting in her prior \( \mathbf{M}' \). For every enumerable semimeasure \( m_j \) other than \( \mathbf{P}_{3rd} \), sufficiently many observations \( (\mathbf{x}, z_1, \ldots, z_k) \) generated by \( \mathbf{P}_{3rd} \) will eventually yield atypical results, in the sense that \( m_j(\mathbf{x}, \mathbf{z}; B) \ll \mathbf{P}_{3rd}(\mathbf{x}, \mathbf{z}; B) \). Thus, the contribution of these semimeasures \( m_j \) in (17) will become very small.

For every finite \( k \), this will already have happened for many enumerable semimeasures \( m_j \), but not for all of them: there will be some semimeasures \( m_j \) that make similar predictions as \( \mathbf{P}_{3rd} \) up to the \( k \)-th observation, but are substantially different from \( \mathbf{P}_{3rd} \) for later observations. But if \( \mathbf{P}_{3rd} \) is very simple and \( k \) is very large, these other semimeasures must be “artificially finetuned” to agree with \( \mathbf{P}_{3rd} \) for the first \( k \) observations and differ from it later on — in other words, they must be very complex. Put differently, there is only a finite number of \( m_i \) with \( K(i) \leq K(j) + c \) for any large but fixed constant \( c \in \mathbb{N} \), where \( m_j = \mathbf{P}_{3rd} \), and if \( k \) is large enough, then all these semimeasures will already have been sorted out as atypical.

We can see nicely in (17) how the given mixture of \( m_j(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) \) concentrates on the \( j \) with \( m_j = \mathbf{P}_{3rd} \), resulting in \( \mathbf{M}'(\mathbf{y}|\mathbf{B}; B) \approx \mathbf{P}_{3rd}(\mathbf{y}|\mathbf{B}; B) \): if \( m_j \) is atypical in the sense that \( m_i(\mathbf{x}, \mathbf{z}; B) \ll \mathbf{P}_{3rd}(\mathbf{x}, \mathbf{z}; B) \), then the second prefactor is very small, suppressing the contribution of \( m_i \). On the other hand, if \( m_j \) is very complex (much more so than \( \mathbf{P}_{3rd} \)), then the first prefactor \( 2^{-K(i)} \) is very small.

For every given finite \( k \), we can therefore expect that \( \mathbf{M}'(\mathbf{y}|\mathbf{B}; B) \approx \mathbf{P}_{3rd}(\mathbf{y}|\mathbf{B}; B) \) if the following requirement holds: the previous observations \( (x_1, \ldots, z_k) \) must be long or “complex” enough to rule out all other semimeasures \( m_i \) with comparable complexity as \( \mathbf{P}_{3rd} \). Let us now reverse this argumentation. To this end, we will specify the enumeration of semimeasures in some more detail. Let \( \varphi \) be any computable bijection from the natural numbers to the set of finite tuples of finite binary strings, i.e. \( \varphi : \mathbb{N} \rightarrow \bigcup_{n \in \mathbb{N}_0} \{0,1\}^n \). For all \( i \) that are powers of two, we will define \( m_i \) to have a very specific form. Namely, if \( i = 2^l \) or \( i = 2^{l+1} \) for \( l \in \mathbb{N} \), then \( m_i \) will be a \( B \)-measure which assigns unit probability to \( \mathbf{w} = \varphi(l) \) (unless \( \mathbf{w} \) is not a valid \( B \)-history, in which case \( m_i \) will be the zero semimeasure). Furthermore, for all extensions of \( \mathbf{w} \) (if it is a valid \( B \)-history), the measure \( m_i \) will assign some arbitrary probabilities, determined by a fixed simple algorithm; and this will be done in a way such that \( m_i \) gives very different values in the cases \( i = 2^l \) versus \( i = 2^{l+1} \).

Now consider in particular \( l := \varphi^{-1}(x, z) \). For at least one of the two values \( i = 2^l \) and \( i = 2^{l+1} \), the measure \( m_i \) will assign probabilities to future observations that are substantially different from \( \mathbf{P}_{3rd}(\mathbf{y}|\mathbf{x}, \mathbf{z}; B) \). Fix this value of \( i \). By construction, we have
\[
K(i) = K(l) + O(1) = K(x, z) + O(1).
\]
The relative weight of \( m_i \) in (17) is \( 2^{-K(i)} m_i(\mathbf{x}, \mathbf{z}; B) = 2^{-K(i)} \), and we will compare this to the relative weight of \( m_j = \mathbf{P}_{3rd} \). We have
\[
K(j) \geq K(m_j; B) - O(1),
\]
which holds since every description of \( j \) and of the corresponding effective enumeration of the semimeasures yields a graph machine that generates \( m_j \). Thus, we get
\[
2^{-K(i)} m_i(\mathbf{x}, \mathbf{z}; B) = 2^{-K(i)} = 2^{-K(x, z) + O(1)},
\]
\[
2^{-PK(i)} m_j(\mathbf{x}, \mathbf{z}; B) \leq 2^{-K(j)} \leq 2^{-K(x, z) + O(1)}.
\]
Now if \( K(x, z) \ll K(\mathbf{P}_{3rd}; B) \), the premise of Observation 10.1, then \( 2^{-K(i)} m_i(\mathbf{x}, \mathbf{z}; B) \gg 2^{-K(j)} m_j(\mathbf{x}, \mathbf{z}; B) \), and so the mixture in (17) will not be peaked on \( \mathbf{P}_{3rd} = m_j \). Instead, the measure \( m_i \) will substantially contribute to Bambi’s next observations \( \mathbf{y} \), and will differ in its predictions from \( \mathbf{P}_{3rd} \). Thus, Bambi will be a “probabilistic zombie”.

Note that \( K(\mathbf{P}_{3rd}; B) \) is determined by two ingredients: first, by the complexity of the graph machine computation (in more detail, by the complexity of the distribution over \( (g(l))_{l \in \mathbb{N}} \)); and second, by the complexity of the locator function \( f_B \). Therefore, we learn that if \( f_B \) is too complex, then Bambi will be a zombie. This makes a lot of sense: if we “look at our world” in a physically non-natural way (i.e. read data from, say, the cosmic microwave background alternating with some radio noise, and postprocess the result with a complicated computer program), then there is no reason to expect the result, as it evolves over time, corresponds to the description of an actual first-person perspective of any observer. On the other hand, if Abby is watching her guinea pig neighbor (who is hopefully not a zombie), she is arguably approximating a locator function \( f_B \) that has small complexity, ensuring emergent objectivity.

51 Another way to see that \( \mathbf{M}' \) should allow us to draw valid conclusions about \( \mathbf{M} \) (and thus \( \mathbf{P} \)) is to acknowledge that all that we are really using here is the property that \( \mathbf{M}' \) is a universal enumerable \( B \)-semimeasure. It is natural to conjecture that \( \mathbf{M} \) itself has a representation analogous to (16), which is also indicated by the inequality in Theorem 4.13.

52 This argumentation is similar to [44, Subsection 3.2.3], where it is however emphasized that this intuition cannot be made fully rigorous.
To make the argumentation above fully rigorous, one would have to study error bounds on Solomonoff induction (see for example [44]), bounding the difference of both sides of (15) for finite $k$; we leave this possibility to future work. However, we can check the intuitive arguments above by means of a simple rigorous example. Suppose that $B$ is the prefix observer graph $B = A_P \subseteq \text{Fin}$ defined in (2), $x = ()$ is empty, and the computable measure $P_{3rd}$ predicts ones with unit probability, i.e., $\nu(\varepsilon, 1, 11, \ldots, 1^k; B) = 1$ for all $k \in \mathbb{N}_0$, where $1^k = 11\ldots1$ is a string of length $k$ containing only ones. Since $B$ is a tree, all (semi)measures are automatically Markovian. Therefore, let us in the following use the abbreviation $m(y|z_k; B) := m(y|x; B)$, where $z = (\varepsilon, \ldots, z_k)$ is the unique B-history that ends with $z_k$. Similarly, we write $m(z_k; B) := m(z; B)$ such that, for example, $P_{3rd}$ can be defined as $P_{3rd}(1^k; B) = 1$ for all $k \in \mathbb{N}_0$.

With this notation, we have $P_{3rd}(0^k|1^k; B) = 0$ for all $k$, and as shown in [95], it holds

$$P(0^k|1^k; B) \approx M(0|1^k) = 2^{-K(k) + O(1)}.$$ 

Therefore, if Bambi’s last observation is $z_k = 1^k$, the probability to see $y := 1^k0$ next satisfies the objectivity condition $P(y|z_k; B) \approx P_{3rd}(y|z_k; B)$ if and only if $1 \ll K(k) = K(z) + O(1)$, that is, if and only if $z = (x, z)$ is complex.

Note that $2^{-K(k)} \approx 1/k$ for most $k$ [78], hence objectivity will typically be satisfied if Bambi is old (i.e. if $k$ is large).

How does the complexity of $P_{3rd}$ (and thus of $f_B$) enter the picture? Suppose that $x$ is an infinite computable binary string (for example the binary digits of $\pi$), then we can define a deterministic measure $P_{3rd} = \nu_x(y; B)$ as 1 if the finite string $y \in \{0,1\}^*$ is a prefix of $x$, and 0 otherwise. (The example above is recovered as $\nu_{11\ldots}$.) For $n \in \mathbb{N}$, consider the infinite string $x(n) := 1^n00\ldots$ and the corresponding measure $\nu_x(n)$. It has complexity

$$K(\nu_x(n); B) = K(n) + O(1).$$

Suppose that the state transition probabilities of $B_{3rd}$ in Abby’s external world are $P_{3rd} = \nu_x(n)$. Then $K(x) = K(z_k) + O(1)$ being large is not sufficient for $P(y|z_k; B) \approx \nu_x(n)(y|z_k; B)$ to hold: consider a large integer $n$ (that will be held fix in the following) such that $K(n)$ is large (hence $\nu_x(n)$ complex), then we have in particular for $k = n$

$$\nu_x(n)(1^k0|1^k; B) = 1,$$

but

$$P(1^k0|1^k; B) \approx M(0|1^n) = 2^{-K(n) + O(1)} \approx 0.$$ 

However, objectivity is restored in particular for those $k$ with $K(z_k) \gg K(\nu_x(n); B)$, i.e. $K(k) \gg K(n)$. To see this, note first that $k \approx n$ would also imply $K(k) \approx K(n)$. Thus, we have to consider two cases:

---

**FIG. 8.** Colorful and (hopefully) humorous illustration of the content of Observations 10.2 and 10.3. The tree represents the possible histories of a computational process that corresponds to Abby’s $(A)$ external world, as explained in Section 8. The possible values of the random variable $g(t)$ (the state of the computation at time $t$) correspond to the vertices of a tree graph, directed upwards. The subset of vertices for which $f_B(g(t))$ yields a valid $B$-history, growing with $t$, is colored in black. However, there are some computational histories (in gray) that do not satisfy this constraint. The bottom left shows Abby and Bambi who are happy and alive and observe an approaching meteorite. Their states are given by $f_A(g(t'))$ and $f_B(g(t'))$, respectively; that is, they are in this sense part of the computational process. They both “share the same world” in the sense of emergent objective reality — this basically corresponds to the scenario of Theorem 9.2. Then, this external world will transition probabilistically into one of two possible scenarios $g(t' + 1)$: first, a meteorite that has previously approached unfortunately hits Bambi, which happens with probability 99% (right-hand side); second, the meteorite fortunately misses Bambi (left-hand side, top), which happens with probability 1%. While both scenarios correspond to perfectly valid histories for Abby, the postulates of our theory say, however, that this is not true for Bambi: according to Postulates 5.1, Bambi must experience a $B$-successor state next. Therefore, the unfortunate meteorite-hitting branch has probability zero for Bambi. This is formally reflected by the fact that the resulting distribution for Bambi will be a $B$-semimeasure, not a measure. Instead of the termination by the meteorite, Bambi will instead experience something else, which leads to a notion of subjective immortality. What that “something else” is (or rather what it not is) and some more details will be discussed in the main text.
Before analyzing this situation in more detail, let us therefore put down the following simple observation:

**Observation 10.2 (Subjective immortality, part 1).**

Let $B$ be any observer graph which is dead-end free in the sense of Lemma 4.10. Then there will always be a “next observation” for $B$. In particular, if $B$ is a directed acyclic graph, the corresponding observer will experience “indefinite novelty” by taking a never-ending and never-repeating path through her observer graph.

In situations like the one in Figure 8, where one observer $A$ sees another observer $B$ as part of her external world, the notion of “objective reality” of Section 9 (in the sense of “agreeing on probabilities of future observations”) must necessarily break down if $B$ is terminated in that world.

We can analyze situations like the one in Figure 8 in more formal detail. First, for times $t \leq t'$, we have a simple read-out function $f_B$ that gives us valid $B$-histories, in the sense that the first part of Assumption 9.1 is satisfied. Intuitively, this is because it is very natural and easy to locate Bambi inside Abby’s world — in fact, Abby has no problem doing this (approximately) herself. However, it is not so clear any more what it means to read out “Bambi’s state” for times $t' + 1$ and larger, at least on the branch where Bambi is terminated. For the simple locator function $f_B$ that we have just described, this will mean that one of the following possibilities will apply:

- either $f_B(g(t))$ simply becomes undefined for times $t \geq t' + 1$ on the terminating branch,
- or $f_B(g(t))$ will, on this branch, violate Assumption 9.1, in the sense that it does not yield consistent $B$-histories any more, or always yields the same $B$-history (which we termed as “Bambi gets frozen”).

Clearly, we can somehow modify or extend $f_B$ to the terminating branch, such that the resulting map (say, $\tilde{f}_B$) will satisfy Assumptions 9.1. But the point is that there is no unique, “natural” way to define such an extension in general. Consequently, there will be many possible $\tilde{f}_B$, and since they are all approximately on “equal footing”, each one of them will be significantly more complex than $f_B$.

In this section, and also in Section 9 above, we have constructed a $B$-measure $P_{3rd}$ which describes the probabilities of observations of Bambi as seen by Abby in her external world. The validity of Assumptions 9.1 guaranteed that $P_{3rd}$ was in fact a computable $B$-measure. If we repeat this construction now, without relying on the validity of Assumptions 9.1, then we can still obtain the measure $P_{3rd}$ up to computational time $t'$. But from time $t' + 1$ on, some computational branches are “cut off” by not supplying any new information.

---

53 For example, think of Bambi waking up (one moment after seeing the meteorite), covered by electrodes and strapped onto a chair, and a team of scientist guinea pigs in white coats telling her: “Bambi, don’t worry: that was all just a simulation. Welcome back from vacation!”

54 As we will argue later, the case where $B$ is not a DAG, i.e. contains cycles, is the more relevant one. Then there could be situations, for example, where an observer gets trapped on a vertex that loops back to itself. Cycles raise interesting and very difficult interpretational issues. We will discuss some of them in Section 12.

55 For example, this happens if $f_B(g(t + 1))$ is not an extension of the history $f_B(g(t))$, but a different and completely unrelated history.
observations for Bambi. This is analogous to a graph machine computation that “crashes” and does not produce any outputs on some inputs. In more detail, define $P_{3rd}(y; B)$ as the probability that the computational process (that is, Abby’s external world) makes $f_B$ consistently generate the $B$-history $y$. Then this construction gives us a computable semimeasure $P_{3rd}$.

For example, in the specific scenario of Figure 8, denote the number of observations that Bambi has made at computational time $t'$ by $k$, and suppose there have not been any dangerous situations whatsoever for Bambi before time $t'$. Then $P_{3rd}$ behaves like a $B$-measure before time $t'$:

$$P_{3rd}(y_1, \ldots, y_n; B) = \sum_{y_{n+1} \in B(y_n)} P_{3rd}(y_1, \ldots, y_n, y_{n+1}; B)$$

for all $n < k$, and thus, for example,

$$\sum_{y \in B^n} P_{3rd}(y; B) = 1$$

for all $n \leq k$, as every good measure should satisfy. But for larger numbers of observations this is violated. For example,

$$\sum_{y \in B^{k+1}} P_{3rd}(y; B) \leq .01 \neq 1$$

since the probability weight of 99%, corresponding to the tragic meteorite incident, is missing from the statistics. Therefore, $P_{3rd}$ is not a measure, but a semimeasure.

While Theorem 7.8 is not valid for computable semimeasures, our analysis from earlier in this section still applies: $M'(y|x; z; B)$ can still peak on the semimeasure $m_i := P_{3rd}$ if $K(i)$ is small and $m_i(x, z; B)$ is large. That is, the non-asymptotic version of emergent objectivity can still hold for $P_{3rd}$. This insight gives us a better understanding of what is going on in situations like the one in Figure 8.

**Observation 10.3** (Subjective immortality, part 2). Situations like the one depicted in Figure 8 can be understood in the following way. At (not too early) computational times $t < t'$, there is “emergent objectivity”$^*$: the probabilities $P_{3rd}$ that determine the fate of Bambi$_{3rd}$’s instance as seen by Abby in her external world are close to the probabilities $P_{1st}$ that Bambi$_{1st}$ actually experiences. This is a finite-time version of Theorem 7.8.

This happens whenever (17) peaks$^{56}$ (quickly enough) on $m_i = P_{3rd}$, which is however a semimeasure instead of a measure if there are branches on which Bambi$_{3rd}$ is terminated. If the total survival probability $\sum_y m_i(y|x, z; B)$ is zero or too small, then the semimeasure $m_i = P_{3rd}$ becomes irrelevant for Bambi$_{1st}$’s future experiences despite $2^{-K(i)} m_i(x, z; B)$ being large. If this is the case, then other semimeasures will dominate her experiences from that moment on, and Abby’s world loses its relevance for Bambi$_{1st}$.

It would obviously be extremely interesting to say in more detail how Bambi$_{1st}$ experiences the situation of Figure 8, but this seems to be a very difficult question. Instead, we can understand quite easily why certain obvious intuitive guesses of what she should see must be wrong.

First, we might guess that Bambi$_{1st}$ sees something like a “renormalized” version $\tilde{P}_{3rd}$ of $P_{3rd}$, obtained from restricting to those computational branches on which Bambi$_{3rd}$ is not terminated. The measure $\tilde{P}$ describes a “magic world” for Bambi. In the scenario of Figure 8, she would definitely survive the meteorite despite the grim predictions of having only a 1% chance. If Bambi boarded an airplane and it crashed, she would be the only survivor by mere chance. Whatever happened, she would always miraculously survive. Attempts of suicide would always fail, similarly as Bill Murray in the 1993 movie “Groundhog Day”. So does Observation 10.2 suggest that Bambi$_{1st}$ will really become part of this bizarre “magic world”?

It is easy to see that the answer must be “no”, via proof by contradiction: if Bambi$_{1st}$ lived long enough in this “magic world”, then all other observers that she meets would necessarily in the long run agree with her predictions (“If I put myself on fire, I will survive with certainty, you will see!”). This is due to Theorem 9.2. But then, Bambi$_{1st}$’s experiences would not be seen as “miracles”, but as ordinary occurrences that fit into the overall pattern that the fellow guinea pigs find in their scientific experiments.

So something is wrong about this idea of a “magic world”, and we can formally understand what it is that goes wrong. The catch is that $\tilde{P}_{3rd}$ is one specific modification of $P_{3rd}$ that yields a measure, but there are many other modifications of $P_{3rd}$, and it is not clear why $\tilde{P}_{3rd}$ should “stand out” among them. Consequently, while $P_{3rd}$ is very “natural” and thus simple, we expect that all modifications $\tilde{P}_{3rd}$ which are measures are equally “unnatural”, having somewhat larger complexity than $P_{3rd}$. Consequently, (17) will not be peaked on $\tilde{P}_{3rd}$, and Bambi will not become part of this magic world. In other words, the idea of “quantum suicide” [72, 111–113], or rather its adaption to our setting, does not work.

The question what Bambi$_{1st}$ will see instead seems very difficult to answer, and the answer may well depend strongly on Bambi’s previous experiences. Maybe the most plausible guess is that Bambi$_{1st}$ returns into some state where no regularities have stabilized themselves yet, in the sense that Theorems 7.8 and 7.3 do not yet apply. This somewhat resembles the idea of a “young zombie” of Observation 10.1.

### 11. Cosmology and Boltzmann brains

If we believe that the theory in this paper captures a grain of truth about physics, then we face a substantial revision of some basic assumptions about the world. Thus, it should not come as a surprise (and may indeed be regarded a sign of predictive power) that our approach suggests revisions in those areas of physics that are asking fundamental questions about the nature of our universe and the role of the observer.

One major research area of this kind is cosmology. In this field of research, various problems and paradoxes arise from the question of how to assign probabilities in various cosmological contexts. A well-known problem that demonstrates

---

56 It is actually sufficient that most of the probability weight is distributed on semimeasures that make the same or very similar predictions as $P_{3rd}$ for the first $k$ observations.
this quite clearly is the Boltzmann brain problem [3, 4]. For our purpose, it can be summarized in the following way:

Suppose that our universe is “very large”, for example due to eternal inflation [114]. Then, because of statistical fluctuations, many observers (“Boltzmann brains”) will come into existence by mere chance, simply appear for a short time, surrounded by chaos, and then disappear again. Under certain assumptions on the cosmological model, there will be far “more” Boltzmann brains out there than there are “ordinary” observers (like we think we are). Thus, in such cases, one would naively assign an astronomically higher probability for an observer (like us) to be a Boltzmann brain rather than being generated by a long evolutionary process, surrounded by an ordered and predictable low-entropy environment. As argued below, this conclusion contradicts our observations.

Not only does this argument rely on the specific choice of cosmological model, but its validity also depends on having a method to count observers (“natural” ones as well as Boltzmann brains). But estimating the number of observers in turn depends on a multitude of detailed choices to be made, e.g. the way that one determines probabilities of universes inside a potential inflationary “multiverse”, or spatial volumes inside a large universe [115]. Some cosmologists try to infer constraints on the cosmological model from assuming that we are not Boltzmann brains [116], but there is no consensus on how the calculations should be done in detail. As an example, [3] and [4] argue that inflation cures the Boltzmann brain problem, but other authors [117] come to the opposite conclusion.

In Section 2, we have rejected the ontology that underlies this standard argumentation: we have argued that the idea of the “one truly existing universe” (or multiverse, defined by some common feature such as having experienced causal connection in the past or obeying the laws of string theory), and us being actual material stuff somewhere inside of it, has to be replaced by a different view, based on the notions of M- and P-existence. But rejecting this standard ontology also leads to a rejection of the naive notion of “observer counting”, and thus of the usual way to deal with the Boltzmann brain problem. We will now show how this problem is resolved within our theory — first, by a very simple phenomenological argument, and then by a more thorough analysis based on properties of algorithmic probability.

So suppose that our observer Bambi is currently in a state where she remembers having lived a rich life full of experiences in a standard, low-entropic planet-like environment. However, within the standard cosmological ontology, there is a possibility that Bambi, or rather her brain with all memories, has just now appeared as a highly improbable thermal fluctuation, surrounded by a soup of thermal gas. In the next moment, this could mean that she makes a very strange and unexpected experience (say, heavy pain due to gas hitting her synapses). Let us call this a “BB-experience”.

Consider a (simple) computable function $f$ on B-histories that assigns the value 1 to those histories that are typical for guinea pigs living in a standard planet-like environment, and 0 to all other histories. Then “having experienced to live in a standard planet environment in the past” corresponds to the function $f$ taking the value 1 on all previous observations. Now recall Theorem 7.3: according to our theory, this means that the function $f$ will attain the value 1 also with high probability in the future. That is, the probability of a BB-experience is very small:

**Observation 11.1** (Resolving the Boltzmann brain problem). According to the principle of persistent regularities, Observation 7.4 (which is based on Theorem 7.3), a BB-experience is unlikely. In other words, if an observer has experienced living in a standard planet-like environment in the past for long enough, then this will remain true with high probability in the future.

This conclusion follows independently of the properties of the cosmological model that would describe Bambi’s external world (which exists due to Observation 8.1). We can also understand it as a consequence of the fact that continuing to observe the planet-like environment in the future leads to larger compressibility of Bambi’s observations, and compressibility is exactly the notion of simplicity that is favored by algorithmic probability $P(\bullet; B)$.

Before analyzing this argument in more quantitative detail at the end of this section, let us return to the bigger picture. The Boltzmann brain problem is only one instance of the more general problem to assign probabilities in cosmology. Another instance is known as the measure problem [2]: to analyze how “typical” our actual universe is inside the landscape of all conceivable universes, how can we assign probabilities to the possible worlds? It is clear that cosmology must try to answer this question at least to some extent: any attempt to explain features of our universe by means of some mechanism (such as its flatness by means of inflation) must lay out alternative scenarios of different possible universes (e.g. strongly curved or short-lived), and at the same time estimate whether a given feature is typical or exceptional in the landscape of possibilities (only in the latter case would one ask for a specific mechanism that explains this feature).

We will now argue that our theory allows us to address this question, leading to the following observation.

**Observation 11.2** (Apriori probability of worlds). Theorem 7.8 and Section 8 show that observers will with high probability make observations which are typical for a probabilistic “external world” that is simple, i.e. that has

- simple initial conditions,
- simple probabilistic evolution laws, and
- a simple algorithm that localizes (“points to”) the observer in that world.

In physics language, this means that the experienced “universe” typically appears as if it had once started in a state of low entropy, and as if it had since then followed a tendency for entropy to increase. Observers should assign to every computable world with initial conditions $I$, probabilistic evolution laws $L$, and observer localization function $f$, roughly the apriori probability

$$2^{-K(I, L, f)} \approx 2^{-K(I) + K(L) + K(f)},$$

where $K$ is Kolmogorov complexity and the latter approximate equality is valid if $I, L$ and $f$ are algorithmically independent (which is generically the case). If the observer has previously made observations $x$, then she should multiply the above number by the initial probability that this
world would make her experience \( x \), to obtain the relative probability that this particular world correctly describes her future observations. That is, (18) should be replaced by

\[
2^{-K(I,L,f)} \frac{\mu(x;B)}{M(x;B)},
\]

where \( \mu(x;B) \) is the probability that the given world would lead observer \( B \) to make observations \( x \), and \( M(x;B) \) is the (unnormalized) universal apriori probability of \( x \) as defined in Definition 4.11 (which is however the same for all worlds, and can thus be treated as a multiplicative constant).

Every specification of initial conditions \( I \), probabilistic evolution laws \( L \) and observer locator function \( f \) determines a graph machine computation and thus, indirectly, either a \( B \)-measure (cf. Section 9) or a \( B \)-semimeasure (cf. Section 10); let us denote the corresponding measure or semimeasure by \( m_{I,L,f} \) (it is simply denoted \( \mu \) in (19)). If \( m_{I,L,f} = m_{I,L,f'} \), then both “worlds” \( (I,L,f) \) and \( (I',L,f') \) are indistinguishable from the point of view of the observer \( B \), and it is an arbitrary choice which of the two \( B \) may want to use to predict her future observations.

The complexity \( K(I,L,f) \) is related to \( K(m_{I,L,f};B) \) from Theorem 4.13 via \( K(m_{I,L,f};B) \leq K(I,L,f) + O(1) \), since every description of \( I,L,f \) can be converted (with constant overhead) into a graph machine computation that generates \( m_{I,L,f} \). The converse is slightly more involved, due to the fact that there are different \( (I,L,f) \) yielding the same (semi)measure, and also because the minimal programs in the definition of \( K(m;B) \) (Theorem 4.13) are not a prefix code\(^{57} \). Using [78, Example 3.13], we get

\[
K(m;B) + O(1) \leq \min_{(I,L,f):m_{I,L,f} = m} K(I,L,f) \\
\leq K(m;B) + K(K(m;B)) + O(1). \quad (20)
\]

Recalling Theorem 7.8, this relates the apriori probability of “world” \( (I,L,f) \) to the apriori probability of seeing the corresponding measure \( m = m_{I,L,f} \) asymptotically. Bambi would assign the measure \( 2^{-K(I,L,f)} \) to that world before she makes any observations.

However, after making observations \( x \), a “Bayesian updating” procedure takes place: if Bambi has previously assigned high probability to a measure \( \mu \), but the actual observations are very atypical for \( \mu \) in the sense that \( \mu(x;B) \) is very small, then Bambi will assign smaller probability to \( \mu \) from that point on. This leads to (19), which can be proven in complete analogy to the argumentation around (17), simply replacing \( M' \) as defined in (16) by

\[
M'(w;B) := \sum_{I,L,f} 2^{-K(I,L,f)} m_{I,L,f}(w;B).
\]

What about the other claims of this observation? In particular, where does entropy and thermodynamics enter the picture? This question also applies to our earlier discussion of Boltzmann brains, since these brains are hypothesized to originate in thermodynamic fluctuations in the first place. At first sight, thermodynamics only comes into play once there is a notion of Hamiltonian dynamics, which is a structure that does not appear in the fundamental postulates of our theory. So how do we reconcile this theory with standard physics and cosmological reasoning, where thermodynamics is a crucial ingredient?

It turns out that there is a bridge between algorithmic probability and thermodynamics which does not rely on any notion of energy: \textit{Kolmogorov complexity} \( K \) can itself be regarded as a notion of entropy. In fact, \( K \) is sometimes called “algorithmic entropy”, and it has been applied directly as a measure of entropy in thermodynamics, cf. Section 8 of [78] or [118]. While standard thermodynamic entropy is a function of a probability distribution (such as the uniform distribution on all accessible microstates), Kolmogorov complexity is defined for \textit{single} realizations of an ensemble (that is, for single microstates). There are numerous close relationships between complexity and entropy [93, 94, 119]. For instance, \textit{average Kolmogorov complexity equals entropy}: if \( P \) is any computable probability distribution on \( \{0,1\}^* \), then [78]

\[
H(P) \leq \sum_{x \in \{0,1\}^*} P(x)K(x) \leq H(P) + K(P) + O(1),
\]

where \( H(P) = -\sum_{x \in \{0,1\}^*} P(x) \log_2 P(x) \) is Shannon entropy. This implies that physical intuition involving entropy will in many situations also work for Kolmogorov complexity.

What does this mean for the computational world that generates the observed measure \( \mu \)? It is a very simple insight that every computation which is not cyclic, but which allows for some “clock” degree of freedom (e.g. a register that counts time steps) must eventually evolve from simple initial conditions to more complex states. This is due to a trivial counting argument: there are only few strings with small Kolmogorov complexity, hence \textit{every} computation that exhausts many states must gradually turn to more complex states. Therefore, we have simple initial conditions, but complexity tending to grow with time.

As we have just seen, complexity can (in some specific sense) be interpreted as entropy. Therefore, we find that Bambi typically sees low-entropic initial conditions, but her world seems to have entropy growing over time. This justifies the corresponding statement in Observation 11.2.

In particular, our theory removes the motivation to come up with a “mechanistic” explanation of simple (thermodynamically atypical) initial conditions. There is no need to postulate, for example, that our universe has developed as a thermodynamic fluctuation from another “meta-universe” [4]; our theory predicts simple initial conditions without any such assumptions. The point of view taken in this paper is that the question of “why there is a world in the first place” requires (and has) an explanation that is of a different category than the usual argumentation with which we explain phenomena \textit{within} our world. Using thermodynamic reasoning, for example, assumes that we already have a certain amount of structure (basically fundamentally reversible dynamics according to some symplectic structure, leading to a notion of energy that is preserved) that is ultimately part of what we want to explain in the first place.

Let us now return to the Boltzmann brain problem, and

\(^{57}\) If they were, then we would have \( \sum_{I,L,f} 2^{-K(m_{I,L,f})} \leq 1 \) by the Kraft inequality (the sum runs over an enumeration of all semimeasures), but we already have \( K(M;B) = 0 \) contradicting this inequality.
analyze it in more detail with the insights of Observation 11.2. Shortly before a possible BB-experience might take place, Bambi’s previous observations are given by a B-history \( x = (x_1, \ldots, x_k) \) which describes observations in a “universe” (or world) with initial conditions \( I \) and probabilistic evolution laws \( L \). A locator function \( f \) reads out Bambi’s state as a guinea pig on some planet in the corresponding universe, generating a B-measure \( \mu \). Bambi’s previous observations \( x \) are very typical for a guinea pig on this planet, i.e. \( \mu \)-typical; therefore, she expects that \( \mu(y|x; B) \) predicts her future very well. That is, she will expect to see the sun rise tomorrow, and to still observe that she lives happily on the same planet.

But suppose that this universe resembles what some cosmological models predict — namely, a world where there is a large number of fluctuations out in the void producing a multitude of Boltzmann brains. Could this have any consequences for Bambi’s observations? Let us try to answer this question with the machinery of Observation 11.2. We are considering the same initial conditions \( I \) and probabilistic evolution laws \( L \) as above, but now we define a different locator function \( f' \) that basically points to Boltzmann brains in Bambi’s universe. We construct \( f' \) such that, at any given time of the corresponding computation, it scans the computational universe until it finds a valid B-history \( w = (w_1, \ldots, w_m) \). Moreover, we construct \( f' \) such that it ensures that the next history that it reads out in the subsequent moment is a valid continuation \((w_1, \ldots, w_m, w_{m+1})\) of the previous one (note that we can make the locator function depend on the previous computational history as long the computation retains a record of it). If there are far more Boltzmann brains than versions of Bambi that have evolved on planets, then \( f' \) will produce observations that are more of the kind of a BB-experience as discussed further above.

If we want, we can even construct \( f' \) to deliberately avoid planets while scanning the universe. This construction will lead to a different measure \( \mu' = m_{1, L, f'} \).

Which measure is more likely to predict Bambi’s actual future observations, \( \mu \) or \( \mu' \)? Observation 11.2 tells us to compare the apriori probabilities \( 2^{-K(I)+K(L)+K(f)} \) and \( 2^{-K(I)+K(L)+K(f')} \). However, both \( f \) and \( f' \) are simple (we have described them in short sentences), and therefore possibly of roughly comparable Kolmogorov complexity. Thus, the apriori probabilities of both “worlds” (or rather of the two ways of locating Bambi inside the same world) are roughly identical. Therefore, according to (19), we have to compare \( \mu(x; B) \) and \( \mu'(x; B) \). But there we see a crucial difference: only very few possible B-histories \( y \) (of identical length) are \( \mu' \)-typical, i.e. are typical to be observed by Bambi on a planet. However, basically all B-histories of this length are \( \mu \)-typical: all of them are more or less equally likely to arise from random fluctuations. In other words,

\[
\mu(x; B) \gg \mu(y; B) \text{ for most } y = (y_1, \ldots, y_k), \\
\mu'(x; B) \approx \mu'(y; B) \text{ for all } y = (y_1, \ldots, y_k).
\]

Therefore \( \mu(x; B) \gg \mu'(x; B) \), and the rule of thumb in Observation 11.2 tells us that is far more likely that \( \mu \) correctly predicts Bambi’s future observation than \( \mu' \). In other words, a BB-experience is extremely unlikely.

What if we model the Boltzmann brain scenario by using another locator function \( f'' \)? For example, we could let \( f'' \) scan the universe only for very specific realizations of Bambi. In the most extreme case, \( f'' \) could simply look for fluctuations (but deliberately ignore standard planet-like environments) that, by mere chance, are stable for a long enough time and reproduce the observations \( x_1, \ldots, x_n \) in \( x \) one after the other. Such fluctuations are even more rare than the fluctuations that we have just talked about, but if the universe is large enough, they will exist with probability close to one. The resulting B-measure \( \mu'' \) would then satisfy \( \mu''(x; B) = 1 \), and our previous argumentation would not work.

However, in this case, the locator function would have to contain a full description of \( x \) (in particular if \( \mu''(x, y; B) < 1 \) for all \( y \)), such that \( K(f'') > K(x) \), and this would make the apriori probability in (18) very small. Therefore, also \( \mu'' \) will have very small probability to correctly predict Bambi’s observations in the future. Another way to see this is that we would get \( K(x) < K(\mu''; B) \) according to (20). Due to Observation 10.1, this implies that Bambi would be a zombie for other observers in this world. In other words, \( \mu'' \) would have no relevance for her first-person perspective.

Thus, our theory gives us several different ways of arguing which all consistently lead to a resolution of the Boltzmann brain problem. These arguments are independent of the cosmological model that is supposed to describe the observer’s external world.

12. CONTEXTUALITY, BELL VIOLATION, AND NO-SIGNALLING

While quantum theory (QT) has been named as a main motivation for this theory in the introduction, the discussion so far has not touched on QT at all. This may seem odd at first sight: why have we only talked about classical probabilities and not about transition amplitudes? Isn’t our theory in contradiction to the observed quantumness of our world, as Section 8 seems to predict a classical external world?

Much of this objection rests on intuition that comes from a certain naive form of wave function realism. According to this view, physics must always talk about material stuff evolving according to differential equations. The quantum Schrödinger equation (or its relativistic or field-theoretic counterparts) are then often seen as instances of this dogma, with an actual “thing” \( |\psi(t)\rangle \) (the quantum state) evolving in time. Since this “thing” is a complex wave function, and not a classical probability distribution, proponents of this view will intuitively think that the emergent external world in our theory must be a classical world.

This view ignores the fact that all empirical content of the quantum state ultimately lies in the prediction of probabilities of measurement outcomes. Therefore, it is consistent (and in many ways advantageous) to regard quantum states as “the same stuff as probability distributions”, namely as states of knowledge, information, or belief in some (yet to be specified) sense [7, 11, 65, 120, 121]. The departure from classical physics is in the properties of these probabilities (for example in the violation of Bell inequalities despite space-like separation, or the appearance of interference patterns in situations where classical physics suggests no such patterns), not in the mathematical description (via complex numbers) that is used to compute these probabilities. One of the clearest arguments for this broadly “epistemic view” comes from the
recent wave of reconstructions of QT [26–35], which proves that the full complex Hilbert space formalism of QT can be obtained by adding a few natural postulates on top of a framework of general “theories of probability”.

Probabilistic predictions comprise everything that we can ever empirically test about QT. All interpretations of QT agree on this point [122]; they only differ in the way that they interpret these probabilities, and in additional claims about unobservable processes that are declared to be causing the observed behavior in some (classically) intuitively comprehensible or mechanistic terms. Indeed, the motivation for many of these approaches comes from the traditional intuition described above. In a traditional view, we have an unsettling situation in QT, which has been termed the measurement problem. From a traditional perspective, the problem is as follows:

- Typically, the quantum state is evolving unitarily, according to the Schrödinger equation $i\hbar \frac{d}{dt} |\psi(t)\rangle = H |\psi(t)\rangle$. This is analogous to time evolution in classical mechanics, and in this sense “nice” and intuitive.

- However, sometimes, there are disturbing exceptions from this rule: this is when we perform a measurement. Then the state vector seems to collapse in some sense, violating unitarity.

The traditional narrative is to declare unitary time evolution as the “standard rule”, and the creation of measurement outcomes with certain probabilities as an apparent violation of this rule which is in need of elaborate explanation. For example, this point of view is very pronounced in Everettian interpretations of quantum mechanics [66]. However, taking actual scientific practice as the starting point, and taking the manifold evidence (mentioned above) of the epistemic nature of the quantum state seriously, the more economic and consistent point of view is this: what is “really happening” is the appearance of measurement outcomes with probabilities as predicted by the quantum state. In order to not fall into an overly instrumentalist perspective, we adopt an insight from QBism [6, 123, 124], namely that the notion of a “measurement outcome” is merely a metaphor (and special case) of experience, which in the terminology of this paper is the same as observation. In summary, all there is are observations (i.e. transitions between observer states), and these observations are non-deterministic. Quantum states are the things that determine the probabilities of these observations (we do not have to settle the question of what “probability” exactly means here to come to this conclusion). Time evolution of a state is ultimately nothing but a correlation of these probabilities with some clock variable [125].

The point of view that observations are the primary notion, and that the quantum state should be interpreted epistemically, dissolves the measurement problem. For more detailed explanations for why this is an attractive position, see e.g. [126]. Moreover, it can do so in a particularly nice way within the ontology of this paper, by refuting the intuitive consequence that quantum states, as a result, would somehow “not be physical enough” (if they are to be understood epistemically) and thus lead to some undesirable kind of “solipsism”:

**Observation 12.1** (QT and the measurement problem). Based on a traditional view of physics, QT is widely regarded to suffer from a (conceptual) measurement problem as sketched above. However, within the theory of this paper, the measurement problem dissolves: quantum states are an observer’s states of knowledge (we will explore in more detail below in what sense), and a measurement update rule simply corresponds to Bayesian updating. This solution to the measurement problem is shared with other epistemic interpretations of the quantum state [7, 11, 65, 120].

Moreover, the theory of this paper is particularly well-suited to support such an interpretation: it does not contain any fundamental notion of “external reality”, and thus it does not provide any reason to expect that the question of “what is really going on in the world” (say, in between measurements or observations) has any meaningful answer at all. Therefore, it actually provides reasons to expect that observers will typically find a theory of the quantum kind (with observations or measurements as a primary notion) describing their world. Furthermore, our theory says that observations are fundamentally private to a single observer, and that the notion of a “common external reality” for different observers is an approximation that is only valid under certain conditions (cf. Theorem 9.2). This makes our approach compatible with “Wigner’s Friend”-type thought experiments. All this will be explored much more thoroughly in the remainder of this section.

So QT fits our theory very well from a conceptual point of view, but can we understand this in more technical detail? To address this point, we have to recall a simple insight that has already appeared in Section 8: namely, that an observer’s external world will correspond to an abstract computational process which need not resemble any of the structure of “graph machines” that we have used to define our theory in Section 4. Instead, we could have constructed our theory, with completely equivalent result, based on any other model of computation that reads input bits and produces output strings sequentially, as long as that model of computation can in principle simulate, and be simulated by, graph machines. This ensures that the corresponding model of computation reproduces the class of “universal enumerable A-semimeasures” for observer graphs $A$.

For example, we could have used some class of cellular automata to define our theory, or, perhaps surprisingly, quantum Turing machines. In fact, quantum computers are algorithmically equivalent to classical computers: either one can simulate the other. The simulation of a quantum computer on a classical computer will probably be extremely inefficient [127], but efficiency is irrelevant for the purpose of this paper — only description length counts for algorithmic probability. Hence, we could have replaced graph machines by quantum Turing machines, as long as we restrict to inputs that are classical (say, qubits diagonal in the computational basis) and formally introduce a measurement process to the output strings. Intuitively, this model of computation resembles an external quantum world for an observer.

While all the aforementioned models of computation are algorithmically equivalent, they are not at all equally “natural” in representing a given abstract computational process, or algorithm. As an example, recall the example of
“Game of Life” that we have briefly discussed in Section 2. Even though Game of Life is typically visualized on a two-dimensional grid, we do not need a 2D cellular automaton to simulate it. If we regard it as an abstract algorithm, with some bits (representing e.g. the color of the grid cells) changing over time, then we can run this algorithm on any machine model that we like. In fact, this is what we are doing when we are simulating Game of Life on our laptop computers.

But if we observed the simulation of Game of Life on, say, a universal 1D cellular automaton, we would see a quite peculiar computation in action: interaction between some neighboring cells on the original 2D grid would have to be mediated by transporting information a long way along the 1D grid. The 1D automaton would thus be “unnatural” in the following sense: its own causal structure as a model of computation would not correspond to the effective causal structure of the abstract algorithm. This is in contrast to the 2D automaton which would be “natural” in this sense.

Therefore, if we regard our physical world (as we know it) as a computation, then it seems to be an important structural feature that some kind of model of quantum computation captures its causal structure more naturally than typical models of classical computation, even though all these models are algorithmically equivalent. The goal of this section is to approach a possible explanation of this fact, by asking the following question: **What is the natural model of computation to represent the algorithm that corresponds to an observer’s external world?** That is, what kind of “machine” does most naturally implement the “computational ontological model” of Observation 8.1? We will study this question in the context of the following assumption which we will motivate below.

**Assumption 12.2.** For a given observer $A$, we assume that algorithmic probability $P(y|x;A)$ converges to a computable measure $\mu(y|x;A)$ asymptotically as described in Theorem 7.8. Furthermore, for the rest of Section 12 (but not the further sections), we assume that $\mu$ is predictive in the sense of Informal definition 7.10 (resp. Definition A.11).

**Remark.** In Section 14, I will argue that the postulates of our theory should in fact be amended: that is, algorithmic probability $P(y|x_1, \ldots, x_n;A)$, as it appears in Postulates 5.1, should be replaced by some Markovian version that only depends on the observer’s current state $x_n$ instead of her full past history. The problem is that I currently do not know how the corresponding Markovian measure should be defined, and to which consequences it would lead (see Section 14 for a more detailed discussion). But if such an amendment can be found, in a way that does not alter the previous results too much, then every computable measure $\mu$ towards which the amended algorithmic measure converges must be Markovian too. Since Markovian measures are predictive (cf. Figure 5), Assumption 12.2 will then follow automatically.

We have introduced the notion of predictivity in Section 7. The motivation was to understand under what conditions observer $A$ (Abby) can directly use the asymptotic measure $\mu$ for prediction, in the spirit of Lewis’ “Principal Principle”. According to Theorem 7.8, Abby should assign conditional probabilities $\mu(y|x;A)$ to future observations $y$ if she has previously experienced the $A$-history $x = (x_1, \ldots, x_n)$. However, all that Abby has access to, at any given moment, is her current state $x := x_n$. Therefore, Abby can only use her knowledge of $\mu$ directly for prediction if $\mu$ allows to derive a well-defined notion of conditional probability $\mu(y|x;A)$.

Even without the anticipated amendment of our postulates as described in the comment above, there is a natural motivation to analyze the special case of predictive measures $\mu$. Namely, if $\mu$ is not predictive, then the observer simply cannot use it directly to predict her future observations — and thus she will have to use something else, e.g. a Bayesian assignment of probabilities that is arbitrarily motivated. In this case, $\mu$ would simply use its relevance for the observer regarding the way that she describes her world. We may also speculate that some future observations can be predicted from the current state alone; formally, there might be some coarsegraining of observations such that the coarsegrained version allows for prediction, but the details that have been removed do not. This “predictable part” of her observations is then what the observer might want to concentrate on in her attempt to make physical predictions.

Let us now turn to the formal definition of predictivity. The main object of interest in predictivity is the set of “looping” histories of the form $(y_1, x, y_3, x, \ldots, y_#, x)$, where the $y_i$ do not contain any $x$, such that $# \in \mathbb{N}$ is the number of $x$’s that appear in this history. Let us denote this set of histories by $\mathcal{H}_{#}(x)$, i.e. the set of histories that end with $x$ and have $# \in \mathbb{N}$ occurrences of $x$. Note that $# = 0$ is not a random variable on the probability space $\mathcal{A}$ a version of $A$-histories, since it cannot be defined as a function on the infinite histories. It denotes a “momentary internal property” of the observer and not an “external property” that can be observed “from the outside”, which is exactly what makes this quantity so interesting.

If a given observer $A = (V,E,A)$ is in the state $x \in V$, and is so for the $#\text{th}$ time, then she could predict future observations $y$ via

$$\mu(y|x;#;A) := \frac{\sum_{w\in\mathcal{H}^{(#)}(x)} \mu(w,y;A)}{\sum_{w\in\mathcal{H}^{(#)}(x)} \mu(w;A)} \tag{21}$$

if she knew the value of $#$ (we show this in more detail in the appendix). If $\mu$ is acyclic, then only $# = 1$ is possible, and this equation reduces to (13). But if $\mu$ is not acyclic, then the observer cannot in general know the value of $#$ (unless $\mathcal{H}^{(2)} = \emptyset$ which implies $# = 1$), since all she sees or knows is encoded in the string $x$. Moreover, as we show in detail in the appendix, there is in general no canonical way for the observer to assign a probability to $#$: the formal definitions do not allow to compute a probability $\mu(\#;x;A)$ from $\mu$ alone. It is all up to the observer to assign a subjective degree of belief to the possible values of $#$. But if this is the case, the only situation in which the observer is still able to compute probabilities for future observations is if the probability in eq. (21) does not depend on $#$, and hence her degree of belief about $#$ is irrelevant. In the appendix, we use this prescription to give a formal definition of predictivity (Definition A.11) which is obtained from a careful analysis of the formalism (what the probability spaces are etc.), and it will confirm what we have just said by allowing us to prove the following:

---

58 A moment’s thought shows that the form of (21) implies that the
As shown in Figure 5, if predictivity measures, let us now look at a simple example. If predictive measures, let us now look at a simple example.

Let us model this situation in our terminology as an observer graph, and a computable $A$-measure. Then $\mu$ is predictive if and only if for all $x \in V$ that can be reached from $\Lambda$ with non-zero probability, the expression $\mu(y|x, \#; A)$ in (21) is the same for all $\# \in \mathbb{N}$ for which the denominator is not zero, in which case this expression will be called $\mu(y|x; A)$. Therefore, predictivity can formally be expressed by the conditional independence relation

$$y \perp \#|x, \quad (22)$$

i.e. if an observer knows her current state $x$, then learning in addition the number of times $\# - 1 \in \mathbb{N}$ that she has seen $x$ before teaches her nothing about her future observations $y$.

Or, equivalently, nothing that the observer sees in the future (which is all encoded in $y$) will teach her anything about whether she has looped, and if so, how often.

The description of the experiment implies the following equations for the $B$-measure $\mu$ that governs Beauty’s observations:

$$\mu(\Lambda, x, z_H; B) = \mu(\Lambda, x, x; B) = \mu(\Lambda, x, x, z_T; B) = \frac{1}{2},$$

and thus, for example, $\mu(\Lambda, x; B) = 1$. First note that $\mu$ is not predictive, due to Lemma 12.3: from learning either $z_H$ or $z_T$ in the future, Beauty can infer the number of times that she has experienced $x$, denoted $\#$. More formally, $\mu$ assigns non-zero probability to $\# = 2$, but zero probability to $\# = 3$, which is impossible for a predictive measure according to Corollary A.13 in the appendix.

This situation has the following feature: if Beauty awakens, then she knows that the coin had shown heads if and only if her next state will be $z_H$. Thus, finding the answer to the Sleeping Beauty Problem is equivalent to determining the probability

$$\mu(z_H|x; B),$$

but this conditional probability does not formally exist since $\mu$ is not predictive. I suspect that the popular disagreement about the correct resolution of the Sleeping Beauty Problem can ultimately be traced back to this fact.

To see this in more detail, note that this probability, if it existed, would have to satisfy the chain rule

$$\mu(z_H|x; B) = \mu(z_H|x, \# = 1; B)\mu(\# = 1|x; B) + \mu(z_H|x, \# = 2; B)\mu(\# = 2|x; B),$$

but $\mu(z_H|x, \# = 2; B) = 0$ and

$$\mu(z_H|x, \# = 1; B) = \mu(z_H|\Lambda, x; B) = \frac{\mu(\Lambda, x, z_H; B)}{\mu(\Lambda, x; B)} = \frac{1}{2},$$

and so

$$\mu(z_H|x; B) = \frac{1}{2}\mu(\# = 1|x; B).$$

In other words, the sought-for probability depends on Beauty’s degree of belief about how many times she has already experienced $x$ before, i.e. how many times she has
looped in the observer graph. There is no objective formal way to determine this degree of belief. If one imagines a scenario where the experiment is repeated many times (in a statistically independent, identically distributed way), and if one additionally posits the average frequency of $\# = 1$ among all awakenings in the long run as the degree of belief, then one obtains $\mu(\# = 1; x; B) = \frac{2}{3}$ and thus $\mu(zH; x; B) = \frac{1}{3}$, which is identical to the solution advocated in [131].

However, this argumentation is not conclusive; seen from the third-person perspective of the experimenters, all of the mathematical structure that describes the experiment is given by a $B$-measure $\mu$ on $B^\infty$, and the random variable $\#$ cannot be defined on this probability space (it is not a function of the outcome of a full experimental run, i.e. of a $B$-history). That is, the degree of belief on $\#$ that Beauty ought to assign from her first-person perspective is formally undefined. This is elaborated in more detail (and made intuitively more plausible) in Examples A.14 and A.15 in the appendix.

This example illustrates what we have discussed further above: non-predictive measures cannot be used directly by observers for prediction, unless they bring an additional, independently justified degree of belief on the number of loopings in the observer graph into the calculation.

Let us now return to the question of a natural model of computation under the assumption of predictivity. The following lemma will be formulated in terms of graph machines, but its conclusions will mostly be independent of the choice of machine model; it gives us a first hint that we may recover certain aspects of quantum theory. Recall that an observer’s external world corresponds to a “computational ontological model”, as described in Observation 8.1. Some of the terminology and interpretation of the lemma will be explained in its proof; see also Figure 5.

**Lemma 12.5 (Contextuality).** Suppose that an observer’s measure $\mu$ is predictive (as assumed in Assumption 12.2), but not acyclic. Then the observer’s external world is described by a contextual computational ontological model.

**Proof.** We are using Spekkens’ definitions of ontological model, context, and contextuality [102]; more precisely, we are adapting these definitions to our setup, similarly as in Observation 8.1. If $\mu$ is predictive, then an observer $A$’s experience of a vertex $x \in V$ of her observer graph $A = (V, E, \Lambda)$ can be interpreted as the preparation of an operational state

$$
\mu(y; x; A)
$$

which encodes the probabilities of all possible future observations $y$. For clarity, let us first consider the case that $\mu$ is acyclic. In this case, the graph machine can output $x$ only once during any given computation. Denote by $\Omega$ the set of all possible configurations of the graph machine, and by $\Omega_x \subset \Omega$ those configurations which describe the state of the machine directly after it has output $x$. That is, every $\omega \in \Omega_x$ describes the full, infinite content of a randomly filled graph machine input tape, together with head positions and output and memory contents which would arise from some valid computation that had started with the corresponding input, and led (at the corresponding snapshot time) to output $x$.

We can assign a probability measure to the $\omega$, i.e. a probability density on $\Omega_x$, by analyzing a procedure that prepares the operational state $\mu(y; x; A)$. The preparation procedure can be described as follows. Write a minimal program $q$ for the computation of $\mu$ (of length $\ell(q) = K(\mu; A)$) onto the first cells of the input tape, and fill the other input tape cells with independent identically distributed random bits. Let the universal graph machine (called $U$) run. As soon as the string $x$ is output, stop and analyze the configuration $\omega$ of the graph machine. In fact, the value of the (infinitely many) unread input bits is irrelevant, so we can consider the equivalence class $[\omega]$ of all those graph machine configurations that are identical, except for the values of the unread input bits. We assign the probability

$$
P([\omega]) := 2^{-\ell(r)}/N
$$

to this set of configurations, where $r$ denotes those input bits that follow $q$ on the input tape and which have actually been read (before $x$ has been output). Furthermore, we assign a probability density on every set $[\omega]$ in the obvious way, as inherited from the input bit distribution. The variable $N$ denotes the normalization, which is defined as

$$
N = \sum_{r:U(qr,A)=(\ldots,x,*)} 2^{-\ell(r)}.
$$

Since $U$ computes the measure $\mu$ on input $q$, and since $\mu$ is acyclic by definition, it follows that the set of strings $r$ that satisfy the definition in the sum is a prefix-free set. Thus, by the Kraft inequality, the sum converges and we have $N \leq 1$. Our probability density $P$ is thus well-defined, and describes the “ontic state” of the computational ontological model that corresponds to the operational state $\mu(y; x; A)$. Formally, one can check this correspondence as follows. Define the “indicator functions” $\xi_y(\omega)$ as 1 if $\omega$ is a graph machine configuration that leads to the further output of $y$, and 0 otherwise. Then

$$
\int_{\Omega_x} \xi_y(\omega)dP(\omega) = \sum_{[\omega]} \frac{2^{-\ell(r([\omega]))}}{N} \sum_{s:U(qr[s],A)=(\ldots,x,y,*)} 2^{-\ell(s)} = \sum_{x=(\lambda,\ldots,x)} \frac{\mu(x,y; A)}{\mu(x; A)} = \mu(y; x; A),
$$

where $r([\omega])$ denotes the input string $r$ that corresponds to the equivalence class $[\omega]$, as described above.

In the case of acyclic measures $\mu$ that we have just discussed, there is a unique procedure (up to the choice of minimal program $q$) that prepares the operational state $\mu(y; x; A)$; we have described it above. To this unique preparation procedure there corresponds a unique (statistical) ontic state. In contrast, for predictive measures that are not acyclic, something more interesting happens. Imagine performing the construction above for a cyclic measure $\mu$. An immediate problem is that the sum in (23) will not in general converge, since the set of those $r$ that satisfy the definition in the sum will not in general be prefix-free. This prevents us from defining the normalization constant $N$, and thus the probabilities $P([\omega])$. In general, there is no natural, formally distinguished way to assign a distribution $dP(\omega)$ over ontic states $\omega \in \Omega_x$: if there was any, then one could define a
unique notion of conditional probability
\[ \mu(#|x; A) := \int_{\Omega_2(#)} dP(\omega) \]
that the observer A should assign to the number of times
\( # - 1 \) that she has experienced x before, where \( \Omega_2(#) \) denotes
the set of graph machine configurations \( \omega \in \Omega_2 \) such that \( x \)
has just been output for the \( # \)-th time.59 But there is no such probability, as we have discussed in detail above.

Therefore, we have to consider the cases of different numbers of loopings \( # \) as different, separate preparations of one and the same operational state \( \mu(y|x; A) \). In the terminology of [102], this means that the value of \( # \) defines a context. We can then repeat the construction of above for every value of \( # \in \mathbb{N}_0 \) separately, giving us distributions \( dP(#)(\omega) \) over ontic states \( \omega \in \Omega_2(#) \). Since the state of the graph machine keeps a record of its past (in particular, the output tape contains all past outputs), the value of \( # \) will be a function of \( \omega \). Thus, the measures \( dP(#) \) will be different (and, in fact, non-overlapping) for different \( \omega \) — which means that the computational ontological model is contextual according to the definition in [102]: “... A natural way to explain the fact that a pair of preparation [...] procedures are operationally equivalent is to assume that they prepare [...] the ontic state of the system in precisely the same way. We shall call such an ontological model noncontextual.” This sort of explanation does not apply to the computational ontological model if \( \mu \) is predictive but not acyclic.

There are important differences between the contextuality properties of our computational ontological model and that of quantum mechanics. First, in quantum theory, an observer will in general be able to distinguish different contexts by observation. An example from [102] illustrates this: “Consider the following different measurement procedures for photon polarization. The first, which we denote by \( M_1 \), constitutes a piece of polaroid along the \( z \) axis, followed by a photodetector. The second, which we denote by \( M_2 \), constitutes a birefringent crystal oriented to separate light that is vertically polarized along the \( z \) axis from light that is horizontally polarized along this axis, followed by a photodetector in the vertically polarized output. [...]”

For our emphasis here is on preparation procedures (instead of measurements), we can consider everything that happens before the photon reaches the detector as a preparation. Then we have two different procedures that prepare identical photon polarization eigenstates. This defines a context. From inspection of the experiment, the observer will be able to tell which of the contexts is the case in the given experimental setup. This is not the case in our computational ontological model: the context is given by the number of loopings \( # \), and the observer has no knowledge of \( # \) whatsoever. By definition, predictivity prevents access to \( # \) at the given computational moment and at any time in the future. This is to be expected, since our operational state \( \mu(y|x; A) \) describes the totality of everything that the observer will ever see, whereas a quantum state usually only describes part of an observer’s experienced world.

The second difference lies in the fact that the statement of contextuality for quantum theory is stronger: quantum theory is contextual in the sense that there are no noncontextual models at all. In contrast, in our case, we only show that the specific computational ontological model(s) that arise in our theory in Observation 8.1 (and that, as we argued, will basically represent the observer’s external world) are contextual. One might even have a stronger reservation against the relevance of our result: its proof relies heavily on the fact that the graph machine’s state at a given computational time contains a record of the number \( # \) of loopings that the observer has experienced. This is due to the fact, for example, that the output tape contains a record of all previous outputs, by definition (cf. Definition 4.7). One might then ask what would have happened if we had started with a different definition (machine model) in the first place. It is not too difficult to imagine an alternative model of computation which is equivalent (in its output statistics, which defines the core of our theory) to graph machines, but that does not in general keep a record of \( # \). In particular, imagine an \( A \)-measure \( \mu \) which is Markovian (and thus predictive). We can imagine a machine that cleans up its memory and tapes after each output, erasing also all previous outputs, such that its (distribution of) ontic state(s) depends only on the last output. This would constitute a noncontextual computational ontological model. The existence of such a model would not directly rule out our conclusions (since the corresponding program for that machine need not be one of minimal length \( K(\mu; A) \) — the “cleaning up” might introduce extra complexity), but it teaches us to interpret the result above carefully.

These reservations, and the fact that contextuality is very formal property, motivate us to have a closer look at what observers “see” if they are part of a computational process that generates a predictive measure, and what this implies for the corresponding natural model of computation. This is what we aim to achieve in the remainder of this section. There is an obvious candidate for a characterizationistically non-classical effect, namely entanglement. As Schrödinger [132] famously wrote in 1935: “I would not call that one but rather the characteristic trait of quantum mechanics, the one that enforces its entire departure from classical lines of thought.” More concretely, it is not the mathematical notion of entanglement in itself that is mysterious, but rather its operational consequences, in particular the violation of Bell inequalities [22, 23, 133] (we will use the usual notion nonlocality for this in the following, without implying a specific interpretation). Quantum information theory has shown us a multitude of ways in which nonlocality can be harnessed for information-theoretic processes that would be classically impossible, such as device-independent cryptography [134, 135] or randomness amplification [91, 92]. Thus, nonlocality is an operationally particularly robust signature of nonclassicality.

In order to study nonlocality in the context of this paper, we need to talk about a notion of locality in the first place. Violation of Bell inequalities is predicted by quantum theory for some entangled states on a bipartite Hilbert space \( AB \). Physically most interesting (and experimentally most relevant [136]) is the case that \( A \) and \( B \) correspond to two

59 According to our graph machine model as defined in Definition 4.7, the output tape contains a full record of all previous outputs, so that \( # \) can be determined from the state \( \omega \) of the graph machine. Further below, we briefly discuss the idea of relaxing this condition by modifying our machine model.
spacelike separated laboratories, in which case the observed
correlations cannot be explained by shared classical randomness
on the causal structure of relativistic spacetime [129].
Therefore, we have to formulate a notion of spacelike sepa-
ratio in the context of our theory.

In Section 8, we have seen that our theory predicts the ap-
pearance of an “external world” that corresponds to a
computational process. There is no prediction (at least so far)
that this computational world admits any representation in
terms of a spacetime structure like the one we observe in
physics. This is one instance of an insight that we have al-
ready described in Section 8: the notion of “computation”
must be understood in abstract terms. In no way is there
any claim that the computational process must respect our
intuitions of computation that we have from our laptop com-
puters, or from our colorful model of “Turing machines”
with their tapes, head, internal state etc. All that matters is that
the corresponding process can in principle be simulated by
a graph machine, but it is in general unclear what its most
useful or intuitive concrete representation would look like.

Nevertheless, there are some constraints that arise from
simulatability. No matter which model of computation we
use, algorithms must proceed in a sequence of finite steps
with rules that are fixed during the computation60. Every
finite step can only process a finite amount of information.
Therefore, if the amount of data in the course of computa-
tion increases (think of a Turing machine, for example, that
reads and writes larger and larger parts of its tapes), then it
must be possible to divide this data into “chunks” such that
only a few of the chunks of data interact with a few of the
others within a finite number of computational steps. Simi-
larly as the tape cells of a Turing machine, this introduces a
notion of “causal neighbors”: declare two chunks of data as
neighbors if they interact in a single step of the computation.
Drawing a graph with the “chunks of data” as the vertices
and neighborliness as the edge relation produces an (ideally,
sparse) graph that encodes the “computational space”61.

It seems plausible that all “reasonable” computational
models allow for such a data representation in a non-trivial
way, and thus admit a notion of locality (though it would be
a matter of thorough theoretical investigation to make sure
that this intuition is not misguided due to lack of imagina-
tion). Certainly all popular models of computation do,
including cellular automata and Turing machines, and in fact
do so in a simple way. We should, however, not expect that
the resulting notions of locality always display graphs that
are as simple or regular as the ones that correspond to our
most popular human-chosen models of computation. Conver-
sely, this also means that the graph, and the way that
information propagates along it, is not necessarily best de-
scribed in terms of a spacetime that resembles the causality
of Newtonian mechanics; for example, it is perfectly possible
to arrive at Lorentz symmetry, see e.g. [137]62, or at some
much more complicated structure without any meaningful
notion of spatial dimension.

In light of these considerations, we will now assume that
observer Abby’s emergent computational world, as described
in Section 8, is equipped with a notion of locality in the
sense described above. For concreteness, we can think of a
cellular-automaton-like structure. Then it makes sense to
consider scenarios as depicted in Figure 9; namely, a situa-
tion in which there is a certain process in Abby’s vicinity A
(represented by the blue box), which takes some “setting” a
(for example, a bit) and produces some “outcome” v (which
might itself be a bit, or a sequence of bits). In general, there
must be another process at a distant point B, turning some
setting b into some outcome w, which is not completely sta-
tistically independent of the process at A. A possible origin
of this statistical dependence is the existence of a random
variable λ that has been distributed to both A and B before-
hand. For example, λ might simply originate from the
random bits on the machine’s input tape, which has been
read and transported to A and to B earlier on.

Let us assume that Abby understands her computational
world well enough to set up a situation of this kind in an
experiment-like fashion. This way, she can basically build
up a “Bell experiment” in her world, as depicted in Figure 9.
Like in an actual Bell experiment, we assume that she can
in principle input any bit a at A (“choose the setting a”) that
she wants, and she can manufacture all involved computa-
tional processes such that any remotely generated bit
b can be used as the setting at B. On the one hand, she
could use two bits a and b that are freely generated locally
at A and B; for example, two random bits that are read
from the input tape and written to A and B (and nowhere
else). In this case, a and b will be uncorrelated with all
random variables except for those in their respective future
“lightcones”, satisfying the unique sensible definition of “free
choice” that is routinely applied in this context, cf. [138, 139].
On the other hand, Abby could also use two bits for the
settings that are generated locally in some pseudo-random
fashion (e.g. by creating a checksum of Twitter messages
that her fellow guinea pigs have sent out close to A resp.
B shortly before the experiment). Most methods of pseudo-
randomness generation should yield outcomes that resemble
“truly free” random bits, since there is no reason to expect
that the graph machine’s simple computational algorithm
will “conspire” with the pseudo-random variables to produce
non-typical outcomes.

Shortly after choosing a and b, the outcomes v and w are
created locally at A resp. B. We assume that Abby knows
the value of a, and she can in principle immediately learn
the value of v. However, due to spacelike separation, she will
in general have to wait a while until she learns the values of
b and w. These outcomes will be distributed according to a
conditional probability distribution

\[ P_0(v, w|a, b) = \sum_{\lambda} q(\lambda) P_{\lambda}(v, w|a, b), \]

where \( q(\lambda) \) is some probability distribution over the possible val-
ues of \( \lambda \), and \( P_{\lambda}(v, w|a, b) = P_0(v, w|a, b, \lambda) \). If the random
variable \( \lambda \) summarizes all randomness that is shared by A
and B, then it follows that

\[ P_\lambda(v, w|a, b) = P_\lambda(v|a) P_\lambda(w|b). \]

In other words, \( P_0 \) is a classical correlation. Not all correla-
tions in physics are classical in this sense. Quantum theory

---

60 If these rules change over time then there must be a “meta rule” that
specifies those changes and is itself constant over time.

61 Note that this graph is completely unrelated to our notion of “ob-
server graphs”; it instead represents the machine’s causal structure.

62 In particular, there need not be a distinguished time foliation.
famously predicts the existence of correlations that are not of this form. Concretely, a correlation \( P(v, w|a, b) \) is quantum (cf. e.g. [140]) if there exist Hilbert spaces \( \mathcal{H}_A, \mathcal{H}_B \) for \( A \) and \( B \), a joint state \( |\psi\rangle \) in \( \mathcal{H}_A \otimes \mathcal{H}_B \), orthogonal projectors \( \pi_a^v, \pi_b^w \) with \( \sum_v \pi_a^v = 1_A, \sum_w \pi_b^w = 1_B \), and \( \pi_a^v \pi_a^\prime = \delta_{v, \prime} \pi_a^v \) as well as \( \pi_b^w \pi_b^\prime = \delta_{w, \prime} \pi_b^w \), such that
\[
P(v, w|a, b) = \langle \psi | \pi_a^v \otimes \pi_b^w | \psi \rangle.
\]
The set of quantum correlations is strictly larger than the set of classical correlations. A simple way to see this is the existence of Bell inequalities [22, 23, 41, 133] which are satisfied by all classical correlations, but violated by some quantum correlations. The CHSH inequality [133] constitutes a famous example. If \( \mathbb{E}_{a,b} \) is the expectation value of \( v \cdot w \) under the choice of settings \( a, b \) (concretely, \( \mathbb{E}_{a,b} = \sum_{v,w \in \{+1,-1\}} tw P(v, w|a, b) \)), then
\[
|\mathbb{E}_{0,0} + \mathbb{E}_{0,1} + \mathbb{E}_{1,0} - \mathbb{E}_{1,1}| \leq 2.
\]
While this inequality is satisfied by all classical correlations, it is violated by some quantum correlations. In particular, there are states and projective measurements that admit to obtain values of up to \( 2\sqrt{2} \), which is known as the Tsirelson bound [141, 142].

It is a simple but important insight that the violation of Bell inequalities (here termed “nonlocality” to comply with physics convention) does not allow one to communicate. This is known as the “no signalling” principle [143, 144], that is, the local measurement outcome probabilities at \( A \) are independent of the choice of settings at \( B \), and vice versa:
\[
\sum_v P(v, w|a, b) = \sum_v P(v, w|a', b) \quad \text{for all } a, a', b, w, \quad (24)
\]
FIG. 9. A private “Bell experiment” that Abby can set up in her emergent external computational world. As explained in the main text, we assume some rudimentary locality structure, admitting a notion of “spacelike separation” which means that information needs some (computational) time to travel from \( A \) to \( B \) and vice versa. Here we assume that \( A \) and \( B \) are very far away, such that the \( a \) and \( v_i \) can arrive at \( B \) only long after the experiment is finished, and the same for the arrival of \( b \) and \( w_i \) at \( A \). By construction, there is a local, classical conditional probability distribution \( P_0(v, w|a, b) \) that describes the probabilities of the outcomes of every single run, given the settings. As explained in the main text, if cycles in the observer graph have non-zero probability, then Abby can “loop back” to her state \( x \) of before the experiment, conditionally on the local outcome \( v_i \), and predictivity enforces that she will not notice that this happens (neither immediately nor at any point in her future). Consequently, she will see a postselected conditional probability distribution \( P(v, w|a, b) \neq P_0(v, w|a, b) \) which, as we prove below, can be non-classical (if the “hidden variables” \( \lambda_i \) are never revealed to Abby), but which will be non-signalling (if the local outcomes \( w_i \) are revealed to Abby with non-zero probability).

FIG. 10. The set of non-signalling correlations (for a fixed number of parties, measurement settings, and outcomes) is a convex polytope, here denoted NS. It contains the convex polytope of classical correlations \( C \), and the convex set of quantum correlations \( Q \) (which is not a polytope) sits strictly in between the two.
\[ \sum_{w} P(v, w|a, b) = \sum_{w} P(v, w|a', b') \text{ for all } a, b, b', v. \] (25)

In particular, this gives us well-defined marginals (reduced states) at \( A \) and \( B \), namely \( P(w|b) \) in terms of (24), and \( P(v|a) \) in terms of (25). We can also say that (24) expresses no signalling from \( A \) to \( B \), and (25) formalizes no signalling from \( B \) to \( A \).

As discovered by Tsirelson \[141, 142\] and Popescu and Rohrlich \[143\], the no-signalling principle alone is not sufficient to characterize the set of quantum correlations. That is, the set of non-signalling correlations is strictly larger than the set of quantum correlations. An example is given by a so-called Popescu-Rohrlich box (or “PR-box” correlation)

\[ P(-1, -1|a, b) = P(+1, +1|a, b) = \frac{1}{2} \text{ if } (a, b) \neq (1, 1), \]

\[ P(-1, +1|a, b) = P(+1, -1|a, b) = \frac{1}{2} \text{ if } (a, b) = (1, 1) \]

and all other probabilities equal to zero, where both \( a \) and \( b \) can take on the values 0 or 1. It is easy to see that this correlation is non-signalling, i.e. satisfies (24) and (25), and

\[ |E_{0,0} + E_{0,1} + E_{1,0} - E_{1,1}| = 4 \]

which is larger than the quantum maximum (Tsirelson bound) of \( 2\sqrt{2} \). In summary, we obtain the picture that is sketched in Figure 10.

Returning to Abby’s private Bell experiment, it is clear that the correlation \( P_0 \) that governs her outcomes must be classical. However, as we will now see, something surprising can happen if Abby’s measure \( \mu \) is predictive, but not acyclic. Denote Abby’s state at the beginning of the experiment by \( x \). Naïvely, think of \( x \) as a binary encoding of something like the following:

\[ x \approx \text{[biographical memory]} + \text{“It is Tuesday, January 14, 2031, 9:00 am, as I have just seen on my wristwatch. I am now inputting } a = 0 \text{ into my half of this Bell experiment, which is the first run of this experiment. I’m so excited to see what happens after I’ve repeated this a thousand times and collected all the data!”} \]

Let us denote all the future states of Abby by \( y = (y_1, y_2, \ldots) \): that is, the history that she experiences is \((A, \ldots, x, y_1, y_2, \ldots)\). If her measure is not acyclic, then there may be a positive probability that she loops back to \( x \), for example that \( y_1 = x \) (as in the Sleeping Beauty Problem). Therefore, it is in principle possible that the graph machine computation causes Abby to loop back conditionally on the value of her local outcome \( v \). For concreteness, suppose that the graph machine computation is in fact doing the following, which is also depicted in Figure 9:

1. At \( A \) and at \( B \), a random variable \( \lambda \) is assessed which has been generated, copied and transported to both places earlier on. This variable \( \lambda \) has been sampled with uniform probability 1/4 from the four-element set

\[ \lambda \in \{+\theta + +, \theta + + - , \theta - - + , -\theta - - \}. \]

We use the notation \( \lambda = \lambda_0 \lambda_1 \lambda'_0 \), where \( \lambda_i \in \{+\theta, -\theta\} \) and \( \lambda'_0 \in \{+\theta, -\theta\} \).

2. The outcome \( w = l'_0 \) is locally generated at \( B \) (and free to spread from there to the rest of the computation, including, later on, to Abby).

3. If \( l_a \neq \emptyset \) then the outcome \( v = l_a \in \{+,-\} \) is locally generated, and Abby learns this outcome. That is, the graph machine outputs a successor state \( y_1 \) for Abby that contains knowledge of \( v \). In other words, \( y_1 \neq x \), and \( v \) is a function of \( y_1 \).

On the other hand, if \( l_a = \emptyset \), then the graph machine outputs \( y_1 = x \): this assumes that Abby’s observer graph contains a loop \( x \rightarrow x \). In this case, the process will restart at step 1, on another random variable \( \lambda \) that has been transported to \( A \) and \( B \) in the meantime.

If Abby’s local outcome is \( \emptyset \), then she does not see this outcome, but “loops back” to her previous state \( x \). By definition, if this happens, then she will not be aware of the fact that she has just looped. Remember what “being in the state \( x \)” means: all that she sees, knows and remembers is reset to her earlier state. In particular, Abby will still think that she is about to run the experiment for the first time, and that it is 9:00am as described above.

But then, can’t Abby simply look at her wristwatch to see that some extra time has passed, and find out in the next moment that she has just looped? Surprisingly, the answer must be “no” due to Assumption 12.2: Predictivity implies that her probability of future observations, \( \mu(y|x; A) \), is the same, no matter how many times \# she has looped in her observer graph. In particular, the probability distribution over the possible readings of times on a clock must be identical before and after the looping. Everything must look for Abby as if she had travelled back in time — or rather, as if she had never looped.

This also explains our choice to demand that the protocol above repeats itself exactly in the case of looping: the graph machine must do something that ensures that the number of loopings \# has no influence whatsoever on Abby’s future experiences, and it seems hard to come up with any other possibility but to go from step 3 back to step 1. Similarly, it is also unavoidable to demand that the random variable \( a \) is chosen once and then fixed, which is enforced here by demanding that \( x \) contains a description of \( a \) such that \( a \) is a function of \( x \): if \( a \) was allowed to change after every looping, then this could in general induce a different distribution over the values of \( a \) than what Abby intends or expects, which is not what we observe in actual Bell experiments. This motivates our choice of nomenclature in Figure 9: while \( a \) and \( b \) are fixed, there are actually several different versions of \( v \) and \( w \) in the graph machine computation, which we enumerate according to the computational time by \( v_1, v_2, \ldots, w_1, w_2, \ldots \); similarly, there are different versions of \( \lambda \), denoted \( \lambda_1, \lambda_2, \ldots \), but as we will soon see, these must remain hidden if Abby is to see violations of Bell inequalities.

In the specific example above, the conditional probability distribution \( P_0(v, w|a, b) = P(v_i, w_i|a, b) \) over all possible outcomes (including \( v = \emptyset \)) turns out to be the following:

<table>
<thead>
<tr>
<th>((a, b))</th>
<th>((0, 0))</th>
<th>((0, 1))</th>
<th>((1, 0))</th>
<th>((1, 1))</th>
</tr>

</tbody>
</table>
This equals the convex combination

\[ P_0 = \frac{1}{4} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{pmatrix} + \frac{1}{4} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} + \frac{1}{4} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \]

which confirms that \( P_0 \) is a classical correlation. The notation is such that \( P_\lambda = P_{\lambda|\varepsilon_0|\varepsilon_1} \) denotes the deterministic behavior that results if the random variable \( \lambda \) attains the corresponding value.

By construction, however, the random experiment only ends for Abby if her local outcome \( l_a \) is different from \( \emptyset \) — the experiment is repeated until this is the case. Thus, the conditional probability \( P(v, w|a, b) \) of the outcome \( v \neq \emptyset \) that Abby actually learns, and of the corresponding outcome \( w \) at \( B \), corresponds to the postselected distribution

\[ P(v, w|a, b) = \frac{P_0(v, w|a, b)}{1 - P_0(|\emptyset|a)} \quad (v \neq \emptyset), \]

where \( P_0(|\emptyset|a) = \sum_w P_0(|\emptyset|a, b) \) for all \( b \). In the special case above, we have \( P_0(|\emptyset|a) = \frac{1}{4} \) and obtain

\[ P = 2 \cdot \begin{pmatrix} 1/4 & 1/4 & 1/4 & 0 \\ 0 & 0 & 0 & 1/4 \\ 0 & 0 & 0 & 1/4 \\ 1/4 & 1/4 & 1/4 & 0 \end{pmatrix}. \]

This is a nonlocal correlation — it is exactly the PR-box correlation \([141–143]\) that we have described above.

How is this possible? What happens in the scenario above is a phenomenon that is well-known under the name of detection loophole \([145, 146]\): if the two parties \( A \) and \( B \) in a Bell experiment have detectors that are not perfect, then postselecting on the successful detection can reproduce the statistics of nonlocal correlations \([147]\). Abby looping into her old state, and forgetting the run of the experiment, can be interpreted, in this instrumentalist language, as an unsuccessful detection event (denoted \( \emptyset \))\(^{63}\).

\[ \text{Lemma 12.6 (Nonlocality). Consider an observer (“Abby”) whose measure } \mu \text{ is predictive (as assumed in Assumption 12.2), but not acyclic (cf. Figure 5). Furthermore, suppose that her computational ontological model admits a notion of locality as described further above. Then there are simple setups in which Abby will generically observe correlations that violate Bell inequalities.} \]

Our example thus shows the following:

\[ \text{How is this notion of nonlocality related to the notion of contextuality that we have identified in Lemma 12.5? To gain some insight into this question, let us have a closer look at the random variable } \lambda \text{. In the context of Bell experiments, } \lambda \text{ is usually called a “hidden variable”, implying that we can typically not observe the value of } \lambda \text{. Let us therefore analyze what happens if we assume the opposite, namely, that there is a non-zero probability that Abby will learn the value of } \lambda \text{ in the future. Intuitively, if Abby learns } \lambda \text{ later on, then this should not teach her anything about whether one run of the experiment has looped or not, since otherwise this would contradict predictivity, see Lemma 12.3. Hence, in this case, we expect that } \lambda \perp \emptyset \text{. We will now derive this relation more carefully, and subsequently discuss its consequences.} \]

\[ \text{First we have to define what we mean by “Alice learning the value of a random variable with non-zero probability in the future” (see also the example after the definition).}^{64} \]

\[ \text{Definition 12.7 (Fair learning). Consider an observer } \lambda (“Abby”) \text{ whose asymptotic measure } \mu \text{ is predictive but not acyclic. Furthermore, suppose that Abby is part of a Bell scenario as explained above and depicted in Figure 9. We assume that the loop } x \rightarrow x \text{ has positive probability, but once Abby’s local outcome is } v \neq \emptyset \text{, this loop is left, and Abby does not loop back to } x \text{ again. For example, Abby’s observer graph could be of a similar structure as that in the Sleeping Beauty Problem, Example 12.4. We regard } x \text{ as fixed, and do not treat it as a random variable.} \]

\[ \text{We introduce two random variables: } #_{\text{max}} \text{ denotes the number of times Abby loops (i.e. how often she experiences state } x); \text{ and for some fixed } m \in \mathbb{N}, \text{ the random variable } z = (z_1, \ldots, z_m) \text{ denotes the subsequent } m \text{ states that Abby experiences (in particular, } x \overset{A}{\rightarrow} z_1 \text{ and } z_1 \neq x; \text{ we will also denote the later states by } z_{m+1}, z_{m+2}, \ldots). \text{ As we show on page 80 in the appendix, predictivity implies} \]

\[ z \perp #_{\text{max}}. \]

\[ \text{We say that Abby learns the value of a random variable } u \text{ with non-zero probability in the future if there exists some future history } y = (y_1, \ldots, y_m) \text{ with } \mu(y|x; A) > 0 \text{ and some } c \in \mathbb{N} \text{ as well as a function } f \text{ with the following property: if } z = y \text{ then Abby learns } u, \text{ namely } f(z_{m+c}) = u. \text{ Furthermore, we say that this learning is } \text{fair} \text{ if the probability of learning is independent of the pair } (u, #_{\text{max}}) \text{, i.e.} \]

\[ u, #_{\text{max}} \perp (z = y). \]

\[ \text{There are also other possible ways to interpret this result. For example, postselecting on Abby’s outcome will in general lead to correlations between the settings } a, b \text{ and the hidden variable } \lambda, \text{ which is an instance of Berkson’s paradox }([148]): \text{ “conditioning on a variable induces statistical correlations between its causal parents when they are otherwise uncorrelated” }([149]). \text{ These correlations in turn lead to the violation of the assumption of free local choice of settings which underlie the derivation of Bell inequalities. However, as explained above, this does not prevent Abby from inputting whatever } a \text{ she likes into her half of the experiment; it rather allows her to effectively intervene on } \lambda, \text{ but not in a way that could be used for signalling, as we will soon see.} \]

\[ \text{By the way, when we have an } \text{event} \text{ (measurable subset of the probability space) in a conditional independence relation, we identify the event with its characteristic function, namely the random variable that attains the value 1 on the event and 0 on its complement.} \]

\[ u, #_{\text{max}} \perp (z = y). \]
Note that (28) implies both

\[ u \perp \#(z = y) \quad \text{and} \quad \#_{\text{max}} \perp \#(z = y). \tag{29} \]

To see why the first one of these two relations is very natural, consider the following example. Suppose that it is the day after the election of the new guinea pig president, and Abby does not know the election result. Denote this state of Abby by \( x \). A few hours later, she switches on her TV, and sees that a show is starting right now which is going to broadcast the election results. This corresponds to the state \( y_m \) of \( y \). A few moments later (when she is in state \( y_{m+c} \)), she will actually see the result (the random variable \( u \), encoding the name of the new president). If this learning event is fair, then her decision of turning on the TV does not depend on the result of the election — which is extremely intuitive. It would only be violated in bizarre situations, such as having one presidential candidate who, (only) if elected, would stand out against the others by starting the presidency with breaking into Abby’s house at night and removing her TV.

The second relation in (29) follows alternatively directly from (27): since the (characteristic function of the) event \( z = y \) is a function of the random variable \( z \), Lemma 4.2 from [150] shows that also this event must be conditionally independent from \( \#_{\text{max}} \), given \( x \). Then why do we not simply postulate the first relation of (29) in Definition 12.7 instead of the stronger condition (28)? After all, this first relation in (29) expresses more directly what we have described in the election example! The reason is that the two relations in (29) do not completely rule out the possibility that learning whether \( z = y \) teaches Abby something about the combination of \( u \) and \( \#_{\text{max}} \) (for example, their correlation), even though it teaches Abby nothing about any single one of the two random variables separately. Such a pathological behavior seems very unlikely, unnatural or “fine-tuned”, and we thus exclude it formally by demanding (28).

If Abby definitely learned some random variable \( u \), then \( u \) would be a function of her future observations \( z \). In this sense, we could again invoke Lemma 4.2 from [150] to conclude from (27) that \( u \perp \#_{\text{max}} \). But we can get the same conclusion from our weaker notion of probabilistic learning:

**Lemma 12.8 (Fair learning implies independence).**

Consider the scenario of Definition 12.7. If Abby learns the value of a random variable \( u \) fairly with non-zero probability in the future, then

\[ u \perp \#_{\text{max}}. \tag{30} \]

**Proof.** In contrast to \( \# \), the quantity \( \#_{\text{max}} \) is a well-defined random variable on the probability space \( \mathcal{A}^\infty \) (and so is \( u \) by assumption). Thus, we can simply calculate

\[
\mu(u|\#_{\text{max}}; A) = \mu(u, z = y|\#_{\text{max}}; A) + \mu(u, z \neq y|\#_{\text{max}}; A) \\
= \mu(z = y, f(z_{m+c}) = u|\#_{\text{max}}; A) \\
+ \frac{\mu(u, z \neq y, \#_{\text{max}}; A)}{\mu(\#_{\text{max}}; A)} \\
= \frac{\mu(z = y, f(z_{m+c}) = u; A)}{\mu(\#_{\text{max}}; A)} \\
+ \frac{\mu(u, \#_{\text{max}}; A)\mu(z \neq y; A)}{\mu(\#_{\text{max}}; A)}.
\]

and we have used eq. (27) and (28) in the last equality. Further rearrangement and renaming yields

\[
\mu(u|\#_{\text{max}}; A) = \frac{\mu(z = y, f(y_{m+c}) = u; A)}{\mu(z = y; A)}.
\]

This is obviously independent of \( \#_{\text{max}} \). \( \square \)

We now apply this to the “hidden variable” \( \lambda \). We have to be careful and specify what we actually mean by \( \lambda \); a single repetition of the experiment (as appearing in Abby’s observed statistics) corresponds to several looping runs (until Abby’s local outcome is different from \( \emptyset \)), and \( \lambda \) has in general different values in every run. For simplicity, let us consider the value of \( \lambda \) during the first looping run, i.e. when Abby attains state \( x \) for the very first time. In the nomenclature of Figure 9, this variable is called \( \lambda_1 \). If we assume that Abby learns this \( \lambda_1 \) fairly with non-zero probability in the future\(^{65}\), then Lemma 12.8 gives us

\[ \lambda_1 \perp \#_{\text{max}}. \tag{31} \]

What are the consequences of this conditional independence relation for the correlation table \( P_0 \) of the Bell experiment? As we have argued above, the setting \( a \) is fixed by \( x \), so what happens in that run determines the probabilities \( P_0(\emptyset, a, \bullet) \). If Abby repeats the Bell experiment many times\(^{66}\), she will choose different settings and empirically determine the postselected correlation table \( P \) which is formally determined from \( P_0 \) by (26). But in every single (possibly looping) run, the distribution on the “hidden variable” \( \lambda_1 \) and the “non-detection event” \( \emptyset \) will factorize, due to (31). That is, \( P_0(\emptyset|\lambda_1, a) = P_0(\emptyset|a) \).

According to Theorem 1 in [151], this has the interesting consequence that the postselected distribution \( P \) is local, i.e. classical. (Our “PR box” example in Lemma 12.6 clearly violates this condition: local looping, i.e. the outcome \( \emptyset \) depends explicitly on the hidden variable \( \lambda \).) In summary, we have proven the following:

**Lemma 12.9 (Local hidden variable models and \( \lambda \)).**

Consider the scenario of Definition 12.7. If Abby fairly learns \( \lambda_1 \) with non-zero probability in the future, then the correlation \( P \) that she sees admits a local hidden variable model. In other words, in order to see violations of Bell inequalities, it is necessary that \( \lambda_1 \) is never fully revealed.

\(^{65}\) By symmetry of the setup, we expect that this is equivalent to fair learning of any of the \( \lambda_i \).

\(^{66}\) In our example, if \( x \) and \( x' \) are states of Abby in two repetitions of the experiment that both make her choose setting \( a \), then in both runs her process will be described by an identical correlation \( P_0(\bullet, \bullet, a, \bullet) \). If we allow instead two different correlations \( P_0^{(1)} \) and \( P_0^{(2)} \), then Abby will see a statistical mixture of those in her observed statistics. Statistical mixtures of classical correlations are classical, which is why Lemma 12.9 should then still remain valid.
Lemma 12.9 relates the phenomenon of nonlocality, as described in and around Lemma 12.6, to our earlier insights on contextuality (cf. Lemma 12.5): the hidden random variable $\lambda$ must be different for different “contexts” # (corresponding to different looping runs of the Bell experiment, and denoted separately by $\lambda_i$), and as such must be invisible to the observer. In other words, predictivity and the existence of cycles supplies us with contextuality, which is the necessary ingredient for nonlocality to emerge in the observer’s computational external world [152]. Finally, note that even though we may call $\lambda$ a “hidden variable”, the computational graph machine model itself (originating in Observation 8.1) is not a hidden variable model in the usual sense (as formulated, for example, in [101]), since the empirical correlations $P$ arise from it in a non-standard way (via postselection and cycles). Thus, its internal locality does not contradict Bell’s Theorem.

So given that the “hidden variables” $\lambda_i$ will never be revealed, it is a generic feature for Abby to see nonlocal correlations in the scenario above. However, as pointed out by Wood and Spekkens [129], causal explanations of Bell inequality violations must achieve much more than that: the really tough challenge is to admit Bell violations, but at the same time to preserve the no-signalling principle. In other words: any mechanism involving some kind of hidden variables which leads to violations of Bell inequalities will typically also lead to signalling.

Therefore, the question of no-signalling can be viewed as an important litmus test for the ideas of this section. In general, it is possible to obtain signalling distributions $P$ from postselecting local correlations $P_0$ as in (26) via imperfect detection. Nevertheless, we have the following:

**Lemma 12.10** (No signalling). Consider the Bell scenario described above (see also Figure 9). Abby’s postselected distribution $P$ will be non-signalling from $B$ to $A$ (this is true even if Abby’s measure $\mu$ is not predictive).

Furthermore, if Abby fairly learns the outcome $w_1$ of the first looping and the setting $b$ with non-zero probability in the future, then $P$ is also non-signalling from $A$ to $B$.

**Proof.** The first claim follows directly from Lemma A.16 in the appendix. The proof of the second claim is analogous to the proof of Lemma 12.9: using Lemma 12.8, we obtain $(b, w_1) \perp \perp \#_{\max}$.

Since the event $\emptyset_1$ of the first run is a function of $\#_{\max}$, this implies $(b, w_1) \perp \perp \emptyset_1$. Applying the “weak union” property [128], we get $w_1 \perp \perp \emptyset_1 | b$. As above, the setting $a$ is considered to be fixed but arbitrary. Thus, this conditional independence relation implies

$$P_0(\emptyset, w | a, b) = P_0(\emptyset | a, b)P_0(w | a, b) = P_0(\emptyset | a)P_0(w | b)$$

for all $a, b$, where the last equality follows from no-signalling of the classical correlation $P_0$. In the language of Bell scenarios, this describes a situation where B’s outcome is conditionally independent from the firing of A’s detector, given the settings (note that our PR-box example above satisfies this conditional independence relation). As shown in Lemma A.16 in the appendix, this implies no-signalling from $A$ to $B$ for the postselected distribution $P$.

So it seems that the ideas of this section pass the litmus test: they disallow signalling but allow the violation of Bell inequalities. This is true, of course, if we have good motivation for the premise of Lemma 12.10: namely that Abby fairly learns the setting $b$ and B’s first outcome $w_1$ in the future. So what is the justification of this assumption?

It is clearly uncontroversial to assume that Abby will learn $b$ in the future, since she needs this data to inspect the correlation table $P$ in the first place (note that by construction, $b$ does not change during Abby’s loopings $x \rightarrow x$ in her observer graph). What about $w_1$? To discuss this, we have to be a bit more specific about how the machine actually implements the computational process that contains the Bell test — which will finally lead us back to our initial question of which model of computation is “natural” for processes that generate predictive measures.

After looping ($\#_{\max} - 1$) times, Abby finally obtains an outcome $v \neq \emptyset$ locally at $A$. After waiting for a while, the value of $w_i$ for the last looping, $i = \#_{\max}$, will be accessible to her, and she will observe this value as the one that “corresponds to” her outcome $v$. It is clearly the case in every kind of Bell experiment that pairs of events have to be identified, and any mistakes appearing in this task can lead to a “coincidence loophole” that mimics Bell violations when there actually are none. This pair identification is here assumed to lead to Abby concluding that her local outcome $v$ and B’s local outcome $w = w_{\#_{\max}}$ “belong together”. This in itself is not particularly mysterious; we can imagine that the machine tags the outcomes $w_i$ according to some internal “computational time”, and then pairs up the value of $v$ with the value of $w_{i}$ that corresponds to “the same” computational time.

Nonetheless, the question which of the $w_i$ will be the “right” one, to be paired up with Abby’s outcome $v$ later on, is not decided locally at $B$. Therefore, locality of the computation means that the machine has to treat all the $w_i$ on equal footing, regarding the properties of the local computation around $B$. This means that if the final outcome, $w = w_{\#_{\max}}$, is free to spread to Abby later on, then the same must in principle be true for the other $w_i$ — no local mechanism will be allowed to “delete” or “hide” these outcomes, as schematically indicated in Figure 9 (“announcement”). This is our main motivation to assume that $w_1$ (and, in fact, all the $w_i$) will be available to Abby later on, at least with non-zero probability.\(^{67}\)

\(^{67}\)Note that “fairly learning $w_1$ with non-zero probability in the future” only means that the value of the random variable $w_1$ may have some effect on Abby’s experience in the future, but it does not necessarily mean that Abby is aware of this fact. Regarding the guinea pig presidential election example below Definition 12.7, Abby could also fairly learn the outcome of the election in the following way: Abby turns on the TV (shortly after the election), and sees the development of the stock prizes in the news. It might be that the stock prize is in direct one-to-one correspondence to the outcome of the election (maybe because one president is regarded as obviously more economically competent), without Abby knowing this. If this was the case, then the outcome of the election would have direct impact on Abby’s observations (in accordance with Definition 12.7), but she would not be aware of this fact. In the Bell test case, we may also think of Abby learning $w_1$ in the future without being aware of this. For example, there could be some very small temperature fluctuation in Abby’s surroundings in the future, depending on the value of $w_1$. 

While this insight seems satisfactory to some extent, one cannot help but wonder how the machine actually performs the computation to enforce predictivity for the computed measure. To see why this computation must be to some extent counterintuitive, consider a Bell experiment that is carried out by our civilization of guinea pigs. Suppose that Abby is in fact an astronaut, one light year away from earth (at some place called A), and she is part of an astronomical Bell test. Suppose that physics is immensely popular in guinea pig world, and the runs of the Bell test are broadcast live on TV. Millions of guinea pigs gather in their cities for public viewing, and cheer and dance, with dance moves depending on the local outcomes $w$ (at their planet, place B) as they are reported one after the other (they will learn Abby’s outcomes only one year later). In such a world, what do the different “pseudo outcomes” $w_i$ correspond to? In what sense is only one of the $w_i$ the “real” one that is paired up with $v$?

It seems as if the machine, in order to enforce predictivity, will somehow have to do its local computation at B in a way that admits all possible values of $\#_{\max}$ to be later on decided at A. In some sense, the machine will have to process all possible $w_{\#_{\max}}$ (that is, all the $w_i$), and compute the different behaviors of the guinea pig world for all possibilities in parallel. That is, similarly as in a “many-worlds” scenario, the machine has to simulate different “versions” of the guinea pig civilization. Only later on, when the computational light cones of A and B intersect (such that Abby learns $b$ and $w$, and the guinea pigs at home learn her setting $a$ and outcome $v$) will the correct “pairing” have to be established — Abby will only see the one realization of her home planet (and its civilization) that corresponds to the correct context $\#_{\max}$, and conceivably vice versa.

We can see this as a hint on the natural model of computation for processes that generate predictive measures. To understand the main idea of such a “natural model” from yet another perspective, recall some of the discussion in Section 4. Imagine a generic Turing machine, with an arbitrary number of input and output tapes. In general, we can program the machine to read and write its tapes in any way we like. In particular, there is in general no guarantee that output bits are written successively; instead, it can happen that some bits are written, then some of the bits get erased, then some other bits are written etc. But if we tried to define a notion of algorithmic probability as in Definition 4.2, then this would bring us into trouble: it would be impossible to write down a unique, natural definition of “probability that the output starts with $x$”, where $x \in \{0,1\}^*$ is some string, if such arbitrary output behavior was possible. The solution in algorithmic information theory is then to introduce a restriction on the Turing machine’s “hardware”: namely, that input and output tapes are unidirectional, such that one bit after the other has to be read and written. This leads to a notion of “monotone Turing machine”, and the working of this type of machine guarantees that it generates a probability distribution with the desired properties.

While the graph machine model (as an extension of the monotone machine model) guarantees that the output statistics corresponds to an A-(semi)measure, we can imagine that there is another model of computation, obtained by adding further restrictions to the graph machine model, which enforces the output statistics to correspond to a predictive measure (or more specifically to a Markovian measure). I do not currently know in any detail what such a model of computation would have to look like, but the discussion above gives us a few hints. Interestingly, the main characteristics of the computational behavior sketched above has recently appeared in the field of quantum foundations as a possible local realist model of quantum theory [153–155]. Since that model does not fall into the usual class of hidden variable models, its existence does not contradict Bell’s theorem.

**Observation 12.11** (A machine model of parallel processes?). Suppose that we would like to modify the graph machine model to enforce that the output statistics always corresponds to a predictive $A$-semimeasure.\(^{69}\) (This would allow us to make a more informed guess what a generic external world for the corresponding observer $A$ would look like, if her asymptotic measure $\mu$ was not acyclic but predictive.)

Then the discussion above suggests that this computational model will typically exhibit features that resemble those of Brassard and Raymond-Robichaud’s [153–155] local realist (non-hidden-variable) model of quantum theory (see in particular the colorful PR-box illustration in [154]). That is, multiple realizations of local physical processes will be computed in parallel and only some of them will be interacting, i.e. come into mutual P-existence.

It would be interesting to work out the details of such a model of computation, and to compare its properties to those of quantum computers. In particular, one might want to analyze which problems can be solved on such a machine in polynomial time (where “time” should possibly be measured with respect to clocks of observers that are part of the computation, as Figure 9 suggests), and how this class of problems would compare to the complexity class BQP.

Now that we approach the end of this section, a coherent picture has emerged. We have started by assuming that an observer’s history contains cycles with non-zero probability, but that this does not prevent her from assigning probabilities to future observations, given only what she currently knows. (See Section 14, in particular Open Problem 14.3, for how this relates to a potential amendment of our postulates.) This “Bayesian” constraint has interesting consequences: namely, it implies that the observer’s external world (which is nothing but an ontological model, cf. Observation 8.1) is contextual and admits scenarios that naturally lead to nonlocal but non-signalling correlations. We have also argued that it leads to a computational world which seems to display a notion of parallelism which is at least in

---

\(^{68}\) Note that we are talking here about “Abby’s private external world”; the fact that other guinea pigs see that world as well is an emergent phenomenon that happens only under certain circumstances, see the discussion in Section 9. How cycles and the resulting phenomena of this section combine with this notion of “emergent objective reality” is a separate question that we will briefly discuss further below.

\(^{69}\) Here we refer to a natural generalization of predictivity from measures to semimeasures; a generalization of Informal definition 7.10 seems straightforward.
vague resemblance to quantum computation: namely, that
different parallel computational branches do not normally
“see each other”, and only some of them interact. In some
sense, this is a “many-worlds”-like picture, though more in
spirit of Brassard and Raymond-Robichaud’s model [153–
155] than Everett’s.

While we have argued in Observation 8.1 that observers’
experiences are described by a “computational ontological
model” which we can interpret as an “external world”, the
observer herself will typically not organize her experiences
in terms of this model, as we have just seen. This is be-
because some aspects of this model are hidden in principle to
the observer, at least if here asymptotic measure \( \mu \) is pre-
dictive and not acyclic. Instead, the observer may use an
“effective description” that summarizes only those aspects
that she can in principle record and remember. In situations
like the “private Bell test” of Figure 9, this means that the
observer will use non-classical conditional probability distri-
butions (corresponding to the postselected distribution \( P \)) to
describe probabilities of events in her world. The idea is that
these conditional distributions will ultimately correspond to
quantum states.

There are obviously many open questions regarding the
relation between our theory and quantum theory. First, how
far can we get in deriving the structure of quantum the-
ory from considerations like the ones above, such that the
aforementioned “non-classical conditional probability distri-
butions” correspond to quantum states? Some progress on
this question might come from constructing the computa-
tional model mentioned in Observation 12.11, but it may
well be that the exact structure of quantum theory is a con-
tingent feature, similarly as the exact choice of asymptotic
measure \( \mu \) in Theorem 7.8 will in general be merely random
(though with strong bias towards simple measures).

There are nonetheless some hints that we might hope
for stronger results. One such hint is given by the recent
wave of reconstructions of the formalism of quantum theory
from simple information-theoretic postulates [26–35], as men-
tioned in Section 2. Similarly, there is progress in delineating
the quantum correlations from the set of all non-signalling
correlations in terms of simple principles [156–160]. What
we can learn from these reconstructions is that a few simple
and intuitive constraints on encoding and processing of in-
formation will automatically lead to (aspects of) the Hilbert
space formalism of quantum theory. There may well be a
way to understand these information-theoretic principles as
consequences of the machine model in Observation 12.11,
or as typical features of experiences of observers that are
part of computational worlds with cycles and try to make
sense of what they record. Furthermore, there are some
hints that the structure of spacetime (another possibly con-
tingent feature that is so far not at all predicted by the ap-
proach of this paper) is directly related to the structure of
quantum theory. Ideas of this kind are coming from high-
energy physics [17, 18, 161–163] as well as quantum founda-
tions [164–167]. Here may be another handle to potentially
go a longer way towards actual physics from our theory, even
though it might be a very long journey.

To conclude this section, let me briefly comment on a
further open question: namely, what does our approach
have to say about the thought experiment of Wigner’s
Friend [168]? As we have argued in Observation 12.1, our
theory does seem to fit these kinds of scenarios particu-
larly well: “outcomes of measurements” simply correspond
to “experiences” which are fundamentally private to a single
observer, and cannot always be organized into a “common
world” for several observers. Concretely, the absence of what
Frauchiger and Renner [46] call “consistency” can be inter-
preted as an instance of our notion of “probabilistic zombies”
from Observation 10.1. It is interesting to note that “reco-
hering” Wigner’s Friend’s state in [46] by definition erases
some of that agent’s (as presenting herself in Wigner’s world)
memory. Given the interpretation of quantum states as post-
selected conditional distributions from above, it is then not
particularly surprising that quantum theory seems to some
extent at odds with these kinds of situations: according to
the derivation above, quantum states do not correspond to
probabilities of events (in an observer’s emergent external
world), but to probabilities of records of events that are held
by observers (for example in their memory). I leave a more
detailed analysis of these emerging connections and open
questions to future work.

13. SIMULATING OBSERVERS ON A COMPUTER

This final section turns from physics to a bundle of broadly
philosophical questions which are closely related to the topic
of this paper. These questions may attain particular rele-
vance in the near future with ongoing technological progress:
namely, the problem to make decisions in situations that in-
volve difficult questions of personal identity.

A specific instance of this problem is the question of brain
emulation: would it make sense to invest in technology that
scans our brains and simulates them to high accuracy af-
ter our death? Would the simulation be “conscious”, and
would we actually “wake up” in the simulation? The theory
of this paper does not claim to make any statements about
consciousness directly, but it does claim to make predictions
about the first-person experience of observers. It is this tech-
nical notion of first-person perspective that is the subject of
interest here, not the specific, high-level, so far ill-defined
notion of consciousness.

Many philosophers, neuroscientists, and computer scien-
tists have thought about the question of brain emulation.
Here I will not discuss any specific details of this problem, but
only its very fundamental information-theoretic basis which,
as I argue below, allows our theory, at least in principle, to
make some concrete predictions. Concretely, I will follow a
discussion in [169] (see also [170]). The authors discuss the
idea to create an “oracle artificial intelligence” (OAI) as an
AI that is confined to some “box”, and only interacts with
the real world by answering questions. Restricting it to be an
“oracle” in this sense (and not allowing it to act as an
agent in the actual physical world) is meant to reduce poten-
tial risks (for example, the risk that the AI takes over
and destroys our planet). However, the authors argue that
not all risks can be eliminated: for example, the OAI might
simulate human minds in its memory if this helps to answer
some questions more accurately. Then, according to [169],
“[…] the problem with the OAI simulating human minds
is mainly ethical: are these simulated humans conscious and
alive? And, if they are, are they not being killed when the
simulation is ended? Are you yourself not currently being simulated by an OAI seeking to resolve a specific question on human psychology [8]? If so, how would you feel if the simulation were to be ended? In view of its speed and the sort of questions it would be asked, the number of humans that the OAI may have cause to simulate could run into the trillions. Thus, the vast majority of human beings could end up being doomed simulations. This is an extreme form of “mind crime” [171] where the OAI causes great destruction just by thinking.

The worldview that underlies this argumentation is clearly reminiscent of the standard cosmological ontology of the Boltzmann brain problem in Section 11, with the “trillions of doomed simulations” analogous to the vast number of Boltzmann brains in a large universe. We have already argued that the approach of this paper implies that naive counting is inappropriate in cosmology: hence it should come as no surprise that it also implies a substantial shift of perspective on the brain emulation problem.

According to Postulates 5.1, observers correspond to sequences of observations $x = (x_1, \ldots, x_n)$: to every such sequence, there is an associated first-person perspective. What is crucial, in the terminology of Section 2, is the M-existence of these observations (as abstractly defined strings). Any external world, in which we can identify persistent patterns (“things”) that P-exist relative to each other, is an emergent phenomenon that is secondary to the observations. Thus, according to our theory, observers cannot be “created” or “destroyed”, neither by physics are we know it nor by computer simulation (see also the discussion on subjective immortality in Section 10). The only way in which the emergent external world (or a computer simulation) can affect observers is by impacting conditional algorithmic probability, which in turn determines the chances of future observations: regarding a “world” as a computational process, what happens in this world influences the statistics of its outputs, which in turn enters the definition of algorithmic probability. This is in which sense Bambi’s probability of suffering increases if Abby decides to beat her up.

Thus, we conclude that starting a computer simulation does not “bring an observer into existence”, and shutting down a simulation does not “kill” the simulated observer. But there still remains the question of what happens, say, if we decide to torture a simulated observer; does it increase someone’s probability of suffering?

Phrasing the question in this form seems to assume that it makes sense to talk about “agency” in our approach, i.e. that we have a choice in the first place. At first glance, this does not obviously make sense, as there is no fundamental notion of “free will” built into our theory: observers passively follow the stochastic random walk on their observer graph. However, exactly the same is true for all other theories of physics that we have: in classical mechanics, observers act perfectly deterministically, whereas in quantum mechanics, their behavior is given by probabilistic laws. Arguably, probabilistic indeterminism does not automatically entail any notion of “free will” (it is more like being slave to a die).

For this reason, the old philosophical debate about free will applies to our theory in exactly the same way as it does to all other physical theories. Even though this is a fascinating problem, its philosophical resolution is not important for the discussion in this section\(^{70}\). Instead, let us follow a pragmatic approach for the time being: whatever “free will” fundamentally means, it is an undeniable experience that we somehow have to decide what to do tomorrow. Therefore, it is essential for practical purposes to treat our actions as not predetermined, and to argue counterfactually what would happen if we decided one way or the other. Henceforth we will treat the actions of our prototype of observer, Abby, in her emergent external world as “free” in this sense.

Equipped with a notion of agency of observers, we can now analyze what our theory has to say about torturing a simulated mind. Let $A = (V, E, A)$ be any observer graph, representing Abby the guinea pig. Suppose that Abby has experienced an $A$-history $x = (\Lambda, \ldots, x)$, where $x \in V$ is a standard “happy state”, describing Abby eating a large and tasty piece of cabbage. However, imagine that there is a “suffering state” $y \in A(x)$, possibly the beginning of a painful medical procedure that we would like to test on emulated Abby in a computer simulation.

Suppose that we have a simulation running (which may be a deterministic or probabilistic algorithm), and we have observed emulated Abby going through the states in $x$. Furthermore, suppose that we know that in the next time step, our simulation is going to perform the transition $x \rightarrow y$ with high probability $P_{\text{sim}}(y|x) \gg 0$ (unity in the deterministic case). Are we ethically allowed to run the simulation? Should we shut it down? Should we have refrained from running it in the first place?

Clearly, what actually matters for Abby is $P(y|x; A) \sim M(y|x; A)$, her first-person probability to experience suffering according to Postulates 5.1. Arguably, it is ethically correct for us to run the simulation either if Abby’s subjective suffering probability is small despite our simulation, or if it is large but our simulation cannot be regarded as the cause for this. In more detail, we have the following two arguably acceptable scenarios:

1. $M(y|x; A) \approx 0$ even though $P_{\text{sim}}(y|x) \gg 0$. This would imply that simulated Abby is a probabilistic zombie in the sense of Observation 10.1.

2. Both $M(y|x; A)$ and $P_{\text{sim}}(y|x)$ are large, but $M$ would also be as large if we decided not to implement the specific simulation.

One way to make sure that one of these scenarios applies is by running a closed simulation. By this I mean a (possibly probabilistic) simulation algorithm that runs completely autonomously, without accepting any data from the external world. Its behavior will only depend on an initially specified program, plus a sequence of random input bits\(^{71}\) if the simulation is meant to be non-deterministic.

\(^{70}\) Even though it is not important for this paper, I would still like to advertise the plausibility of a compatibilist point of view, as laid out very clearly, for example, by Dennett [172]. Furthermore, theoretical computer science can add an important twist to it via the notion of computational irreducibility [58, 173–175], which can be used to justify the assignment of autonomy or agency to algorithms. Identifying “ourselves” with the information processing in our brains will then allow us to claim a status of information-theoretically well-defined autonomy or “freedom”.

\(^{71}\) Since our external world is in general probabilistic (cf. Section 8), we
As long as simulated Abby is still very simple, she will automatically be a probabilistic zombie in the sense of Observation 10.1. If our simulation tortures her at this point (by implementing a transition like \(x \rightarrow y\)), this will be of no relevance for Abby’s subjective experience; we are in Scenario 1\(^{72}\). But we know from Theorem 9.2 that this situation cannot very long: if the simulation runs long enough, Abby will lose zombie status, and simulated Abby will more and more become an accurate representation of Abby’s subjective experience\(^{73}\). However, in this case we run into Scenario 2: if the simulation tortures Abby with high probability at this point, we have \(P_{\text{sim}}(y|x) \approx M(y|x; A) > 0\), but the cause of \(M\) being large is not that we have launched the simulation: rather, the cause is that the simulated world \(M\)-exists as a simple abstract computational process which generates the transition \(x \rightarrow y\) with non-negligible probability. The simulated world \(M\)-exists even if we do not run the simulation.

To see this, recall equation (17) and the discussion around it, which allows us to refer to \(M'(y|x; A)\) (defined in (16)) in place of \(M(y|x; A)\). The \(A\)-semimeasure \(M'\) is a mixture of \(A\)-semimeasures \(m_j\), and (at least) one specific choice of \(j\) will yield the measure \(m_j\) which describes Abby’s statistics within our simulation. If Abby has lost zombie status, and Theorem 7.8 applies, then this specific \(m_j\) will dominate the statistical mixture of semimeasures in (17), by having small \(K(j)\) and large \(m_j(x; A)\) (in comparison to other semimeasures). However, these properties are mathematical statements that are completely independent of our choice whether to implement the simulation or not. Neither the decision not to run the simulation in our world, nor its termination will have any causal influence on these facts.

In other words: running a closed simulation merely displays the world which is simulated; it does not bring it into existence (the simulated world \(M\)-exists anyway, and does not start to \(P\)-exist relative to us when we start the simulation since, by construction, we are not interacting with it). Thus, running a closed torturing simulation (or terminating a closed simulation) is ethically unproblematic since it has no causal effect, similarly as watching a documentary about the second world war (or stopping to watch it) does not actually affect any soldier that is portrayed in the documentary.

The situation is completely different if we run an open simulation, that is, if information is allowed to flow from the external world into the simulation. Imagine, for example, that a team of programmers regularly intervenes with the simulation (similarly as in Gary Larson’s cartoon “god at his computer”), or that we start to communicate with simulated Abby. Exactly as in the closed case, we may still have an initial phase where Abby is a zombie in the sense of Scenario 1, and in the long run, Theorem 9.2 implies that Abby’s subjective probabilities converge towards the distribution that we observe in the simulation. It is a measure generated by a simple computational process.

What is this simple computational process? In the closed case, it is simply the simulation algorithm itself; this algorithm will ultimately represent the best possible compression of simulated Abby’s observations and thus dominate her chances of future observations. In the open case, however, computable patterns of the external world will ultimately enter the simulation. Thus, asymptotically, the best possible compression of the simulated experiences will ultimately correspond to a computational process that involves (all or part of) the external world and the simulation. But then, we become part of the relevant computational process and will gain causal influence on the fate of simulated Abby. That is, her conditional probability \(M(y|x; A) \approx P_{\text{sim}}(y|x; A)\) will depend substantially on our choices as agents in our external world.

Thus, in the case of an open simulation, none of the two scenarios applies, and torturing becomes an actual “mind crime”. This should not be surprising, given that actual material guinea pig Abby is a special case of an open simulation, with the hardware given by the brain, and the behavior of other guinea pigs clearly having causal impact on her subjective experience\(^{74}\).

While the discussion above identifies closed simulations as unproblematic, we have deliberately ignored a minor detail: there is still a price we have to pay for running closed torturing simulations, even though it is extremely small. To see why this is the case, we have to return to the definition of Abby’s first-person probability \(P(y|x; A)\), as given in Definitions 4.9 and 4.11. It is lower-bounded by \(M(y|x; A)\), which in turn is proportional to

\[
M(x, y; A) = \sum_{p: U(p, A) = (x, y, *)} 2^{-\ell(p)},
\]

where \(U\) is our reference universal graph machine. Every program \(p\) that leads to the sequential output of \(x\) and then \(y\) thus contributes to Abby’s subjective suffering probability.

Thus, if a civilization of guinea pigs decides to start a closed simulation of Abby, subjecting her to painful drug testing procedure, then this creates another computer program \(p\) with \(U(p, A) = (x, y, *)\), namely the computer program that describes the full guinea pig universe at that point, together with the closed simulation. Arguably, this program will be much longer than the simulation program itself, and thus contributes only a very tiny amount to the sum in (32). But this contribution is non-zero, and it is a contribution for which the guinea pigs that started the simulation have to take responsibility, since they act as agents in their own world.

### 14. CONCLUSIONS, AND 1.5 AMENDMENTS

Regardless of the details of the formulation, the main idea of the approach of this paper can be summarized as follows.

---

\(^{72}\) The transition between open and closed will be continuous to some extent. It thus seems plausible that a small amount of intervention is still compatible with Scenarios 1 and 2.

\(^{73}\) In more detail, it will become an accurate representation of that instance of Abby which happened to take the same path through her observer graph as the simulation.
• Instead of assuming the existence of a “physical world”, we have postulated that the fundamental laws act directly on the level of observers (or rather of their observer states).

• In the simplest case, there is only one such law, determining the probability of future observations, given all of the observer’s current (and possibly past) observations. We have argued that this should correspond to some kind of “universal apriori probability”, i.e. some version of algorithmic probability.

• Since compressible sequences of observations are more likely, this will lead to a “stabilization” of (computable) regularities, and ultimately to the appearance of an external physical world that looks in many fundamental respects like our own. Due to properties of Solomonoff induction, we also obtain a notion of emergent objective reality for setups involving more than one observer.

• The architecture of the theory allows us to address a number of questions that are systematically hard to address within standard approaches. This leads to predictions in the context of brain emulation and cosmology and to phenomena like probabilistic zombies or subjective immortality.

This blueprint of a theory can certainly be realized in different ways; the definitions that we have followed in this paper are not the only possible ones (though they are arguably among the simplest possibilities). In fact, there is an obvious adjustment (a simplification) of our postulates that suggests itself in light of what we have learnt. Recall that the notion of a “successor state”, first introduced in Informal definition 3.1, seemed to play an important role in our construction. Basically, it formalized the idea that “observers do not suddenly switch identities”, but remain in some sense coherent over time: there should be something in an observer’s current memory \( x_n \) that “links” her to her earlier state \( x_{n-1} \), similarly as Parfit’s “Relation R”. This has been explained in great detail before Informal definition 3.1, see in particular the computer example. It has motivated us to define observer graphs (cf. Definition 4.1) as admitting only a subset of transitions which preserve this part of the memory, but, say, forbids transitions that lead her to instead think “I am Bambi”, together with the exchange of further large parts of her memory. However, even if her observer graph does in principle allow for these implausible transitions, they become increasingly unlikely due to the principle of persistent regularities, Observation 7.4: the memory “I am Abby” represents a computable regularity, and if Abby has observed this computable regularity for a long enough time in the past, then it will continue to hold in the future with high probability.

In other words: regularities that represent personal identity do not have to be “hard-wired” into the observer graph, but they may simply emerge as regularities in the asymptotic behavior of algorithmic probability, in exactly the same way as other regularities which will correspond, as we have seen in Section 8, to an observer’s “external world”. The notion of a “valid successor state” (cf. Informal definition 3.1) is simply defined by an observer’s past. This makes sense if we think again about our hypothetical guinea pig civilization: after all, a guinea pig’s memory will have a physical realization in terms of some properties of her brain, and this should ultimately appear on the same ontological level as all the other aspects of a guinea pig’s (emergent) external world.

In summary, we can get rid of the idea that some transitions are fundamentally forbidden (such that the observer graph \( A \) encodes personal identity), and instead allow all transitions. This leads us to an amendment and simplification that was already announced in Postulates 5.1: namely, that every observer graph should be a complete graph. In light of the intuition that we have gained in the previous sections, we also change the wording of the postulates, not just the technical content:

**Postulates 14.1 (Amended postulates).**

1. To every sequence of binary strings \( x = (x_1, \ldots, x_n) \), there is an associated first-person perspective of an observer that has previously been in observer states \( x_1, \ldots, x_{n-1} \) and is in state \( x_n \) now.

2. From this first-person perspective, another observer state \( y \) is going to come next, with probability (chance) of \( P(y|x; A) \), where \( A = (V,E,\Lambda) \) is a complete observer graph with \( \Lambda = x_1, V = \{0,1\}^* \) and \( E = V \times V \).

Do the results of the previous sections remain valid after implementing this amendment? Almost, except for slight modifications of some definitions. In Definition 4.7, we have defined a “graph machine” as a multi-tape monotone Turing machine which accepts input bits together with an input observer graph \( A \) and subsequently outputs an \( A \)-history. This definition should be simplified to restrict to complete observer graphs. A complete observer graph is fully determined by its root \( \Lambda \), and can thus be denoted \( A_\Lambda \). Hence we can modify the definition of a graph machine by allowing the extra input of some root \( \Lambda \in \{0,1\}^* \), and enforcing the output to be an \( A_\Lambda \)-history. Let us call the resulting class of machines “history machines”.

---

75 We can also imagine that this was true only from some point on, i.e. for all \( x_i \) with \( i \geq m \) for some fixed \( m \), but this will not change the essentials of the argument.
Then all definitions and lemmas of Subsections 4.1 and 4.2 survive unchanged, and the only definition that needs adjustment is that of “covariance”, Definition 4.14 in Subsection 4.3: the computomorphism \( \varphi \) must in fact be a computable bijection (i.e. a proper computable permutation) of \( \{0,1\}^* \), such that completeness of \( A \) implies completeness of \( \varphi \circ A \circ \varphi^{-1} \). Adjusting that definition in the form just explained leads to the following consequence:

**Theorem 14.2.** There exists a universal covariant history machine.

This theorem is proven on page 80 in the appendix. Thus, the results of this paper remain valid if we replace “graph machines” by “history machines”, and define \( P(y|x; A) \) with respect to a universal covariant history machine. On page 80 in the appendix, I discuss a slightly different perspective on covariance that we can obtain from the amended definition.

The role of the root \( \Lambda \) seems somewhat mysterious and questionable. There are a couple of technical reasons to have it; for example, having such a root allows us to prove that the set of enumerable \( A \)-semiabstracts coincides exactly with the set of graph (or history) machine semiabstracts as stated in Theorem 4.13. For this to hold, it is crucial that \( M_U(\Lambda; A) < 1 \) is possible, which would not be the case if there was no root \( \Lambda \) (the probability of “no output at all (yet)” would otherwise be unity, leading e.g. to somewhat more clumsy formulations like Lemma 1 in [84]). Furthermore, the freedom to specify a root \( \Lambda \) seems crucial to have a notion of “covariance” and a result like Theorem 14.2 (on the other hand, this insight makes the notion of covariance perhaps seem a bit less magic).

There is one obvious further way in which we might want to amend the postulates, and this amendment will not only simplify the theory but also make the discussion about the role of the root \( \Lambda \) obsolete. Namely, we would like to improve on a conceptual deficiency of our theory that has been mentioned before in this paper, e.g. at the end of Section 7: that is, the fact that the probability of the next observation \( y \) does not only depend on the observer’s current state \( x_n \), but on her full history of observations \( x = (x_1, \ldots, x_n) \).

In fact, much of our earlier discussion in Section 3 can be understood as first motivating that observers \( A \) should experience transitions from their current state \( x \) to a successor state \( y \), and then to ask for a transition probability of \( x \rightarrow y \). The arguably most straightforward implementation of this idea would be have a transition probability that is Markovian, i.e. that only depends on the observer’s current state \( x \) and not on its past. This would also more directly realize the general philosophy of this paper, which started out by arguing that all of an observer’s personal identity is in her “current memory”, and there is no “matter of fact” to an observer’s past. Applications of this theory would be easier, too, if this Markovianity property were to hold. For example, recall the discussion of brain emulation in Section 13. In this context, we can ask: Should our predictions on simulated minds really depend on the whole history of a simulation? What if we do not know this history, or we start the simulation somewhere in the middle? Shouldn’t all questions on the first-person perspective only depend on the current state of the simulated agent?

This suggests to formulate the following open problem:

**Open Problem 14.3.** Is there a natural choice of a Markovian version of algorithmic probability, i.e. a canonical algorithmic distribution \( P(y|x_1, \ldots, x_n; A) \) which only depends on \( y \) and \( x_n \)? If so, can we reformulate our theory in terms of this distribution (e.g. by amending 1. in Postulates 14.1 to have single strings as observer states), and will the resulting theory still have similar properties as the theory in this paper? In particular, will it realize the blueprint of the beginning of this section?

Solving this open problem would have multiple benefits, in particular conceptually. It would also, for example, automatically lead to predictivity as it is assumed in Section 12, allowing us to drop Assumption 12.2. After the first amendment of Postulates 14.1 above, we thus arrive at a second amendment: replace algorithmic probability by a Markovian version. Unfortunately, I do not currently know how to do this. The main problem is that this will force departure from the well-worn paths of algorithmic information theory and its multitude of results (like Solomonoff induction) which made the results of the previous sections possible. Therefore, it is a “1.5th” amendment — not yet a complete amendment to the postulates, but rather a desire to construct such an adaptation in the future.

To elaborate a bit on the difficulty of this goal, note that convex combinations of Markovian measures are not in general Markovian, which means that there is no notion of a “universal Markovian semimeasure” in the usual sense (see also Example A.14). This blocks access to many of the standard techniques of algorithmic information theory. Intuitively, all the “memory” that accumulates after many observations (and that leads to certain asymptotically simple behavior, like convergence to a computable measure) must, in the Markovian case, accumulate inside the actual state of the observer. This is automatically the case if, within the formalism of this paper, the observer graph \( A \) is, for example, a tree; but we have just committed ourselves to a complete observer graph, since forgetting is arguably of relevance for observers. This is why Open Problem 14.3 seems so hard.

Despite Open Problem 14.3 and several other remaining difficulties, it is arguably fair to say that we have achieved what we have aimed for in the introduction: we have constructed the prototype of a simple and consistent theory that starts with the first-person perspective of observers as its fundamental building block, and that does not from the outset assume the existence of a “world” or “physical laws” in the usual sense. However, this theory predicts an emergent notion of external world, and an emergent notion of objective reality for several observers. It is interesting to see how such a world emerges in terms of “persistent regularities” (Theorem 7.3 and Observation 7.4) and “convergence to a computable measure” (Theorem 7.8), and how objectivity emerges due to the mathematics of Solomonoff induction (Theorem 9.2).

As intended, our theory gives us novel tools to address some notorious problems in and around physics that are related to the first-person perspective: for example, it resolves at least some versions of the Boltzmann brain problem of cosmology, and it yields in principle predictions for some fundamental aspects of the problem of brain emulation. This contrasts with our current way of doing science which reflects...
Cartesian dualism in a methodological sense: the empirical realm of physics and the first-person realm of, say, the philosophy of mind are treated as separate and, in many cases, irreconcilable regimes. This is not in itself a bad idea — on the contrary. Banning the first-person perspective from physics was one of the major prerequisites for its success, and most attempts to unify both regimes are simply manifestations of pseudoscience.

But keeping the two regimes separate may not be the best strategy under all circumstances. One such circumstance which is perhaps more important now than in the past is the development of computer technology, and with it the prospect of disturbing technologies like brain emulation to become available in the not so distant future. We need a good theory that allows us to give precise answers to some urgent questions that arise in this context. In a complementary development, the first-person perspective has shown up in physics despite its initial banishment, manifesting itself in questions like: what should observers expect to see in a very “big” universe? How is the formalism of quantum mechanics related to the notion of observation or measurement? As the latter question demonstrates, it can be a very bad idea to not be careful and to rush to phantasies about “consciousness” being relevant in QT and the like. Most of this is highly controversial. Nevertheless, if we are very careful and aim for mathematical rigor, simplicity of assumptions, and consistency with known physics, then we may hope to obtain some valuable insights that span both regimes. As I have argued in the introduction, having a theory of this kind may have the advantage that we can test its predictions in one regime (of physics), and thus increase our confidence in its predictions in the other regime (of the first-person perspective).

This does not mean that the theory of this paper is intended to be some kind of “theory of everything”. I regard this approach as merely a prototype of a novel class of theories, namely ones that start with the first-person perspective of observers and do not fundamentally assume the existence of an external world. Several steps in the construction can be done differently; this is already made explicit in Open Problem 14.3. More importantly, this theory actually predicts its own limitations: Theorem 7.8 claims that there are simple probabilistic laws of nature, but that the precise form of these laws is contingent and not predicted by our theory. Concretely, I expect that this approach will never be of any use in the search for a theory of quantum gravity, for example. The nature of its predictions is (at least currently) simply too far from the usual regime of physics, where we measure cross sections in particle collisions or the acceleration rate of the universe’s expansion. It will be very hard to extract concrete quantitative experimental predictions from it, though it may not be impossible: as I have argued in Section 12, we can possibly understand some key features of quantum theory as consequences of this approach, or rather of some simple properties of the measure $\mu$ that it predicts according to Theorem 7.8. Maybe more concrete predictions can be obtained along similar lines.

The “proof of principle” obtained in this work has also a broader implication: it gives arguments to refute a common criticism which is faced by broadly epistemic approaches to physics (like QBism), namely the reproach of being “solipsistic”. This is simply a fancy catchphrase subsuming the following objection: How can you deny the relevance of an objective external world, given that this notion is so obviously successful and important in physics? What the approach of this paper shows is that one can successfully deny the fundamentality of the notion of an objective external world, and obtain it as an emergent phenomenon from weaker assumptions. As shown above, this “methodological solipsism” even allows us to address questions that one has difficulties addressing otherwise.

The results of this paper are an invitation to take a bolder perspective on some foundational questions. Relying strictly on our traditional view of the world might not be the right strategy under all circumstances; perhaps we are missing something truly important, as the conceptual questions of Table 1 seem to suggest. Exploring alternatives, in a mathematically rigorous way that prevents us from fooling ourselves, may well hold surprises that are crucial for solving some important problems that lie ahead.

ACKNOWLEDGMENTS

This work would not have been possible without invaluable feedback and support by many friends and colleagues. I am grateful to Sebastian Guttenberg and Dierk Schleicher for encouragement in early stages of this work, to Lee Smolin for discussions on how this relates to other topics in fundamental physics, and to Sona Ghosh, Daniel Gottesman, Philippe Guérin, Lucien Hardy, Philipp Höhn, Philippos Papayannopoulos, Renato Renner, Lidia del Rio, Rüdiger Schack, Robert W. Spekkens, and Cozmín Ududec for helpful discussions and comments. Special thanks go to Marcus Hutter for pointing out a mistake in an earlier formulation of Theorem 7.3.

I am indebted to my colleague Michael Cuffaro, from whom I have learnt an invaluable amount of philosophy of physics. The paper benefited immensely from our discussions. I would also like to thank the Foundational Questions Institute for funding of the project “Emergent objective reality — from observers to physics via Solomonoff induction”, and I thank the Rotman Institute of Philosophy for funding via a Catalyst Grant. This research was undertaken, in part, thanks to funding from the Canada Research Chairs program.

I would also like to thank the staff of cafés St. Oberholz and Szimpla in Berlin as well as Coffee Culture and Princess Café in Waterloo, where most of the write-up was accomplished, for hospitality. Sincere thanks go to the Perimeter Institute for Theoretical Physics, which allowed me to pursue this speculative research during my times as a postdoc and associate faculty member. Research at Perimeter Institute is supported by the Government of Canada through the Department of Innovation, Science and Economic Development Canada and by the Province of Ontario through the Ministry of Research, Innovation and Science.

Finally, I would like to thank Anne for allowing me to abuse her guinea pigs Tiffy and Bambi for teleportation (thought!) experiments. They shall rest in peace — or rather have a good journey along their observer graphs.

Appendix A: Mathematical proofs and further details

At the beginning of Section 4, it was claimed that the transition probabilities \( P_U(y|x; A) \) can be interpreted as a statistical mixture of computable deterministic worlds; now we will see that this is indeed the case. This result yields an interesting instance of self-consistency of our theory: We have derived the definition of “observer graphs” and “histories” above with the help of the insight that infinitely many worlds \( M \)-exist, and that observers never know exactly in which world they are.
located (Observation 2.4). Our transition probabilities should thus have an interpretation within that point of view as well.

To see that they do, fix an arbitrary observer graph $A$. Let $W$ be any computable world; for example, a finite complete description of some initial state of $W$, together with an algorithm that computes its future time evolution. For the moment, we additionally assume that $W$ is deterministic (the generalization to probabilistic worlds might be possible without too much effort, but will not be discussed here). For example, $W$ might be an instance of “Game of Life” introduced in Section 2.

Suppose that $W$ contains some object that can be interpreted as an instance of the observer described by $A$. As a simple mathematical example, suppose that $A$ is a directed graph on the binary strings of length 2, such that every string is connected to every other string (except for itself); that is, $A = (V,E,\Lambda)$ with $V = \{00,01,10,11\}$, $\Lambda = 11$ arbitrarily, and $E$ is the set of all non-symmetric pairs from $V$. The world $W$ consists of a large square (a “billiard table”) and a particle inside the square (the “billiard ball”) that moves in two dimensions with constant velocity; when it hits the square’s boundary, it bounces off as described by the laws of classical mechanics. (The square might be discretized, such that the particle effectively “hops” on the points of a square grid.) As initial state, the particle starts at an arbitrary point moving in some angle towards the upper right. After some time, the simple computable time evolution makes the particle collide with the square’s boundary and the particle changes direction.

We associate a string of two bits $b = b_1 b_2$ with the particle’s state at each time step: if the particle moves right (left), then $b_1$ shall be 1 (resp. 0); if the particle moves up (down), $b_2$ shall be 1 (resp. 0). The billiard ball starts moving upper right, so it starts in state 11; later, it hits the right boundary, and its state changes to 01, as shown in Figure 11. Hence the billiard ball is an instance of the observer described by $A$: it experiences a transition of states which is an $A$-history.

There are many other computable deterministic worlds $W$ that contain objects that can be interpreted as an instance of the observer described by $A$: clearly, there are infinitely many. Each such $W$ is associated with one or more $A$-histories, namely the $A$-histories that are seen by the one or more instances of the $A$-observer inside that world.

Given any world $W$ of this kind, we can construct a corresponding graph machine program that computes $W$, and produces outputs on its tapes in accordance with the locator function of the observer state. For example, a graph machine can simulate the billiard ball world from Figure 11, and produce a new output on its tapes whenever the billiard ball direction changes. This is a particular graph machine program that is read from the input tape and then runs indefinitely and deterministically.

Vice versa, we can interpret every running graph machine (with a given content of its input tape that has been chosen before the start of computation) as a deterministic computable world (the content of the input tape may be an infinite bit string, but only finitely many bits are ever read at finite times that are relevant for observers.) Since these define the algorithmic transition probabilities of our theory, we arrive at the following observation:

Observation A.1 (Statistics over deterministic worlds). Recall the transition probabilities from Definition 4.11 for a given observer graph $A = (V,E,\Lambda)$. Up to normalization in $y$, they are given by

$$P_U(y|x; A) \sim M_U(x,y; A) = \sum_{p:U(p,A)=(x,y)} 2^{-\ell(p)},$$

where $U$ is the reference covariant universal graph machine.

The right-hand side has a natural interpretation as follows: every (in general infinitely long) input string to the graph machine $U$ defines a deterministic world, namely the computational process that this graph machine follows on the given input, containing an instance of the observer $A$ given by the output tape history. All worlds are weighted equally, such that the set of all infinitely long inputs starting with $p \in \{0,1\}^*$ gets weight $2^{-\ell(p)}$. Thus, the sum on the right-hand side equals the probability that a randomly chosen deterministic world which contains an instance of observer $A$ has the property that $A$ experiences $y$ after (first) having experienced $x$.

In Observation 2.4, we found that observers never know exactly in which world they are located. Observation A.1 shows that our transition probabilities can (but do not have to) be interpreted as arising from this lack of knowledge. In more detail, we should say that not only does the observer not know in which world she is located, but her location is genuinely indeterminate, leading to a probabilistic transition as in Thought experiment 3.2.
Now we prove that $M_X$ from Definition 4.11 is a semimeasure in the sense of Definition 4.9:

**Proof.** If $X(p, A) = (A, *)$ and $X(q, A) = (A, *)$ such that $p \neq q$, then $p$ cannot be a proper prefix of $q$ and vice versa. Thus, the Kraft inequality [80] yields

$$M_X(A; A) = \sum_{p: X(p, A) = (A, *), 2^{-\ell(p)} \leq 1.}$$

Now fix some $A$-history $(x_1, \ldots, x_n)$. Let $Q$ be the set of all strings $q \in \{0, 1\}^*$ such that there exists some string $y \in \{0, 1\}^*$ with $X(q, A) = (x_1, \ldots, x_n, y, *)$. If $q \in Q$, then at some time step during the computation, the string $x_n$ must have been written, hence $q = pr$ with $p = q(p) \in \{0, 1\}^*$ and $r = r(q) \in \{0, 1\}^*$ (r may be the empty string) such that $X(p, A) = (x_1, \ldots, x_n, *)$. By construction of the machine $X$, if $pr \in Q$ and $pr' \in Q$ with $r \neq r'$, then the set $\{r, r'\}$ is prefix-free. Thus, if $p$ is any fixed string, we have for every fixed $p$

$$\sum_{q \in Q: p(q) = p} 2^{-\ell(r(q))} \leq 1$$

by the Kraft inequality. Hence

$$M_X(x_1, \ldots, x_n; A) = \sum_{p: X(p, A) = (x_1, \ldots, x_n, *)} 2^{-\ell(p)} \geq \sum_{p: X(p, A) = (x_1, \ldots, x_n, *)} 2^{-\ell(p)} \sum_{q \in Q: p(q) = p} 2^{-\ell(r(q))} = \sum_{q \in Q} 2^{-\ell(q)} \sum_{x_{n+1} \in A(x_n)} M_X(x_1, \ldots, x_{n+1}; A).$$

This proves the relevant inequalities to have a semimeasure.

To prove Theorem 4.15 (the existence of a covariant universal graph machine) we need two lemmas. Here is the first one:

**Lemma A.2.** There exists a universal graph machine $W$ that satisfies the additional requirement that the emulation string $p_{X, A}$ from Definition 4.12 does not depend on $A$.

**Proof.** The set of graph machines is recursively enumerable. Hence there is a simple prefix code $\{p_i\}_{i=1}^\infty \subset \{0, 1\}^*$ such that code word $p_i$ encodes the $i$-th graph machine. Thus, we can construct our universal machine $W$ in the following way: $W$ detects whether the input starts with code word $p_i$. If it does, then $W$ simulates the $i$-th graph machine, working on the rest of the input. This construction is completely analogous to that of a universal monotone Turing machine.

We also need a simple condition for universality:

**Lemma A.3.** Let $A$ be any observer graph, and let $X$ be a graph machine. Then, $X$ is $A$-universal if and only if there exists a string $p \in \{0, 1\}^*$ such that $X(p, A, x) = W(x, A)$ for all strings $x \in \{0, 1\}^*$, where $W$ is the machine from Lemma A.2.

**Proof.** “$\Rightarrow$” If $X$ is $A$-universal, then such a string $p$ exists by definition.

“$\Leftarrow$” Since $W$ is $A$-universal, we know that for every graph machine $Y$ there exists some string $p_Y \in \{0, 1\}^*$ such that $W(p_Y x, A) = Y(x, A)$ for all $x \in \{0, 1\}^*$. But then, we have

$$X(p_{p_Y} x, A) = W(p_Y x, A) = Y(x, A),$$

so $X$ is $A$-universal, too.

**Proof of Theorem 4.15:** We construct an explicit example of a covariant machine and show afterwards that it is universal, too. The construction needs some preparation. First, let $s_n$ be the $n$-th string in lexicographical order, that is,

$$s_1 = 0, \quad s_2 = 0, \quad s_3 = 1, \quad s_4 = 00, \quad s_5 = 01, \quad \ldots$$

If $S \subset \{0, 1\}^*$ is any subset of the strings, we define $\|S\|$ to be the number of strings at the beginning of the sequence ($\varepsilon, 0, 1, 00, 01, \ldots$) which are not contained in $S$. That is, $\|S\|$ is the smallest integer $n$ such that $s_{n+1} \in S$, but $s_i \notin S$ for all $i \leq n$. (If $\varepsilon \in S$, then $\|S\| = 0$ by definition.)

We define a shift map $T$ that shifts the lexicographically ordered sequence of strings by some offset. For every $k \in \mathbb{N}$, define an injective map $T_k : \{0, 1\}^* \to \{0, 1\}^*$ via

$$T_k(s_n) := s_{n+k}.$$  

For $k \in \mathbb{Z}$ with $k < 0$, we define $T_k$ by the same equation, but now it is a bijective map $T_k : \{s_{|k|+1}, s_{|k|+2}, \ldots \} \to \{0, 1\}^*$. It follows that $T_{-k} = T_k^{-1}$ for all $k \in \mathbb{Z}$, and every $T_k$ is a computomorphism.
Given any observer graph $A$ with map $A : V \to 2^V$ and $k := \|V\|$, we define a “shifted” version $A_l$ for $l \in \mathbb{N}_0$ by

$$A_l : T_{l-k}(V) \to 2^{T_{l-k}(V)}$$

$$x \mapsto T_{l-k} \circ A \circ T_{l-k}^{-1}(x).$$

The resulting map $A_l$ defines an observer graph $A_l = (V_l, E_l, A_l)$ with $V_l := T_{l-k}(V)$, $A_l := T_{l-k}(A)$, and $(v_1, v_2) \in E \iff (T_{l-k}(v_1), T_{l-k}(v_2)) \in E_l$. This is the same graph as $A = (V, E, A)$, except that the labelling of the vertices has been shifted by some offset. As a consequence, we have $\|V_l\| = l$, $A_k = A$, and $(A_j)_l = A_l$ for all $j, l \in \mathbb{Z}$.

Let $\alpha : \mathbb{N}_0 \to \mathbb{N} \times \mathbb{N}_0 \times \{0, 1\}^*$ be a computable bijection. We give an explicit construction of a covariant universal graph machine $C$ by describing how it works. Since graph machines may compute indefinitely, we have to define what $C$ does if a potentially infinite sequence of bits $x \in \{0, 1\}^\infty$ is given as input, together with a machine $T_A$ which computes an observer graph $A = (V, E, \Lambda)$:

1. First, the machine determines $k := \|V\|$. Note that this can be done without having any explicit description of $A$ or $V$ at hand: $C$ simply has to query $T_A$, asking for all strings in lexicographical order whether they are an element of $V$ or not, until it arrives at the first string where the answer is “yes”.

2. The machine computes $(m, n, s) := \alpha(k)$ and simulates the $m$-th graph machine $Y$ (in some fixed enumeration) on observer graph input $A_n$, except if the input starts with the string $s$, in which case it simulates the universal graph machine $W$ from Lemma A.2 on the rest of the input. Specifically, the machine $C$ starts to read the input bits one after the other. Let $x'$ denote the bits that have been read so far. Then $C$ proceeds as follows:

   - As long as $x'$ is a proper prefix of $s$, the machine waits and reads more bits to see whether $x$ really starts with the string $s$.
   - If $x' = s$, i.e. if $C$ has detected that $x$ really starts with $s$ such that $x = sy$, it continues by emulating the machine $W$ on inputs $y$ and $A_n$ — that is, it works on the remaining bits exactly as $W$. With one difference: instead of giving the same output as $W$, that output is shifted. That is, it produces $T_{k-n}(W(y, A_n))$, that output is shifted. That is, it produces $C(x, A_k) = T_{k-n}(Y(x, A)) = C(x, T_{k-n} \circ A \circ T_{k-n}^{-1})$ for all $x \in \{0, 1\}^*$.

Note that is no problem for $C$ to simulate another graph machine (like $Y$ or $W$), given a description of that machine, on observer graph input $A_n$: even though $C$ does not know exactly what $A$ is (that is, $C$ does not have an explicit description of $A$), it can compute $A_n$ by querying $T_A$, and by “translating” the corresponding inputs and outputs via the proper shift map $T_{k-n}$ that intertwines $A$ and $A_n$.

The machine $C$ is constructed such that for all $A$,

$$C(sy, A) = T_{k-n}(W(y, A_n))$$

(note that $k, n$, and $s$ are functions of $A$). Let $A = (V, E, \Lambda)$ be any observer graph, $n := \|V\|$, and $Y$ any $A$-universal graph machine which has some number $m \in \mathbb{N}$ in the enumeration chosen above. According to Definition 4.12, there is a string $s \in \{0, 1\}^*$ such that $Y(sy, A) = W(y, A)$ for all $y \in \{0, 1\}^*$. Let $k := \alpha^{-1}(m, n, s)$. Since $A = A_n$, carefully checking the algorithm above and recalling the definition of $A_k$ shows that

$$C(x, A_k) = T_{k-n}(Y(x, A)) = C(x, T_{k-n} \circ A \circ T_{k-n}^{-1})$$

for all $x \in \{0, 1\}^*$.

Since $A$ and $Y$ were arbitrary, this proves that $C$ is covariant.

Now let $A = (V, E, \Lambda)$ be any observer graph and $X$ any graph machine. Let $k := \|V\|$ and $(m, n, s) := \alpha(k)$. Define another graph machine $X_{n-k}$ by

$$X_{n-k}(x, A') := T_{n-k}(X(x, T_{n-k}^{-1} \circ A' \circ T_{n-k}))$$

for all $x \in \{0, 1\}^*$ and $A' = (V', E')$ with $\|V'\| = n$ (for other $A'$, the machine shall be undefined, i.e. never halt). Since $W$ has the strong universality property described in Lemma A.2, there is a string $e_{n-k} \in \{0, 1\}^*$ such that $W(e_{n-k}x, A') = X_{n-k}(x, A')$ for all $A'$ and all $x \in \{0, 1\}^*$. Hence

$$C(se_{n-k}x, A) = T_{k-n}(W(e_{n-k}x, A_n)) = T_{k-n}(X_{n-k}(x, A_n)) = X(x, A).$$

Thus, $C$ is $A$-universal. Since $A$ was arbitrary, this shows that $C$ is universal.

\[\square\]

Note that covariant graph machines need not be universal in general: for example, suppose that $C$ is a covariant universal graph machine with

$$X(x, A) = \varphi_{A,X}^{-1} \left( C(x, \varphi_{A,X} \circ A \circ \varphi_{A,X}^{-1}) \right)$$
for every $A$-universal graph machine $X$. Define a new graph machine $C'$ by replacing every $\varphi_{A,X}$ by $\varphi'_{A,X} := 1 \varphi_{A,X}$, that is, by appending the single bit 1 to every string such that the observer graph $\varphi'_{A,X} \circ A \circ (\varphi_{A,X})^{-1}$ has only strings as vertices that start with bit 1. Obviously, $C'$ is still covariant. Then we may define $C'$ to work on all other observer graphs $A$ in arbitrary ways — that is, in ways which manifestly destroy the $A$-universality of $C'$.

Here is a lemma that was used in Theorem 4.13:

**Lemma A.4.** For every enumerable $A$-semimeasure $m$, there exists a graph machine $Y$ such that

$$M_Y(x; A) = m(x; A)$$

for all finite $A$-histories $x$.

**Proof.** We construct the machine $Y$ explicitly; our proof closely follows the lines of Theorem 4.5.2 in [78] where an analogous proof for monotone Turing machines is given (see however the correction in [84, Lemma 1]). Since $m$ is enumerable, there is a sequence of computable functions $\{\psi_n\}_{n \in \mathbb{N}}$, mapping finite $A$-histories $x$ to rational numbers $\psi_n(x) \geq 0$, such that

- $\lim_{n \to \infty} \psi_n(x) = m(x; A)$ for all $x$,
- $\psi_n(x) \leq \psi_{n+1}(x)$ for all $n \in \mathbb{N}$.

We now modify this function in three subsequent steps. First, we define a sequence of computable functions $\{\phi_n\}_{n \in \mathbb{N}}$: if $(x_1, \ldots, x_k)$ is any finite $A$-history, we set

$$\phi_n(x_1, \ldots, x_k) := \begin{cases} \psi_n(x_1, \ldots, x_k) & \text{if } \ell(x_i) \leq n \text{ for all } i \\ 0 & \text{otherwise}; \end{cases}$$

if $(x_1, \ldots, x_k)$ is not an $A$-history, we set $\phi_n(x_1, \ldots, x_k) := 0$. This sequence of functions still has the two properties $\lim_{n \to \infty} \phi_n(x) = m(x; A)$ and $\phi_n(x) \leq \phi_{n+1}(x)$, but we additionally know that it is zero if one of the argument strings has length larger than $n$. Moreover, while $\psi_n$ was defined only on finite $A$-histories, $\phi_n$ is defined on all finite sequences of strings.

We modify the function once more to obtain a sequence $\tilde{\phi}_n$. We define $\tilde{\phi}_n(x_1, \ldots, x_k)$ recursively in $k$: for $k = 1$, we set $\tilde{\phi}_n(x_1) := \phi_n(x_1)$ (this is only non-zero if $x_1 = \Lambda$, the root of $A$). For $k \geq 2$, we set

$$w(x_1, \ldots, x_{k-1}) := \sum_{y \in \{0,1\}^*} \phi_n(x_1, \ldots, x_{k-1}, y).$$

Then, for every $x = (x_1, \ldots, x_{k-1}, x_k)$, define

$$\tilde{\phi}_n(x) := \begin{cases} \phi_n(x) & \text{if } w(x_1, \ldots, x_{k-1}) \leq \tilde{\phi}_n(x_1, \ldots, x_{k-1}) \\ \tilde{\phi}_n(x_1, \ldots, x_{k-1})/w(x_1, \ldots, x_{k-1}) & \text{otherwise.} \end{cases}$$

This enforces directly the inequalities

$$\tilde{\phi}_n(\Lambda) \leq 1,$n \in \mathbb{N}$.

$$\sum_{x_k} \tilde{\phi}_n(x_1, \ldots, x_{k-1}, x_k) \leq \tilde{\phi}_n(x_1, \ldots, x_{k-1}).$$

We claim that $\lim_{n \to \infty} \tilde{\phi}_n(x) = m(x; A)$ for all $x = (x_1, \ldots, x_k)$ which are finite $A$-histories; we prove this statement by induction in $k$. For $k = 1$, let $n \geq \ell(\Lambda)$, then

$$\tilde{\phi}_n(\Lambda) = \phi_n(\Lambda) = \psi_n(\Lambda) \xrightarrow{n \to \infty} m(A; A).$$

The induction step $k \to k + 1$ follows from

$$\phi_n(x) \geq \tilde{\phi}_n(x) = \phi_n(x) \cdot c_n$$

with $c_n = \min \left\{ 1, \frac{\tilde{\phi}_n(x_1, \ldots, x_{k-1})}{w(x_1, \ldots, x_{k-1})} \right\}$. Since

$$\frac{\tilde{\phi}_n(x_1, \ldots, x_{k-1})}{w(x_1, \ldots, x_{k-1})} = \frac{\tilde{\phi}_n(x_1, \ldots, x_{k-1})}{\sum_{x_k} \phi_n(x_1, \ldots, x_{k-1}, x_k)} \xrightarrow{n \to \infty} \sum_{x_k} m(x_1, \ldots, x_{k-1}, x_k; A) \geq 1,$$
For all $x \in J$ and so on. It is easy to see that $j$ corresponds to $n$ on. (Those numbers exist for the same reason as in the case $k = 1$.) We would like to show that $\hat{j}$ exists for all strings $y$. Continuing recursively, we get a sequence $\{j_i\} \in \mathbb{N}_0$ of numbers (with the convention that $j_0 := 1$), and we define

$$\phi_n(x_1) := \begin{cases} 
\hat{\phi}_1(x_1) & \text{if } n < j_1 \\
\hat{\phi}_{j_1}(x_1) & \text{if } j_1 \leq n < j_2 \\
\hat{\phi}_{j_2}(x_1) & \text{if } j_2 \leq n < j_3 \\
\ldots & \ldots 
\end{cases}$$

For all $x_1 \in \{0,1\}^*$, we clearly have $\phi'_n(x_1) \leq \phi'_{n+1}(x_1)$. Moreover, $\lim_{n \to \infty} \phi'_n(x_1) = \lim_{n \to \infty} \hat{\phi}_n(x_1) = m(x; A)$, and $\sum_{x_1} \phi'_n(x_1) < \sum_{x_1} \hat{\phi}_n(x_1) \leq 1$ for all $n$, where $l \in \mathbb{N}$ is the index with $\phi'_n(x_1) = e_j \hat{\phi}_j(x_1)$. We continue the construction for the case $k = 2$, i.e. $x = (x_1, x_2)$. Denote the previously found numbers $\{j_0 = 1, j_1, j_2, \ldots\}$ by $J$. Set $j'_0 := 1$, and let $j'_1 > 1$ be the smallest number in $J$ such that $e_{j'_1} \hat{\phi}_{j'_1}(y_1, y_2) \geq e_{j_1} \hat{\phi}_j(y_1, y_2)$ for all $(y_1, y_2)$. Then, let $j'_2$ be the smallest number in $J$ which is larger than $j'_1$ and satisfies $e_{j'_2} \hat{\phi}_{j'_2}(y_1, y_2) \geq e_{j'_1} \hat{\phi}_{j'_1}(y_1, y_2)$ for all $(y_1, y_2)$ and so on. (Those numbers exist for the same reason as in the case $k = 1$.) We then define

$$\phi'_n(x_1, x_2) := \begin{cases} 
\hat{\phi}_1(x_1, x_2) & \text{if } n < j'_1 \\
\hat{\phi}_{j'_1}(x_1, x_2) & \text{if } j'_1 \leq n < j'_2 \\
\hat{\phi}_{j'_2}(x_1, x_2) & \text{if } j'_2 \leq n < j'_3 \\
\ldots & \ldots 
\end{cases}$$

This definition is now recursively generalized to arbitrary $k \in \mathbb{N}$. To simplify notation, we abbreviate the number $j_i \in J$ that corresponds to $n$ by $j^{(1)}(n)$, such that $\phi'_n(x_1) = e_{j^{(1)}(n)} \hat{\phi}_{j^{(1)}(n)}(x_1)$ for all $x_1 \in \{0,1\}^*$. More generally, we use the notation $j^{(k)}(n)$ to denote

$$\phi'_n(x_1, x_2) = e_{j^{(2)}(n)} \hat{\phi}_{j^{(2)}(n)}(x_1, x_2)$$
$$\phi'_n(x_1, x_2, x_3) = e_{j^{(3)}(n)} \hat{\phi}_{j^{(3)}(n)}(x_1, x_2, x_3)$$

and so on. It is easy to see that

$$\lim_{n \to \infty} \phi'_n(x) = \lim_{n \to \infty} \hat{\phi}_n(x) = m(x; A)$$

for all finite A-histories $x = (x_1, \ldots, x_k)$. Moreover, by construction,

$$\phi'_n(x) \leq \phi'_{n+1}(x).$$

We would like to show that $\sum_{x_{k+1}} \phi'_n(x_1, \ldots, x_{k+1}) \leq \phi'_n(x_1, \ldots, x_k)$. To this end, we first prove that

$$\text{for all } n \in \mathbb{N} \text{ there is } n' \leq n \text{ with } j^{(k+1)}(n) = j^{(k)}(n').$$

To see this, let $j^{(k+1)} := j^{(k+1)}(n)$; that is, $m$ is the index in the ordered sequence $\{j^{(k+1)}(l) \mid l \in \mathbb{N}\}$. It follows that $j^{(k+1)} \leq n < j^{(k+1)}$. By construction of the sequence, there is some $l$ such that $j^{(k+1)} = j^{(l)}$, so $j^{(l)} \leq n$, hence $j^{(k)}(n) \geq j^{(l)}$. Thus, there must be some $n' \leq n$ with $j^{(k)}(n') = j^{(l)} = j^{(k+1)} = j^{(k+1)}(n)$. We use this in the following calculation, involving histories $x = (x_1, \ldots, x_k)$ of length $k+1$:

$$\sum_{x_{k+1}} \phi'_n(x) = \sum_{x_{k+1}} e_{j^{(k+1)}(n)} \hat{\phi}_{j^{(k+1)}(n)}(x) \leq e_{j^{(k+1)}(n)} \hat{\phi}_{j^{(k+1)}(n)}(x_1, \ldots, x_k) = e_{j^{(k)}(n')} \hat{\phi}_{j^{(k)}(n')}(x_1, \ldots, x_k) \leq \phi'_n(x_1, \ldots, x_k).$$

This complicated construction now yields a computable function $\phi'$ that approximates $m(\cdot; A)$ from below and at the same time respects all inequalities for observer semimeasures as given in Definition 4.9. This will now enable us to construct a graph machine $Y$ with $M_Y(\cdot; A) = m(\cdot; A)$.

This construction is almost equivalent to the proof in the classical case of a monotone Turing machine, which is why we omit some details. The key idea is to construct prefix codes, that is, sets of strings $S_n(x_1, \ldots, x_k) \subset \{0,1\}^*$ that are prefix-free and have the properties
\[ \sum_{y \in S_n(x_1, \ldots, x_k)} 2^{-\ell(y)} = \phi''(x_1, \ldots, x_n), \]
\[ S_n(x_1, \ldots, x_k) \subseteq S_{n+1}(x_1, \ldots, x_k), \]
\[ \text{every string } y \in S_n(x_1, \ldots, x_k, x_{k+1}) \text{ has a prefix in the set } S_n(x_1, \ldots, x_k). \]

It is easy to enforce additionally that all strings in \( S_{n+1}(x) \setminus S_n(x) \) have length at least \( n+1 \). Then, we can associate a graph machine \( Y \) to this sequence of sets: given an infinite binary string as input, the machine reads one bit after another. Let \( z \) be the finite sequence of bits that it has already read, and \( n := \ell(z) \). For all \( x_1 \in \{0, 1\}^* \), \( Y \) checks whether \( z \in S_n(x_1) \) or not (this is only possible for the finitely many sets \( S_n(x_1) \) with \( \phi''(x_1) \geq 2^{-n} \)). If the answer is “no” for all those sets, it reads the next bit.

Otherwise, it outputs the string \( x_1 \) on the first output tape and checks whether \( z \in S_n(x_1, x_2) \) for some string \( x_2 \) (again, there are only finitely many possibilities). If this is the case, it outputs \( x_2 \) on the next free output tape and goes on to check for \( z \in S_n(x_1, x_2, x_3) \); otherwise, it reads the next bit from the input and goes on.

This machine \( Y \) is constructed such that
\[
M_Y(x; A) = \lim_{n \to \infty} \sum_{y \in S_n(x)} 2^{-\ell(y)} = \lim_{n \to \infty} \phi''(x) = m(x; A)
\]
for all finite \( A \)-histories \( x = (x_1, \ldots, x_k) \).

Now we turn to the proof of Lemma 4.17. This lemma will follow from Lemmas A.5 and A.6 below, together with a straightforward calculation for the expressions \( M_Y \) and \( P_Y \).

**Lemma A.5.** Let \( X \) be a graph machine and \( \varphi : \{0, 1\}^* \to \{0, 1\}^* \) a computomorphism. For all \( x \in \{0, 1\}^* \) and all observer graphs \( A \), define
\[
Y(x, A) := \varphi(X(x, \varphi^{-1} \circ A \circ \varphi)).
\]
Then \( Y \) defines a valid graph machine. Moreover, if \( X \) is covariant then \( Y \) is also covariant.

**Proof.** It is straightforward to construct the model of a graph machine that produces outputs according to the function \( Y \): simulate the machine \( X \) on all computations; whenever properties of \( A \) are determined (by querying the connected machine \( T_A \), see Figure A) use \( \varphi \) to transform this into a query of the observer graph \( \varphi^{-1} \circ A \circ \varphi \); whenever the simulated machine \( X \) produces some output \( x_i \) output \( \varphi(x_i) \) instead.

Now suppose in addition that \( X \) is covariant. Let \( A = (V, E, \Lambda) \) be any observer graph, and let \( U \) be an \( A \)-universal graph machine. Since \( X \) is covariant, there is a computomorphism \( \varphi_{A,U} : V \to \{0, 1\}^* \) such that
\[
\varphi_{A,U}(U(x, A)) = X(x, \varphi_{A,U} \circ A \circ \varphi_{A,U}^{-1}) = \varphi^{-1}(Y(x, \varphi \circ \varphi_{A,U} \circ A \circ \varphi_{A,U}^{-1} \circ \varphi^{-1}))
\]
for all \( x \in \{0, 1\}^* \). Let \( \psi := \varphi \circ \varphi_{A,U} \), then \( \psi(U(x, A)) = Y(x, \psi \circ A \circ \psi^{-1}) \), hence \( Y \) is covariant.

**Lemma A.6.** Let \( U' \) be a universal graph machine, let \( A = (V, E, \Lambda) \) be an observer graph, and let \( \varphi : V \to \{0, 1\}^* \) be a computomorphism. Suppose that \( U \) is any graph machine satisfying
\[
\varphi(U(x, A)) = U'(x, \varphi \circ A \circ \varphi^{-1}).
\]
Then \( U \) is \( A \)-universal.

**Proof.** Let \( X \) be any graph machine, and set
\[
Y(x, B) := \varphi(X(x, \varphi^{-1} \circ B \circ \varphi))
\]
for all \( x \in \{0, 1\}^* \) and observer graphs \( B \), which defines a valid graph machine according to Lemma A.5. Since \( U' \) is in particular \( (\varphi \circ A \circ \varphi^{-1}) \)-universal, there exists a string \( p \in \{0, 1\}^* \) such that
\[
U'(px, \varphi \circ A \circ \varphi^{-1}) = Y(x, \varphi \circ A \circ \varphi^{-1}) = \varphi(X(x, \varphi^{-1} \circ \varphi \circ A \circ \varphi^{-1} \circ \varphi)) = \varphi(X(x, A))
\]
and thus \( U(px, A) = X(x, A) \) for all \( x \in \{0, 1\}^* \).

Next we discuss the construction of a \( \sigma \)-algebra on the set of infinite \( A \)-histories, for dead-end free observer graphs \( A = (V, E, \Lambda) \). This (non-empty) set is defined as
\[
A^\infty := \{ x = (x_1, x_2, \ldots) \mid x_1 = \Lambda, x_i \not\sim x_i+1 \text{ for all } i \in \mathbb{N} \}.
\]
We consider $A^\infty$ as a subset of the one-way infinite sequences of vertices, $V^\infty = \{ x = (x_1, x_2, x_3, \ldots) \}$. The following steps will differ slightly from the usual definitions [177, 178], since we have to deal with an “infinite alphabet” situation: we may have $\#V = \infty$, which is the generic situation for observer graphs. Nevertheless, since $V$ is a discrete countable set, we will define all subsets of $V$ to be measurable, which defines a $\sigma$-algebra of measurable (“Borel”) subsets of $V^\infty$ via the usual product space construction [179]. This $\sigma$-algebra is generated by the cylinder sets $[S]$, defined in the following way. If $n \in \mathbb{N}$ and $S \subseteq V^n$ is any subset, then

$$[S] := \{ x \in A^\infty \mid (x_1, \ldots, x_n) \in S \},$$

that is, the set of all infinite sequences that start like some element of $S$. Note that $A^\infty$ is measurable, i.e. an element of the $\sigma$-algebra of $V^\infty$, since $V^\infty \setminus A^\infty$ can be written as a countable union of cylinder sets:

$$V^\infty \setminus A^\infty = \bigcup_{n \in \mathbb{N}} \{ x \in V^\infty \mid (x_n, x_{n+1}) \notin E \} = \bigcup_{n \in \mathbb{N}} \bigcup_{(y,z) \in V^2 \setminus E} \bigcup_{x \in V^{n-1}} \{ (x, y, z) \}.$$

Thus, there is a subspace $\sigma$-algebra on $A^\infty$, given simply by the elements of the $\sigma$-algebra of $V^\infty$ intersected with $A^\infty$. For what follows, we need the following simple consistency condition:

**Lemma A.7.** Let $A$ be a dead-end free observer graph, and let $\mu(\bullet; A)$ be an $A$-measure in the sense of Definition 4.9. Suppose that $S \subseteq V^m$ and $S' \subseteq V^n$ such that $[S] = [S']$. Then

$$\sum_{x \in S} \mu(x; A) = \sum_{y \in S'} \mu(y; A).$$

**Proof.** Without loss of generality, assume that $m \leq n$. Fix some $x = (x_1, \ldots, x_m) \in S$. Since $[S] = [S']$, we know that $(x_1, \ldots, x_m, x'_{m+1}, \ldots, x'_n) \in S'$ for every choice of $x'_{m+1}, \ldots, x'_n \in V$. Denote the set of all those sequences of length $n$ by $S_x$. Clearly, $S_x \cap S_x' = \emptyset$ if $x \neq x'$, and every $y \in S'$ is an element of some set $S_x$. Decompose $S_x$ into the disjoint union $S_x = S_x^A \cup T_x$, where $S_x^A$ denotes the set of elements of $S_x$ which are valid $A$-histories. Note that if $x$ is itself not a valid $A$-history, i.e. $x \notin A^m$, then $S_x^A = \emptyset$. Thus, using the measure properties of $\mu$ given in Definition 4.9, we get

$$\sum_{y \in S'} \mu(y; A) = \sum_{x \in S} \left( \sum_{y \in S_x^A} \mu(y; A) + \sum_{y \in T_x} \mu(y; A) \right) = \sum_{x \in A^m} \sum_{y \in S_x^A} \mu(y; A) = \sum_{x \in S} \mu(x; A),$$

completing the proof. \[\square\]

If $\mu(\bullet; A)$ is an $A$-measure in the sense of Definition 4.9, then the previous lemma shows that it makes sense to define

$$\mu([S]; A) := \sum_{x \in S} \mu(x; A)$$

since the right-hand side is independent of the cylinder set’s representation. By virtue of Kolmogorov’s Extension Theorem [179, 180], there exists a unique extension of $\mu$ to a measure on the $\sigma$-algebra of $V^\infty$ (and thus on the $\sigma$-algebra of $A^\infty$). The following lemma is used in the proof of Theorem 7.8 in Section 7.

**Lemma A.8 (Comparison of measures).** Let $A$ be any dead-end free observer graph, and let $\mu$ and $\nu$ be $A$-measures such that there is some constant $c \in \mathbb{R}$ with

$$\mu(x_1, \ldots, x_n; A) \geq c \cdot \nu(x_1, \ldots, x_n; A)$$

for all finite $A$-histories $(x_1, \ldots, x_n)$ of all lengths $n \in \mathbb{N}$. Then we have $\mu(S; A) \geq c \cdot \nu(S; A)$ for all Borel subsets $S \subseteq A^\infty$.

**Proof.** The inequality extends to the algebra $\mathcal{A}$ of cylinder sets: if $R \subseteq A^n$, then

$$\mu([R]; A) = \sum_{x \in R} \mu(x; A) \geq c \sum_{x \in R} \nu(x; A) = c \cdot \nu([R]; A).$$

The $\sigma$-algebra on $V^\infty$ is generated by the cylinder sets. Hence, these sets can be used to approximate Borel subsets, where “approximation” is quantified with respect to $\mu$: according to [177, Thm. 11.4], to every Borel subset $S$ and every $\delta > 0$, there is a sequence $\{ [R^{(k)}] \}_{k \in \mathbb{N}}$ of mutually disjoint cylinder sets $[R^{(k)}] \in \mathcal{A}$ such that

$$S \subset \bigcup_{k \in \mathbb{N}} [R^{(k)}] \text{ and } \mu \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}] \setminus S \right) < \delta.$$
Since \( \bigcup_{k \in \mathbb{N}} [R^{(k)}] = S \cup \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}] \setminus S \right) \), this implies
\[
\mu \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}]; A \right) = \mu(S; A) + \mu \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}] \setminus S; A \right) < \mu(S; A) + \delta.
\]

Consequently,
\[
c \cdot \nu(S; A) \leq c \cdot \nu \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}]; A \right) = c \cdot \sum_{k \in \mathbb{N}} \nu \left( [R^{(k)}]; A \right) \leq \sum_{k \in \mathbb{N}} \mu \left( [R^{(k)}]; A \right) = \mu \left( \bigcup_{k \in \mathbb{N}} [R^{(k)}]; A \right) < \mu(S; A) + \delta.
\]

Since this is true for all \( \delta > 0 \), we get the desired inequality.

The following lemma is used in the proof of Theorem 7.7.

**Lemma A.9.** Let \( A \) be a dead-end free observer graph, and \( \mu(\bullet; A) \) an \( A \)-measure. For every \( n \in \mathbb{N} \), let \( f_n : A^n \to \mathbb{R} \) be any function, and set \( F_n := \sum_{x \in A^n} \mu(x; A)f_n^2(x) \). Then, \( \sum_{n=1}^{\infty} F_n < \infty \) implies that for some \( S \subseteq A^\infty \) of \( \mu \)-measure one,
\[
\lim_{n \to \infty} f_n(x_1, \ldots, x_n) = 0 \text{ for all } x \in S.
\]

**Proof.** For every rational number \( \delta > 0 \) and \( m \in \mathbb{N} \), define
\[
B_{m, \delta} := \left\{ x \in A^\infty \mid \exists n \geq m : f_n(x_1, \ldots, x_n) \geq \sqrt{\delta} \right\}.
\]

By the union bound and Markov’s inequality,
\[
\mu(B_{m, \delta}; A) = \mu \left( \bigcup_{n \geq m} \{ x \mid f_n(x_1, \ldots, x_n)^2 \geq \delta \}; A \right) \leq \sum_{n=m}^{\infty} \mu \left( \{ x \mid f_n(x_1, \ldots, x_n)^2 \geq \delta \}; A \right) \leq \sum_{n=m}^{\infty} \frac{1}{\delta} \cdot \mathbb{E}(f_n^2) = \frac{1}{\delta} \sum_{n=m}^{\infty} F_n.
\]

Under the assumptions of the lemma, this is finite and converges to zero, hence
\[
\lim_{m \to \infty} \mu(B_{m, \delta}; A) = 0. \tag{A1}
\]

Now set \( B_\delta := \bigcap_{m \in \mathbb{N}} B_{m, \delta} \). That is, \( B_\delta \) is the set of infinite histories \( x \in A^\infty \) with the property that there exist arbitrarily large \( n \) with \( f_n(x_1, \ldots, x_n) \geq \sqrt{\delta} \). But (A1) implies that \( \mu(B_\delta) = 0 \), and \( \mu(A^\infty; A) = 1 \). Thus, the set
\[
S := A^\infty \setminus \bigcup_{\delta > 0} B_\delta = \bigcap_{\delta > 0} (A^\infty \setminus B_\delta),
\]
where union and intersection are over all positive rational \( \delta \), has \( \mu \)-measure 1. The set \( S \) has the required property. \( \square \)

The following lemma is used in the proof of Lemma 7.11; however, due to its similarity to the Kraft inequality for classical bit strings, it is interesting in its own right.

**Lemma A.10** (Generalized Kraft inequality). Let \( A \) be any observer graph, and \( m(\bullet; A) \) an \( A \)-semimeasure. Suppose that \( \mathcal{H} \) is a set of finite \( A \)-histories which is prefix-free in the sense that \( x \in \mathcal{H} \) implies \( (x, y) \notin \mathcal{H} \) for all non-empty \( y \). Then
\[
\sum_{x \in \mathcal{H}} m(x; A) \leq 1.
\]

**Proof.** We may assume that \( \mathcal{H} \) is finite; the case that \( \mathcal{H} = \emptyset \) is trivial, and the case of infinite \( \mathcal{H} \) follows by taking an appropriate limit. Let \( n \) be the maximal length of any \( A \)-history \( x = (x_1, \ldots, x_n) \in \mathcal{H} \). We argue by induction in \( n \). If \( n = 1 \), then \( \mathcal{H} = \{ A \} \), hence
\[
\sum_{x \in \mathcal{H}} m(x; A) = m(A; A) \leq 1
\]
by definition of an \( A \)-semimeasure. Now suppose that \( n > 1 \). For any given set \( \mathcal{H} \), define a corresponding set \( \mathcal{H}' \) as \( \mathcal{H}' := \mathcal{H}_{<n} \cup \mathcal{H}_n \), where \( \mathcal{H}_{<n} \) denotes the set of all histories in \( \mathcal{H} \) that have a length of at most \( n - 1 \), and
\[
\mathcal{H}_n := \{ x' \mid x \in \mathcal{H}, \ x \text{ is an } A\text{-history of length } n \},
\]
In A. Appendix: Mathematical proofs and further details.
where for any given \( x = (x_1, \ldots, x_{n-1}, x_n) \), we use the notation \( x' = (x_1, \ldots, x_{n-1}) \). Since \( \mathcal{H} \) is prefix-free, we have \( \mathcal{H}_{<n} \cap \mathcal{H}_n = \emptyset \), and \( \mathcal{H}' \) is prefix-free, too. Moreover, the maximal length of any history in \( \mathcal{H}' \) is at most \( n-1 \). Thus, by the induction hypothesis and the semimeasure properties of \( m \), we have

\[
1 \geq \sum_{x \in \mathcal{H}'} m(x; A) = \sum_{x \in \mathcal{H}_{<n}} m(x; A) + \sum_{y = (y_1, \ldots, y_{n-1}) \in \mathcal{H}_n} m(y; A) \geq \sum_{x \in \mathcal{H}_{<n}} m(x; A) + \sum_{y \in \mathcal{H}_n} \sum_{z \in A(y_{n-1})} m(y, z; A).
\]

We now give a proof of Theorem 7.3.

**Proof.** We define a function \( m : \{0, 1\}^* \to \mathbb{R} \) in the following way. If \( b_1, \ldots, b_n \in \{0, 1\} \) are \( n \) bits, set \( m(\varepsilon) := M(A; A) \) and

\[
m(b_1b_2 \ldots b_n) := \sum_{x \in A^{n+1} : f(x_1, x_2) = b_1, \ldots, f(x_1, \ldots, x_{n+1}) = b_n} M(x; A).
\]

(Since \( x_1 = A \), the function \( f \) will effectively only depend on \( x_2, \ldots, x_{n+1} \).) It is easy to see that \( m \) is an enumerable semimeasure in the sense of Definition 4.3. We want to show that \( m \) is universal. To this end, let \( \mu \) be any enumerable semimeasure. For every sequence of bits \( b_1, \ldots, b_n \), we can find an \( A \)-history \( x = (x_1, \ldots, x_{n+1}) \) with \( b_i = f(x_1, \ldots, x_{i+1}) \) in the following way: first, find some arbitrary \( x_2 \) such that \( f(A, x_2) = b_1 \). Then, due to the premises of the theorem, we can find a suitable \( x_3 \in A(x_2) \) such that \( b_2 = f(A, x_2, x_3) \). We repeat this recursively until we have found \( x_1 = A, x_2, \ldots, x_{n+1} \), and we fix an algorithm that does this. This way, we obtain an enumerable \( A \)-semimeasure \( \mu^A \), defined as

\[
\mu^A(x_1, \ldots, x_{n+1}) := \begin{cases} 
\mu(b_1 \ldots b_n) & \text{if } x_1, \ldots, x_{n+1} \text{ is what this algorithm generates from } b_1, \ldots, b_n, \\
0 & \text{otherwise}
\end{cases}
\]

(in particular \( \mu^A(A; A; \varepsilon) = m(\varepsilon) \)). Since \( M(\varepsilon; A) \) is a universal enumerable \( A \)-semimeasure, there is a constant \( c > 0 \) such that \( M(x; A) \geq c \cdot \mu^A(x; A) \) for all finite \( A \)-histories \( x \). This gives us

\[
m(b_1 \ldots b_n) \geq c \cdot \sum_{x \in A^{n+1} : f(x_1, x_2) = b_1, \ldots, f(x_1, \ldots, x_{n+1}) = b_n} \mu^A(x; A) = c \cdot \mu(b_1 \ldots b_n).
\]

Since \( \mu \) was arbitrary, this shows that \( m \) is a universal enumerable semimeasure. Thus [95] shows that \( m(01^{n-1}) = 2^{-K(n-1)+O(1)} = 2^{-K(n)+O(1)} \), which is by definition equal to \( M(f(x_1^{n+1}) = 0 \mid f(x_2^1) = 1, \ldots, f(x_7^1) = 1) \). However, according to the postulates of our theory, it is the probability \( P(M; A) \) that determines an observer’s experiences. Hence we define \( p(b_1b_2 \ldots b_n) \) in complete analogy to (A2), with “\( M \)” replaced by “\( p \)” on the right-hand side and \( p(\varepsilon) := 1 \). Then \( p \) is a (probability) measure in the sense of Definition 4.3, though it is not in general enumerable. Unfortunately there does not seem to be any simple relation between the semimeasure \( m \) and the measure \( p \). Nevertheless, \( p \) is universal in the sense that for every computable measure \( \mu \) there is a constant \( c_\mu > 0 \) such that \( p(\mu(x) \mid x \in \{0, 1\}^\ast) \geq c_\mu \mu(x) \) for all \( x \in \{0, 1\}^\ast \); the proof of this statement is identical to the case of \( m \) above (using that \( P(x; A) \geq M(x; A) \)). But then we can consider the special case \( \mu(1^n) = 1 \), i.e. the deterministic measure on the strings that consist of ones only. This shows that there is non-zero probability that \( f(x_1, \ldots, x_{n+1}) = 1 \) for all \( n \). The remaining parts of the statement of the theorem follow from adapting the proof of the paragraph “Convergence for deterministic environments” in [95].

Now we will motivate and give a formal definition of predictivity as used in Section 12. Consider an observer \( A = (V, E, A) \) (Abby) who is asymptotically seeing (in the sense of Theorem 7.8) a computable \( A \)-measure \( \mu \). Predictivity should express the fact that \( \mu \) allows Abby to assign probabilities to future observations, even though she will in general have forgotten her past observations. At any given moment, we assume that Abby knows her current state \( x \in V \) and the measure \( \mu \). Clearly, if she knows \( \mu \), and \( x \) is her current state, then a description of \( \mu \) is somehow encoded in \( x \). As discussed in more detail in Section 3, we should not think of the current state \( x \in V \) of Abby as something that she “consciously knows”, but it is still a useful idealization to think along these lines. Setting all questions aside as to whether Abby has practically access to \( x \) or \( \mu \), we will now formulate predictivity as a necessary condition for Abby to extract a probability measure on her future observations from \( \mu \), but we will keep in mind that it may not be sufficient due to practical limitations on accessing a description of \( x \) or \( \mu \).

If \( A \) is acyclic, then there is a notion of probability of the event “Abby has experienced some history that has currently ended with \( x^n \)” let us call this event \( X \) (following notation of the proof of Lemma 7.11). Furthermore, define the event \( Y \) as the experience of \( x \), followed by experience of further states \( y \). Both \( X \) and \( Y \) are measurable subsets of \( A^\infty \). Thus, there is a unique way to define \( \mu(X) \) and \( \mu(Y) \), and one obtains

\[
\mu(y|x; A) = \mu(Y|X) = \mu(Y)/\mu(X).
\]

However, \( \mu(X) \) and \( \mu(Y) \) cannot be assigned values in the case that \( \mu \) is not acyclic. In fact, it is not even clear how to define the event \( Y \) as a subset of \( A^\infty \), the infinite \( A \)-histories: in order for \( h \in A^\infty \) to be an element of \( Y \), should all appearances of \( x \) be followed by \( y \), or some of them, or...?
If the observer knew that it is the \#-th time that she experiences \( x \) (i.e. if she knew how often she has “looped” in the past), then she could compute the sought-for conditional probability. We can formally define the event \( X_\# \) as all infinite \( A \)-histories \( h \) which have at least \# appearances of \( x \), and \( Y_\# \) all those histories in \( X_\# \) where the \#-th appearance of \( x \) is followed by \( y \). Knowing \# would allow to assign \( \mu(Y_\#|X_\#) \) as the conditional probability \( \mu(y|x;A) \). But for general non-acyclic measures \( \mu \), there is no way for Abby to know \#.

Is there a natural probability distribution on the possible values of \# that Abby may resort to? Unfortunately the answer is “no”. If we would like to define, say, \( \mu(#|x) \) as a probability that Abby sees her current state the \#-th time, given that she currently sees \( x \), then one runs again into the problem that there is no formal way to define the corresponding events that would give rise to this conditional probability. However, Abby may have a degree of belief about the value of \#; let us call this \( \nu_x(#) \). In principle this degree of belief is completely arbitrary, up to a single condition: if there simply are no finite \( A \)-histories \( x \) that contain \# appearances of \( x \) and that have non-zero \( \mu(x;A) \), then \( \nu_x(#) \) should be zero. We call this condition “\( \mu \)-consistency”.

Formally, we then have a sample space \( A^\infty \times \mathbb{N} \), and a product measure \( \tilde{\mu}_x := \mu \times \nu_x \), which gives us on the one hand the probability distribution over histories, and on the other hand the probability Abby assigns to \# if she experiences \( x \) during one of those histories. We can then formally define two events \( X \) and \( Y \), both sets of pairs \((x, #) \in A^\infty \times \mathbb{N} \), where \( X \) is the set of such pairs such that \( x \) contains at least \# times the string \( x \), and \( Y \) is the set of pairs in \( X \) where in addition the \#-th appearance of \( x \) is followed by \( y \). Then we can formally define the conditional probability

\[
\hat{\mu}_x(Y|X) := \mu(y|x;A).
\]

If the probabilities of future observations are independent of the degree of belief \( \nu_x \), then we may still say that these probabilities are determined by the measure \( \mu \) alone, and that \( \mu \) is predictive:

**Definition A.11** (Predictive measure).
Let \( A = (V,E,\Lambda) \) be any observer graph. An \( A \)-measure \( \mu \) is called predictive if for every \( x \in V \) that can be reached with non-zero \( \mu \)-probability from \( \Lambda \), the conditional probability \( \hat{\mu}_x(Y|X) \) as defined above is independent of the choice of the \( \mu \)-consistent assignment of probability \( \nu_x(#) \). If this is the case, then we define \( \mu(y|x;A) := \hat{\mu}_x(Y|X) \).

Now we give a proof of Lemma 12.3.

**Proof.** Let \( x \in V \) be any string that can be reached from \( \Lambda \) with positive \( \mu \)-probability. Then, by the definition of \( \hat{\mu}_x \) and \( \mu \),

\[
\hat{\mu}_x(Y|X) = \frac{\hat{\mu}_x(Y)}{\hat{\mu}_x(X)} = \frac{\sum_{\# = 1}^{\infty} \nu_x(\#) \sum_{w \in H(\#)} \mu(w,y;A)}{\sum_{\# = 1}^{\infty} \nu_x(\#) \sum_{w \in H(\#)} \mu(w;A)} = \frac{\sum_{\# = 1}^{\infty} \nu_x(\#) \mu(y|x,#;A) \sum_{w \in H(\#)} \mu(w;A)}{\sum_{\# = 1}^{\infty} \nu_x(\#) \sum_{w \in H(\#)} \mu(w;A)}. \tag{A3}
\]

Suppose that \( \mu(y|x,#;A) \) is independent of \#, where we only consider values of \# in \( \mathbb{N} \) such that the denominator in (21) is not zero (it is only those values that can have non-zero \( \nu_x(#) \) due to \( \mu \)-consistency). Then we can pull it out of the sum in the numerator, and everything cancels, leading to \( \hat{\mu}_x(Y|X) = \mu(y|x,#;A) \) which is thus independent of the choice of \( \nu_x \). Thus, \( \mu \) is predictive, with the expression for \( \mu(y|x;A) \) as claimed.

Conversely, suppose that \( \mu \) is predictive. Then \( \hat{\mu}_x(Y|X) \) as in (A3) will be independent of the choice of \( \nu_x(\#) \); in particular, we can set \( \nu_x(#) = \delta_{#k} \), as long as \( k \in \mathbb{N} \) is an integer such that there exist finite \( A \)-histories that contain at least \( k \) appearances of \( x \) and have non-zero \( \mu \)-probability. This collapses the sum over \# and yields \( \hat{\mu}_x(Y|X) = \mu(y|x,# = k;A) \) which is thus independent of \# = \( k \).

The following characterization of predictivity will be used below, but is interesting in its own right. It uses the notation of Lemma 12.3.

**Lemma A.12.** Let \( A = (V,E,\Lambda) \) be any observer graph. An \( A \)-measure \( \mu \) is predictive if and only if for every \( x \in V \) that can be reached from \( \Lambda \) with positive probability, there exists some constant \( c_x \geq 0 \) such that

\[
\sum_{w \in H(\#)} \mu(w,y;A) = c_x^{#-1} \sum_{w \in H(1)} \mu(w,y;A) \quad \text{for all } y \text{ and all } \# \in \mathbb{N}, \tag{A4}
\]

with the convention \( 0^0 := 1 \).

Note that acyclic measures \( \mu \) satisfy (A4) with \( c_x = 0 \) for all \( x \).

**Proof.** Suppose that eq. (A4) holds, then it is easy to check that \( \mu(y|x,#;A) \) as defined in (21) will be equal to \( \mu(y|x,1;A) \) and thus independent of \#. Then Lemma 12.3 establishes predictivity of \( \mu \).

Conversely, suppose that \( \mu \) is predictive, and let \( x \in V \) be a string that can be reached from \( \Lambda \) with positive probability. Define the set

\[
G_x := \{(g_1, \ldots, g_k) \in V^k \mid k \in \mathbb{N}, g_1 \neq x, \ldots, g_{k-1} \neq x, g_k = x\},
\]

as all infinite \( \# \)-histories that contain \# appearances of \( x \) during

and thus independent of \#. Then Lemma 12.3 establishes predictivity of \( \mu \).

Conversely, suppose that \( \mu \) is predictive, and let \( x \in V \) be a string that can be reached from \( \Lambda \) with positive probability. Define the set

\[
G_x := \{(g_1, \ldots, g_k) \in V^k \mid k \in \mathbb{N}, g_1 \neq x, \ldots, g_{k-1} \neq x, g_k = x\},
\]

as all infinite \( \# \)-histories that contain \# appearances of \( x \) during
i.e. finite tuples of vertices (not necessarily $A$-histories) that contain $x$ once as their final entry. Suppose that $w \in \mathcal{H}_x(^\#)$ and $y \in \mathcal{G}_x$ such that $\mu(w, y; A) > 0$, then $(w, y) \in \mathcal{H}_x(^{#+1})$, and every element of $\mathcal{H}_x(^{#+1})$ can be obtained in this way. Hence

$$\sum_{y \in \mathcal{G}_x} \sum_{y \in \mathcal{H}_x(^{#})} \mu(w, y; A) = \sum_{w \in \mathcal{H}_x(^{#+1})} \mu(w; A).$$

If looping $#$ times is impossible then looping $(# + 1)$ times is also impossible. Therefore, there exists some $k_x \in \mathbb{N} \cup \{+\infty\}$ (the maximal number of loopings through $x$) such that

$$\sum_{w \in \mathcal{H}_x(^{#})} \mu(w; A) \begin{cases} > 0 & \text{if } # \leq k_x \\ = 0 & \text{if } # > k_x \end{cases}$$

(note that these sums are finite due to Lemma A.10 since $\mathcal{H}_x(^{#})$ is prefix-free.) Due to predictivity, for all $# \leq k_x$, the expression $\sum_{y \in \mathcal{G}_x} \mu(y|x; #; A)$ (which might apriori be infinite) is independent of $#$. Thus

$$\sum_{y \in \mathcal{G}_x} \mu(y|x; #; A) = \frac{\sum_{y \in \mathcal{G}_x} \sum_{w \in \mathcal{H}_x(^{#})} \mu(w, y; A)}{\sum_{w \in \mathcal{H}_x(^{#})} \mu(w; A)} = c_x$$

(A5)

is in fact finite and also independent of $#$ for all $# \leq k_x$. If $k_x = 1$, then Abby can see $x$ only once, and then (A4) holds trivially with $c_x = 0$. If $k_x \geq 2$, then eq. (A5) in the special case $# = 1$ shows that $c_x > 0$. But then, if $k_x$ is finite, eq. (A5) in the special case $# = k_x$ shows that $\sum_{w \in \mathcal{H}_x(^{k_x})} \mu(w; A) > 0$, which is a contradiction. We must therefore have $k_x = +\infty$, and eq. (A5) is valid for all $# \in \mathbb{N}$. But then, using (21), Lemma 12.3, and eq. (A5) recursively, we get

$$\sum_{w \in \mathcal{H}_x(^{#})} \mu(w; A) = \mu(y|x; #; A) \sum_{w \in \mathcal{H}_x(^{#})} \mu(w; A) = \mu(y|x; A) c_x^{#-1} \sum_{w \in \mathcal{H}_x(^{1})} \mu(w; A) = c_x^{#-1} \sum_{w \in \mathcal{H}_x(^{1})} \mu(w; A).$$

This concludes the proof.

We obtain the following simple consequence that we have used in Example 12.4:

**Corollary A.13.** Let $A = (V, E, \Lambda)$ be any observer graph, and $\mu$ a predictive $A$-measure. Then, for all $x \in V$ that can be reached from $A$ with positive probability, one of the following two statements must be true:

- either $x$ can only be experienced *once* with positive probability, i.e.
  $$\mu(y, x, z; A) = 0 \text{ for all } y, z,$$
  - or $x$ can be experienced an *arbitrary number of times* with positive probability, i.e.
  $$\text{for every } # \in \mathbb{N} \text{ there exist } y_1, \ldots, y_{#} \text{ such that } \mu(y_1, x, y_2, x, \ldots, y_{#}, x; A) > 0.$$

**Proof.** Let $c_x \geq 0$ be the constant from Lemma A.12. If $c_x = 0$ and $# \geq 2$ then $\sum_{w \in \mathcal{H}_x(^{#})} \mu(w, y; A) = 0$, and thus $\mu(w, y; A) = 0$ for all $w \in \mathcal{H}_x(^{#})$. Thus, $x$ can only be experienced once with positive probability. On the other hand, if $c_x > 0$, then we have $\sum_{w \in \mathcal{H}_x(^{#})} \mu(w, y; A) > 0$ for all $# \in \mathbb{N}$ (since $\mathcal{H}_x(^{1})$ has positive probability by assumption). Consequently, for every $# \in \mathbb{N}$, there exists some $w \in \mathcal{H}_x(^{#})$ and some $y$ such that $\mu(w, y; A) > 0$, hence $\mu(w; A) \geq \mu(w, y; A) > 0$.

As stated in the main text in Section 12, it may seem puzzling at first sight that the set of predictive measures (for a given, fixed observer graph $A$) is not convex. This is because of the following apparent contradiction: suppose that $\mu$ and $\mu'$ are predictive $A$-measures, and set $\nu := \frac{1}{2} \mu + \frac{1}{2} \mu'$. Informal definition 7.10 says that predictivity is equivalent to the existence of a conditional probability distribution $\mu(y|x; A)$ resp. $\mu'(y|x; A)$. Then why not set $\nu(y|x; A) := \frac{1}{2} \mu(y|x; A) + \frac{1}{2} \mu'(y|x; A)$ and conclude that $\nu$ is predictive too? The following two examples show how the apparent contradiction can be resolved.

**Example A.14 (Non-convexity of the set of predictive measures).** Consider an observer graph $A$ of the following form:
That is, the graph is tree-like except for a single cycle that allows the transition 0 $\xrightarrow{A} 0$. Consider two computable $A$-measures $\mu_p$ and $\mu_q$, which are by definition Markovian and differ in the probability of this transition: for $\mu_p$ this probability is $p$, and for $\mu_q$ it is $q$. Since $\mu_p$ and $\mu_q$ are Markovian, these $A$-measures are also predictive, cf. Figure 5.

Set $\mu := \frac{1}{2}\mu_p + \frac{1}{2}\mu_q$. Then we obtain

\[
\mu(1|0, \#; A) = \frac{\mu(\Lambda, 0, \ldots, 0, 1)}{\mu(\Lambda, 0, \ldots, 0)} = \frac{\frac{1}{2}p\#^{-1}(1-p) + \frac{1}{2}q\#^{-1}(1-q)}{\frac{1}{2}p\#^{-1} + \frac{1}{2}q\#^{-1}}
\]

and this is identical for all $\#$ if and only if $p = q$ (e.g. compare $\# = 1$ and $\# = 2$). In other words, the convex combination $\mu = \frac{1}{2}\mu_p + \frac{1}{2}\mu_q$ of the predictive $A$-measures $\mu_p$ and $\mu_q$ is not a predictive $A$-measure if $p \neq q$.

To see why this is in fact quite intuitive, suppose that the observer ("Abby") would like to predict whether she experiences transition 1 $\rightarrow$ 0, which is determining her future fate. She should then predict to see 10 is one, but the $\mu_p$-probability of the transition 1 $\rightarrow$ 0 is one, whereas a knowledge of $\# = 1$ would only make her predict 10 with probability close to 1/2. That is, her assignment of future probabilities depends on the number of loopings $\#$.

While this example shows that the non-convexity of the set of predictive measures can be understood quite intuitively, it raises another concern: maybe then our definition of predictivity is not the right notion to consider in the first place? It turns out (as we shall show below) that the measures in Example A.14 all have an interesting property: namely, they induce a natural probability distribution on the number of cycles $\#$, even though (as remarked in Example 12.4) we cannot derive such a notion of probability from the underlying probability space alone. Thus, should we give up to study predictive measures, and instead consider the set of measures that induce a natural probability distribution on the number of cycles $\#$ to make sense of $\mu(y|x; A)$? The following example provides strong arguments against this idea.

**Example A.15** (Attempts to define a distribution on $\#$, and why they fail in general). Let $A = (V, E, A)$ be an observer graph, and $\mu$ a computable $A$-measure for which there exists some $x \in V$ that can be experienced at least twice with positive probability (implying that $\mu$ is not acyclic). We can try to define a probability distribution $\nu$ on the possible numbers of cycles $\# \in \mathbb{N}$ via the following algorithm:

1. Fix some $n \in \mathbb{N}$; set the counter variables to $c := (c_1, \ldots, c_n) = (0, \ldots, 0) \in \mathbb{R}^n$.

2. Sample an $A$-history $z = (z_1, \ldots, z_n)$ according to $\mu$.

3. Consider all appearances of $x$ in $z$, i.e. all $z_i = x$. Count the first appearance of $x$ as the realization of "$\# = 1$", and increase the corresponding counter $c_1$ by one. Count the second appearance of $x$ as a realization of "$\# = 2$" and increase $c_2$ by one. And so forth, until all appearances of $x$ have been incorporated.

4. Repeat steps 2) and 3) many times (say, $N$ times). The limit $N \to \infty$ of $c_i / \sum_i c_i$ defines a probability distribution over the possible values of $\#$.

5. Determine the limit $n \to \infty$ of the distribution obtained in 4., which yields the final sought-for probability distribution $(\mu(\# = 1|x; A), \mu(\# = 2|x; A), \ldots)$ over the number of cycles $\#$.

This prescription works in the following cases:

- In the case of the Sleeping Beauty Problem, Example 12.4, applying this to the corresponding non-predictive $B$-measure $\mu$ yields $\mu(\# = 1|x; B) = \frac{2}{3}$, which suggests a solution of the problem exactly as proposed in [131].

- For the $A$-measure $\mu_p$ of Example A.14, this method yields $\mu_p(\#|0; A) = (1-p)p\#^{-1}$. An analogous equation holds for $\mu_q$ (with $p$ replaced by $q$), and also $\mu(\#|0; A) = \frac{(1-p)(1-q)}{2-p-q}(p\#^{-1} + q\#^{-1})$ for the non-predictive measure $\mu = \frac{1}{2}\mu_p + \frac{1}{2}\mu_q$. However, this gives us

\[
\mu(1|0; A) = \sum_{\# = 1}^{\infty} \mu(1|0, \#; A)\mu(\#|0; A) = \frac{2(1-p)(1-q)}{2-p-q},
\]

and this is not the same as $\frac{1}{2}\mu_p(1|0; A) + \frac{1}{2}\mu_q(1|0; A)$ if $p \neq q$. 

\[A. \text{ Appendix: Mathematical proofs and further details}\]
As this last example shows, even in cases where we can somehow make sense of a probability distribution over #, this will not allow us to simply assign a convex combination of probabilities \( \mu(y|x; A) \) if we have a convex combination of \( A \)-measures (mainly because the expected number of realizations of \( x \) in any sample will be different for the different measures).

More importantly, the simple algorithm above only works for the example measures because those measures have such a simple structure. In general, computable measures can behave in a much more complicated way such that the procedure above does not converge. As an arbitrary example, let \( C \) be the complete graph on \( V = \{0, 1\} \), with \( 1 = \Lambda \) as the root, and let \( \mu \) be the deterministic measure which assigns probability one to the \( C \)-history

\[
( (1, 0), (1, 0, 1, 0, 0), (1, 0, 1, 1, 0, 0, 0), \ldots ) \in C^\infty
\]

(the brackets are for illustration only). Clearly \( \mu \) is not predictive: the probability \( \mu(1|0, \#; C) \) is either zero or one, depending on \#.
Also, it is clear that neither the algorithm above nor any other reasonable method will yield a distribution \( \mu(#|0; C) \); all the values of \# \in \mathbb{N} seem to be on equal footing, and there is no uniform distribution on \mathbb{N}. The value \( \mu(1|0, \#; C) \) oscillates irregularly, and thus a direct sampling of this value will not yield a valid conditional probability distribution either.

Even in those cases where the algorithm above works, we may question its justification. After all, the algorithm somehow allows us to simply assign a convex combination of probabilities \( \mu(X|y, A) \) to any arbitrary \( X \)-measures because those measures have such a simple structure. In particular, it is sufficient to check factorization for the “yes”-outcome due to the following implication for arbitrary discrete random variables:

\[
\bar{x} \perp \bar{y} | a, b \quad \Rightarrow \quad \bar{X} \perp \bar{Y} | a, b \quad \text{(A7)}
\]

i.e. it states that Alice’s non-detection event and Bob’s outcome are to be conditionally independent, given the settings.

A comment on the notation: the event “\( \emptyset \)” can be understood as a binary random variable which takes the value “yes” if \( \bar{x} = \emptyset \) and “no” if \( \bar{x} \neq \emptyset \). Then (A7) is just an ordinary conditional independence relation between random variables. In particular, it is sufficient to check factorization for the “yes”-outcome due to the following implication for arbitrary discrete random variables \( X, Y, Z \) which is straightforward to verify:

\[
P(X = x_0, Y|Z) = P(X = x_0|Z) \cdot P(Y|Z) \quad \Rightarrow \quad P(X \neq x_0, Y|Z) = P(X \neq x_0|Z) \cdot P(Y|Z).
\]

Proof. Using that \( P_0 \) is non-signalling, we get

\[
\sum_{y \in Y} P(x, y|a, b) = \sum_{y \in Y} \frac{P_0(x, y|a, b)}{1 - P_0(\emptyset|a)} = \sum_{y \in Y} \frac{P_0(x, y|a, b')}{1 - P_0(\emptyset|a)} = \sum_{y \in Y} P(x, y|a, b') \quad \text{for all } x \in X, a, b, b',
\]

that is, \( P \) is non-signalling from Bob to Alice. We also have

\[
\sum_{x \in X} P(x, y|a, b) = \sum_{\bar{x} \in X} \frac{P_0(\bar{x}, y|a, b) - P_0(\emptyset, y|a, b)}{1 - P_0(\emptyset|a)} = \frac{P_0(y|b) - P_0(\emptyset, y|a, b)}{1 - P_0(\emptyset|a)},
\]

and if we assume eq. (A6), then this simplifies to \( P_0(y|b) \), which is manifestly independent of \( a \) for all \( y \in Y \). No-signalling of \( P_0 \) also implies that \( P_0(\emptyset|a) = P_0(\emptyset|a, b) \) and \( P_0(y|b) = P_0(y|a, b) \), such that (A6) is equivalent to (A7).

Here is a proof of eq. (27) from the main text.
Proof. Using Lemma A.12, we get for all z

\[ \mu(z|\#_{\text{max}}; A) = \frac{\sum_{w \in \mathcal{H}_{\#_{\text{max}}}^{(1)}} \mu(w, z; A)}{\sum_{z_1 \neq x} \sum_{w \in \mathcal{H}_{\#_{\text{max}}}^{(1)}} \mu(w, z_1; A)} = \frac{c_{\#_{\text{max}}-1}^{(1)}}{\sum_{z_1 \neq x} c_{\#_{\text{max}}-1}^{(1)}} \mu(w, z; A) \]

and the factor \( c_{\#_{\text{max}}-1}^{(1)} \) cancels out, making this expression manifestly independent of \#_{\text{max}}.

Finally, here we prove Theorem 14.2 from the main text.

Proof. We construct a covariant history machine \( C \) and show that it is also universal. By construction, the machine operates as follows, given some potentially infinite sequence of bits \( x \in \{0,1\}^\infty \) and root string \( \Lambda \in \{0,1\}^* \) as input:

- \( C \) first reads the input root string \( \Lambda \in \{0,1\}^* \).
- Given any fixed computable bijection \( \alpha : \{0,1\}^* \to \mathbb{N} \times \{0,1\}^* \times \{0,1\}^* \), \( C \) computes \((m, \Lambda', s) := \alpha(\Lambda)\). Define the computable permutation \( \pi : \{0,1\}^* \to \{0,1\}^* \) by

\[
\pi(z) := \begin{cases} 
\Lambda' & \text{if } z = \Lambda \\
\Lambda & \text{if } z = \Lambda' \\
z & \text{otherwise.}
\end{cases}
\]  

(A8)

- \( C \) simulates the \( m \)-th history machine \( Y \) (according to some enumeration) on root input \( \Lambda' \) (i.e. corresponding to the complete observer graph \( A_{\Lambda'} \)) except if the input starts with the string \( s \), in which case it simulates the universal machine \( W \) from Lemma A.2 (or rather its history machine version). Specifically, the machine \( C \) starts to read the input bits one after the other. Let \( x' \) denote the bits that have been read so far. Then \( C \) proceeds as follows:

  - As long as \( x' \) is a proper prefix of \( s \), the machine waits and reads more bits to see whether \( x \) really starts with \( s \).

- If \( x' = s \), i.e. if \( C \) has detected that \( x \) really starts with \( s \) such that \( x = sy \), it continues by emulating the machine \( W \) on inputs \( y \) and \( A_{\Lambda'} \) — that is, it works on the remaining bits exactly as \( W \). With one difference: instead of giving the same output as \( W \), that output is permuted. That is, it produces \( \pi(W(y, A_{\Lambda'})) \), where \( W(y, A_{\Lambda'}) \) denotes (for the sake of the present argument) the potentially infinite sequence of outputs generated by \( W \).

- If \( x' \) is not a prefix of \( s \), then \( C \) has detected that \( x \) does not start with \( s \). In this case, \( C \) simply emulates the machine \( Y \) on inputs \( x \) and \( A_{\Lambda'} \) — again, with the single modification that the output is permuted by the map \( \pi \).

The machine \( C \) is constructed such that for all \( \Lambda \in \{0,1\}^* \)

\[ C(sy, A_{\Lambda}) = \pi(W(y, A_{\Lambda'})) \text{ for all } y \in \{0,1\}^* \]

(note that \( \pi, \Lambda' \) and \( s \) are functions of \( \Lambda \)). Let \( X \) be an arbitrary history machine, set \( X'(x, A_{\Lambda}) := \pi(X(x, A_{\Lambda})) \) which defines a new history machine \( X' \). Due to the universality of \( W \), there is some string \( e \in \{0,1\}^* \) such that \( W(ex, A_{\Lambda'}) = X'(x, A_{\Lambda'}) \) for all \( x \in \{0,1\}^* \), and thus

\[ C(sex, A_{\Lambda}) = \pi(W(ex, A_{\Lambda'})) = \pi(X'(x, A_{\Lambda'})) = X(x, A_{\Lambda}) \text{ for all } x \in \{0,1\}^*. \]

This proves that \( C \) is \( A_{\Lambda} \)-universal. Since \( \Lambda \) was arbitrary, we conclude that \( C \) is universal.

It remains to show that \( C \) is covariant. To this end, let \( \Lambda' \in \{0,1\}^* \) be arbitrary, let \( Y \) be any \( A_{\Lambda'} \)-universal history machine, and let \( m \in \mathbb{N} \) be its number in the enumeration above (which will not in general be unique). Due to the definition of universality, there exists some \( s \in \{0,1\}^* \) such that \( Y(sy, A_{\Lambda'}) = W(y, A_{\Lambda'}) \) for all \( y \in \{0,1\}^* \) (note that \( s \) depends on \( \Lambda' \)). Let \( \Lambda := \alpha^{-1}(m, \Lambda', s) \), and \( \pi \) the permutation in (A8). Let us determine \( C(x, A_{\Lambda}) \) in three different cases. First, if \( x = sy \) then \( C(x, A_{\Lambda}) = C(sy, A_{\Lambda}) = \pi(W(y, A_{\Lambda})) = \pi(Y(sy, A_{\Lambda})) = \pi(Y(x, A_{\Lambda})). \) Second, if \( x \) is a prefix of \( s \) then both \( C(x, A_{\Lambda}) \) and \( Y(x, A_{\Lambda}) \) give empty output (i.e. have not output anything yet), which follows for \( Y \) from the fact that it could not otherwise emulate \( W \) on input \( s \). Third, if neither of these cases apply, then \( C(x, A_{\Lambda}) = \pi(Y(x, A_{\Lambda})) \) by construction. In all cases, it thus holds \( C(x, \pi \circ A_{\Lambda'} \circ \pi^{-1}) = \pi(Y(x, A_{\Lambda'})) \), and since \( \Lambda' \) was arbitrary, this proves covariance of \( C \).

As announced in Section 14, here is a slightly different perspective on covariance which corroborates the discussion of Section 4.3. Consider pairs \((y, V)\), where \( y = (y_1, \ldots, y_n) \) is any finite sequence of strings, and \( V \) is any universal covariant history machine. Define two such pairs as equivalent, denoted

\[(x, U) \sim (y, V),\]

if and only if there is a computable bijection \( \pi : \{0,1\}^* \to \{0,1\}^* \) such that \( \pi(x) = y \) (i.e. \((\pi(x_1), \ldots, \pi(x_n)) = (y_1, \ldots, y_n)\)) and \( U(p, A_{x_i}) = \pi^{-1}(V(p, A_{y_i})) \) for all \( p \in \{0,1\}^* \). It is not difficult to see that \( \sim \) defines an equivalence relation. Moreover, for any given pair \((x, U)\), we can always “transform to another arbitrary choice of universal covariant machine
V”, in the sense that there exists some y such that (x, U) ∼ (y, V). In other words, we always have the freedom to choose our universal covariant machine as we like. On the other hand, if we interpret x as an encoding of an observer’s history into binary strings, then we are always free to choose a different encoding (with the same computability structure), namely by applying a computable bijection π to x, as long as we adjust for this by transforming to a new machine V := π ◦ U. This will also give us (x, U) ∼ (y, V).

This motivates to define an “abstract observer history” as an equivalence class [(x, U)]; every x represents a possible encoding of the abstract history into a sequence of binary strings, and U a possible choice of universal covariant history machine which defines a specific realization of encoding computability structure into strings. An abstract observer history has a well-defined probability

\[ P([[(x, U)]] ) := P_U(x; A_{x_1}), \]

and similarly as in the proof of Lemma 4.16, it is easy to see that this probability is independent of the choice of representative (x, U). Our definition of “abstract observer history” here resembles the possible definition of a “differentiable manifold” by an equivalence class of parametrizations [176], returning to the comparison with differential geometry from Subsection 4.3.

Thus, in some sense, our theory can be interpreted as claiming that observers experience “abstract observer histories” [(x, U)], but at any given point in time (where x = (x_1, ..., x_n)), all they see and remember is their current state x_n. In fact, even this statement cannot be literally true: after all, whatever observers really see and remember must be an invariant with respect to the equivalence relation above, which x_n itself is not. We leave the question of how such an “encoding-free” definition of abstract information can be understood and treated more concretely to future work.
