Quantum state discrimination through quantum state distinguishability

Seyed Arash Ghoreishi, Seyed Javad Akhtarshenas and Mohsen Sarbishaei
Department of Physics, Ferdowsi University of Mashhad, Mashhad, Iran

For a discrimination problem $\Phi$, consisting of $N$ linearly independent pure quantum states $\Phi = \{\{\phi_i\}\}$ and the corresponding occurrence probabilities $\eta = \{\eta_i\}$ we associate, up to a permutation over the probabilities $\{\eta_i\}$, a unique pair of density matrices $\rho_x$ and $\eta_p$ defined on the $N$-dimensional Hilbert space $\mathcal{H}_N$. The first one, $\rho_x$, provides a representation of a generic full-rank density matrix in terms of the parameters of the discrimination problem, i.e. the mutual overlaps $\gamma_{ij} = \langle \phi_i | \phi_j \rangle$ and the occurrence probabilities $\{\eta_i\}$. The second one on the other hand is defined as a diagonal density matrix $\eta_p$ with the diagonal entries given by the probabilities $\{\eta_i\}$ with the ordering induced by the permutation $p$ of the probabilities. When the set $\Phi$ can be discriminated unambiguously with probability one then $\rho_x \rightarrow \eta_p$. On the other hand if the set lacks its independency and cannot be discriminated anymore the distinguishability of the pair, measured by the fidelity $F(\rho_x, \eta_p)$, becomes minimum. This enables one to associate to each discrimination problem $\Phi$ a unique distinguishability problem between two states $\rho_x$ and $\eta_p$, and define the maximum fidelity between them (maximum over all permutations of the probabilities $\{\eta_i\}$) as the extent to which the set is discriminable. Calculating this quantity does not require any optimization and we study its behaviour with some examples.

I. INTRODUCTION

Quantum mechanics has brought many surprising results in recent decades. One of the fundamental consequences of quantum mechanics is about superposition principle for quantum states. According to this principle there must exist nonorthogonal states with nonzero overlap which results in that there is no way to determine them with certainty. From the principles of quantum mechanics, we know that the information is encoded in the state of the quantum systems. Therefore discrimination of quantum states is an essential problem in quantum information theory, especially in quantum communication [1] [2] and quantum cryptography [3].

In quantum state discrimination, the task is to determine the best measurement for detecting the correct states from a set of given states [4]. In general, there are two schemes for discriminating among states, minimum-error discrimination and unambiguous state discrimination. In minimum-error scheme there is always an answer with a non-zero probability of wrong detection. In this strategy the task is to minimize the probability of occurring error [2] [3]. Some examples for which explicit results are known include symmetric states with equal a priori probability [3], three mirror symmetric qubit states [2] [8] and discrimination between subsets of linearly dependent quantum states [9].

The other approach, which is known as unambiguous discrimination of quantum states, had been first introduced by Ivanovic [10], Peres [11] and Dieks [12]. In this method, if the output $i$ corresponding to the state $\rho_i$ is detected by a receiver, one can claim with certainty that the state is $\rho_i$; however, for nonorthogonal states, there is always a non-zero probability for failure in detection of state and the condition may be applied is to minimize this failure probability. They showed that for two arbitrary states $|\phi_1\rangle$ and $|\phi_2\rangle$ with equal a priori probability, the optimized probability of success is given by

$$P_{\text{success}} = 1 - |\langle \phi_1 | \phi_2 \rangle|,$$

Finding an analytical solution for more than two pure states is not easy. In 1998, Cheffes has shown that a set of pure states can be unambiguously discriminated if and only if they are linearly independent [14]. Moreover, he has established the conditions on POVM elements which describe an unambiguous state discrimination and showed that any unambiguous discrimination of $N$ states consists of $N + 1$ POVM elements $\{E_k\}_{k=1}^{N}$ such that $\{E_k\}_{k=1}^{N}$ is required for $N$ pure states $\{|\phi_k\rangle\}_{k=1}^{N}$ and $E_0$ for the inconclusive result. One of the problems solved analytically is symmetric set with equal probabilities [13]. After that, Elder showed that the problem of finding an optimal measurement can be formulated as a semidefinite programming problem [15] [17]. In [18], the authors have studied the problem of optimum unambiguous discrimination of $n$ linearly independent pure states and have derived some analytical properties of the optimum solution. The problem of finding the set of quantum states that can be deterministically discriminated is analyzed by Markham et al. [19]. From a geometric point of view, they have shown that this problem is equivalent to that of embedding a simplex of points whose distances are maximal with respect to the Bures distance or trace distance.

Since unambiguous discrimination is possible only when the states are linearly independent, for other cases that the states are linearly dependent there is another strategy which is called maximum confidence measurements [20]. This strategy allows us to be as confident
as possible that when the outcome of measurement leads us to identify a given state \( \rho_i \), that was indeed the state prepared. As a result, for linearly independent states this strategy becomes unambiguous state discrimination.

In this paper, we follow the problem of quantum state discrimination from a geometrical approach. For this purpose, we consider a set of linearly independent but not necessarily orthogonal states \( \{ |\phi_i \rangle \} \), with the prior probabilities \( \{ \eta_i \} \), and construct a linear invertible transformation \( T_{\eta_p}^c \) that transforms the original nonorthogonal set to the orthogonal set \( \{ \sqrt{\eta_i} |e_i \rangle \} \). The elements of this transformation matrix are expressed in terms of the mutual overlaps \( \gamma_{ij} = \langle \phi_i | \phi_j \rangle \) and the occurrence probabilities \( \eta_i \). This transformation matrix can be used to provide a POVM measurement for the unambiguous discrimination problem. We then show that although construction of such transformation matrix is not unique, it provides, up to a permutation of the probabilities \( \eta_i \), a unique pair of density matrices \( \rho_x \) and \( \eta_p \). This pair enables one to associate to each problem of discrimination of a set of \( N \) pure states the corresponding problem of distinguishability of two density matrices defined on the \( N \)-dimensional Hilbert space \( \mathcal{H}_N \). By using the notion of fidelity as a measure of distinguishability of the two density matrices \( \rho_x \) and \( \eta_p \), we define the notion of discrimbinability of the set of \( N \) pure states \( \{ |\phi_i \rangle \} \) with the prior probability \( \{ \eta_i \} \).

The organization of the paper is as follows. In section II, we construct the linear invertible operator \( T_{\eta_p}^c \) and define unambiguous discrimination detectors by using this operator. In section III, we associate to each discrimination problem a corresponding distinguishability problem. In this section we also provide a parametrization for a generic density matrix. Section IV is devoted to introduce the notion of discrimbinability and investigate its properties. We examine this notion by providing some examples. The paper is concluded in section V with a brief discussion.

II. UNAMBIGUOUS QUANTUM STATE DISCRIMINATION

Let \( \Phi = \{ |\phi_i \rangle \}_{i=1}^N \) denotes a set of linearly independent and normalized but not necessary orthogonal states. For such set one can define the dual (reciprocal) set \( \tilde{\Phi} = \{ |\tilde{\phi}_i \rangle \}_{i=1}^N \) in such a way that [21]

\[
\langle \tilde{\phi}_i | \phi_j \rangle = \delta_{ij}.
\]  

(2)

Evidently, both sets span the same subspace \( V \), i.e. \( V = \text{span}\{ |\phi_i \rangle \} = \text{span}\{ |\tilde{\phi}_i \rangle \} \). Now consider a discrimination problem consisting of a quantum system prepared in one of the states of the set \( \Phi \) with associated nonzero probability \( \{ \eta_i \}_{i=1}^N \). For simplicity, we denote such discrimination problem by \( \Phi_{\eta} \). Let also \( \{ |e_i \rangle \}_{i=1}^N \) serves an orthonormal basis for \( V \). For such orthonormal basis \( \{ |e_i \rangle \}_{i=1}^N \) and the discrimination problem \( \Phi_{\eta} \), one can define a linear invertible transformation \( T_{\eta_p}^c \) such that

\[
T_{\eta_p}^c |\phi_i \rangle = \sqrt{\eta_i} |e_i \rangle,
\]  

(3)

where \( p = \{ p_1, \ldots, p_N \} \) is any permutation of \( \{1, \ldots, N\} \). Indeed, for an orthonormal basis \( \{ |e_i \rangle \}_{i=1}^N \) and linearly independent vectors \( \{ |\phi_i \rangle \}_{i=1}^N \) with associated probability \( \{ \eta_i \}_{i=1}^N \), the linear transformation \( T_{\eta_p}^c \) is unique up to a permutation over the set \( \{ \eta_i \}_{i=1}^N \). More precisely

\[
T_{\eta_p}^c = \sum_{i=1}^N \sqrt{\eta_i} |e_i \rangle \langle \phi_i |,
\]  

(4)

\[
T_{\eta_p}^{-1} = \sum_{i=1}^N \frac{1}{\sqrt{\eta_i}} |\phi_i \rangle \langle e_i |.
\]  

(5)

Defining \( T_{\eta_p}^{-1} \) as Hermitian conjugate of \( T_{\eta_p}^c \), one can easily see that the linear transformation

\[
T_{\eta_p}^{-1} T_{\eta_p}^c = \sum_{i=1}^N \eta_i |\phi_i \rangle \langle \phi_i |,
\]  

(6)

transforms the linearly independent set \( \Phi \) to its corresponding dual set \( \tilde{\Phi} \), i.e.

\[
T_{\eta_p}^{-1} T_{\eta_p}^c |\phi_k \rangle = \eta_k |\phi_k \rangle,
\]  

(7)

for \( k = 1, 2, \ldots, N \). More interestingly

\[
\langle \phi_l | T_{\eta_p}^{-1} T_{\eta_p}^c |\phi_k \rangle = \eta_{lk} \delta_{lk},
\]  

(8)

which can be used to define the positive operators

\[
E_k = x_{pk} \eta_{pk} |\tilde{\phi}_k \rangle \langle \tilde{\phi}_k | = x_{pk} T_{\eta_p}^{-1} T_{\eta_p}^c |\phi_k \rangle \langle \phi_k | T_{\eta_p}^{-1} T_{\eta_p}^c ,
\]  

(9)

with the following property

\[
\langle \phi_l | E_k |\phi_l \rangle = 0 \text{ for } k \neq l.
\]  

(10)

Using the above structure for \( E_k \), one can construct a POVM measurement for unambiguous discrimination. To this end, we need an extra element \( E_0 \) as

\[
E_0 = I - \sum_{k=1}^N E_k.
\]  

(11)

In order to maximize the rate of success probability, we have to increase \( x_{pk} \) as large as possible with the restriction that \( E_0 \) remains positive. Although in our terminology the optimal value of \( x_{pk} \) depends, in general, on the particular permutation we have chosen, it is not the case for \( \tilde{x}_k = x_{pk} \eta_{pk}^{-2} \) and therefore for the optimal measurement \( E_k \).

Note that a quantity similar to Eq. (9), but the success probabilities replaced by the priori probabilities, is introduced in [18]. However, despite they are similar in form, they will be different in spirit in a sense that \( T_{\eta_p}^{-1} T_{\eta_p}^c \) is
completely defined as soon as we define the discrimination problem \(\Phi_\eta\), i.e. the set \(\Phi = \{|\phi_i\rangle\}\) and its associated priori probabilities \(\{\eta_i\}\), but the quantity defined in Ref. 13 includes the unknown success probabilities that we are looking for. Notably, the operator \(T^e_{\eta_p}\) plays a central role in the unambiguous discrimination of the set \(\Phi\). Indeed, if we perform a unitary transformation \(V\) on the vectors of the set \(\Phi\) and transform it to the new set \(\Phi' = \{|V\phi_i\rangle\}\), the success probability of the discrimination is not affected under such operation. In the light of this the corresponding POVM for \(\Phi'\) is obtained just by applying the unitary transformation \(V\) on the original POVM, i.e. \(E_k \to VE_kV^\dagger\), which is obtained by changing \(T^e_{\eta_p} \to T^e_{\eta_p}V^\dagger\), so that \(T^e_{\eta_p}T^e_{\eta_p} \to VT^e_{\eta_p}T^e_{\eta_p}V^\dagger\). This simple result has an important consequence revealing the importance of the unitary invariants of \(T^e_{\eta_p}T^e_{\eta_p}\). We then arrive at the following lemma

**Lemma 1** Suppose a quantum system prepared in one of the states of the set \(\Phi\) with associated probabilities \(\{\eta_i\}_{i=1}^N\). Then the success probability of the discrimination of the set is a function of the unitary invariants of the linear transformation \(T^e_{\eta_p}T^e_{\eta_p}\), where \(T^e_{\eta_p}\) is defined in Eq. (3).

In what follows, we turn our attention to the simplest case \(N = 2\). For a given two linearly independent pure states \(|\phi_1\rangle\) and \(|\phi_2\rangle\) with the prior probabilities \(\eta_1\) and \(\eta_2\), respectively, one can use the familiar Gram-Schmidt procedure ²² to construct a specific orthonormal basis \(|e_1\rangle\) and \(|e_2\rangle\) as

\[|e_1\rangle = |\phi_1\rangle, \quad |e_2\rangle = -\gamma|\phi_1\rangle + |\phi_2\rangle \frac{\sqrt{1 - |\gamma|^2}}{\sqrt{1 - |\gamma|^2}},\]  

(12)

where \(\gamma = \langle\phi_1|\phi_2\rangle\). Using this orthonormal basis, we can represent \(|\phi_1\rangle\) and \(|\phi_2\rangle\) as

\[|\phi_1\rangle = |e_1\rangle, \quad |\phi_2\rangle = \gamma|e_1\rangle + \sqrt{1 - |\gamma|^2}|e_2\rangle.\]  

(13)

One can also express the dual set \(\tilde{\Phi} = \{|\tilde{\phi}_1\rangle, |\tilde{\phi}_2\rangle\}\) as

\[|\tilde{\phi}_1\rangle = |e_1\rangle - \frac{\gamma^*}{\sqrt{1 - |\gamma|^2}}|e_2\rangle, \quad |\tilde{\phi}_2\rangle = \frac{1}{\sqrt{1 - |\gamma|^2}}|e_2\rangle.\]  

(14)

In this orthonormal basis \(\{|e_1\rangle, |e_2\rangle\}\), \(T^e_{\eta_p}\) is represented as \(T^e_{\eta_p}|e_i\rangle = \sqrt{\eta_i}|\tilde{\phi}_i\rangle\), so that for a particular permutation \(\eta = \text{diag}\{\eta_1, \eta_2\}\), we find

\[T^e_{\eta} = \begin{pmatrix} \sqrt{\eta_1} & \frac{-\gamma\sqrt{\eta_2}}{\sqrt{1 - |\gamma|^2}} \\ 0 & \frac{\gamma\sqrt{\eta_2}}{\sqrt{1 - |\gamma|^2}} \end{pmatrix}.\]  

(15)

The corresponding unitary invariants related to the above upper triangular matrix are \(I_1 = \text{Tr}[T^e_{\eta_p}T^e_{\eta_p}^\dagger] = \frac{1}{1 - |\gamma|^2}\) and \(I_2 = \text{Tr}[T^e_{\eta_p}T^e_{\eta_p}^\dagger]^2 = \frac{1}{(1 - |\gamma|^2)^2} - \frac{2\gamma^2\eta_2}{1 - |\gamma|^2}\).

### III. DISCRIMINATION AND THE QUANTUM STATES PARAMETRIZATION

As we see in the previous section, the operator \(T^e_{\eta_p}\) transforms the linearly independent set of states \(\Phi = \{|\phi_i\rangle\}_{i=1}^N\) to an orthonormal basis \(\{|e_i\rangle\}_{i=1}^N\). Using the standard Gram-Schmidt process, one can construct this particular basis in such a way that \(T^e_{\eta_p}\) takes an upper triangular matrix representation \(22\). However, \(\{|e_i\rangle\}_{i=1}^N\) does not provide an arbitrary basis obtained from \(\Phi\). Indeed, starting from a given linearly independent set \(\Phi\) and for an arbitrary unitary operator \(U\), we can obtain an arbitrary orthonormal basis \(\{|u_i\rangle = U\{|e_i\rangle\}_{i=1}^N\}\) by means of the invertible transformation \(T^u_{\eta_p} = UT^e_{\eta_p}U^\dagger\), i.e.

\[T^u_{\eta_p}|\phi_i\rangle = \sqrt{\eta_i}|u_i\rangle.\]  

(16)

Looking at Eqs. (3) and (16), one can see that if the original set \(\Phi\) be orthonormal, i.e. \(|\phi_i\rangle = |e_i\rangle\) for \(i = 1, \cdots, N\), then the upper triangular matrix \(T^u_{\eta_p}\) becomes a diagonal matrix

\[T^e_{\eta_p} \to \eta P = \sum_{i=1}^N \eta_i|e_i\rangle\langle e_i|,\]  

(17)

where \(\eta P = \text{diag}\{\eta_1, \cdots, \eta_n\}\) is a diagonal density matrix in the orthonormal basis \(\{|e_i\rangle\}\). In this case although \(T^u_{\eta_p} = U\sqrt{\eta P}\) takes a nondiagonal form with matrix elements \(\langle T^u_{\eta_p}\rangle_{ij} = \sqrt{\eta_j}\langle e_i|U|e_j\rangle\), the positive matrix \(T^u_{\eta_p}T^u_{\eta_p}\) is still diagonal and equal to \(\eta P\). Motivated by this, we define the projection map \(\Pi\) and associate to each linear transformation \(T\) a density matrix \(\rho_T\) as

\[\Pi : T \rightarrow \frac{T}{\text{Tr}[T^\dagger T]} \rightarrow \rho_T = \frac{T^\dagger T}{\text{Tr}[T^\dagger T]}.\]  

(18)

Clearly, the above map results in the same state \(\rho_T\), if we change \(T \to T' = UT\) for an arbitrary unitary transformation \(U\).

To fix our terminology, suppose \(\mathcal{F}\) represents the set of all linear transformations \(T^e_{\eta_p}\) that construct a general orthonormal basis \(\{|u_i\rangle\}\) from an arbitrary discrimination problem \(\Phi_\eta\), following the route of Eq. (16). Suppose also that \(\mathcal{M}\) consists of all density matrices \(\rho_T\) that can be obtained by applying the map \(\Pi\) on all transformations \(T^e_{\eta_p} \in \mathcal{F}\). For the sake of simplicity we drop all the indices and use the simplified notation \(\rho_T\) for the states associated to the transformations \(T^e_{\eta_p}\), but it is clear that \(\rho_T\) depends both on the parameters of the discrimination problem and also on the particular permutation \(p\). Since by definition \(\mathcal{F}\) consists of invertible transformations, the elements of \(\mathcal{M}\) are full rank density matrices defined on the \(N\)-dimensional Hilbert space \(\mathcal{H}_N\). With this terminology, the map \(\Pi\) can be regarded as the bundle projection map, \(\Pi : \mathcal{F} \rightarrow \mathcal{M}\), with \(\mathcal{M}\) as the base space and \(\mathcal{F}\) as the bundle space. This enables one to construct a fiber bundle structure such that the set of all
transformations $T_{\eta_p}^u$ that project to the same state $\rho_T$ is considered as the fiber over $\rho_T$. On the other hand, as we have mentioned previously, if the original set $\Phi$ be orthonormal then $T_{\eta_p}^u \to \sqrt{\eta_p}$, so that to each fiber $T_{\eta_p}^u \in F$ over $\rho_T \in M$ we associate the corresponding fiber $\sqrt{\eta_p} \in F$ whose projection down to the diagonal state $\eta_p \in M$.

Note that parameterizing quantum states using a map similar to Eq. (18) was also considered already. Obviously, different parametrization of $T$ leads to different parametrization of quantum state $\rho_T$. Very recently, the authors of [23] defined $T$ as a nonzero Hermitian matrix parameterized by a real $(N^2 - 1)$-dimensional vector, and introduced a parametrization of quantum states. The essence of our method is that the matrix $T$ naturally parameterized in terms of the $N^2 - 1$ real parameters of the discrimination problem: the $N(N - 1)/2$ complex parameters $\gamma_{ij} = \langle \phi_i | \phi_j \rangle$ provided by the mutual overlap of the states to be discriminated, and the rest $N - 1$ real parameters given by the prior probabilities $\{\eta_i\}_{i=1}^N$ (recalling the normalization condition $\sum_{i=1}^N \eta_i = 1$).

IV. QUANTUM STATE DISCRIMINABILITY

In the previous section we show that to each discrimination problem $\Phi_\eta$, consisting of $N$ linearly independent pure quantum states $\Phi = \{ \rho_i \}$ and the corresponding occurrence probabilities $\eta = \{ \eta_i \}$, one can associate, up to a permutation over the probabilities $\{ \eta_i \}$, a unique pair of density matrices $\rho_T$ and $\eta_p$ defined on the $N$-dimensional Hilbert space $H_N$. This pair of states is obtained from projection of the pair of operators $T_{\eta_p}^u$ and $\sqrt{\eta_p}$, respectively, following the route of map $F$. Clearly, if the set is completely discriminable these operators are equal, up to unitary transformation, however, any deviation from perfect discriminability makes them different in nature. Motivated by this, we define the distance between two states $\rho_T$ and $\eta_p$ as the length of the shortest path between two operators $T_{\eta_p}^u$ and $\sqrt{\eta_p}$. The squared Hilbert-Schmidt distance of $T_{\eta_p}^u$ and $\sqrt{\eta_p}$ gives us

$$D_B^2 (\rho_T, \eta_p) = \min_U \left\| \frac{U T_{\eta_p}^u}{\sqrt{\det [T_{\eta_p}^u T_{\eta_p}^u]}} - \sqrt{\eta_p} \right\|_2^2$$

$$= 2 - \frac{1}{2} F(\rho_T, \eta_p),$$

where

$$F(\rho_T, \eta_p) = \left( \frac{\eta_1 (1 - |\gamma|^2) - \gamma \eta_1 \sqrt{1 - |\gamma|^2}}{\eta_1 |\gamma|^2 + \eta_2} \right).$$

This relation gives us the distance between $\rho_T$ and $\eta_p$. By construction, $D_B(\rho_T, \eta_p)$ is nothing but the Bures distance between $\rho_T$ and $\eta_p$. We can also define the Bures angle $D_A(\rho_T, \eta_p)$ by $\cos D_A(\rho_T, \eta_p) = F(\rho_T, \eta_p)$. If the original set $\Phi$ be orthonormal, then $\rho_T = \eta_p$, and we get $F(\rho_T, \eta_p) = 1$. Note that for a given discrimination problem $\Phi_\eta$, both associated density matrices $\rho_T$ and $\eta_p$ are unique up to a permutation over the set of the prior probabilities $\{\eta_i\}_{i=1}^N$. Having this in mind, we define the following quantity as a measure of how and in what extent the set $\Phi_\eta = \{ |\phi_i\rangle \}_{i=1}^N$ is discriminable

$$D(\Phi_\eta) = \max_p F(\rho_T, \eta_p),$$

where $\max_p$ is taken over all permutations $p = \{p_1, \ldots, p_N\}$ of $\{1, \ldots, N\}$, recalling that $\rho_T$ is also dependent on the permutation $p$. For a given set $\{\phi_i\}$, the discriminability $D(\Phi_\eta)$ reaches its minimum value if and only if $\eta_i = \frac{1}{N}$ for $i = 1, \ldots, N$. In this case we have

$$D(\Phi_\eta = \frac{1}{N}) = \min \{ D(\Phi_\eta) = \frac{1}{N} \left[ \text{Tr} \sqrt{\eta_p} \right]^2 \}.$$  

Using this and the fact that $\text{Tr} \sqrt{\eta_p} \geq \text{Tr} \rho_T \geq 1$, we find that $\frac{1}{N} \leq D(\Phi_\eta) \leq 1$. The lower bound $D(\Phi_\eta) = \frac{1}{N}$ is attained if and only if the set becomes dependent. On the other hand the full discriminability, i.e. $D(\Phi_\eta) = 1$, happens if and only if the set $\Phi$ be an orthonormal set, i.e. if and only if the set can be discriminated unambiguously with probability one. Furthermore $D(\Phi_\eta)$ is invariant under any unitary transformation $V$ performed on the set $\Phi$, i.e. $D(\Phi_\eta) = D(\Phi_{V \Phi})$. To see this note that the associate density matrix $\rho_T$ is expressed in terms of the overlap parameters $\gamma_{ij} = \langle \phi_i | \phi_j \rangle$ and the probabilities $\{\eta_i\}$, both are invariant under such transformations. Another way to see this is the use of the fact the associated pair of density matrices $\rho_T$ and $\eta_p$ transform as $\rho_T \to V \rho_T V^\dagger$ and $\eta_p \to V \eta_p V^\dagger$ under such transformation, but this leaves the fidelity between them invariant. In the following we provide some examples and compare the success probability $P_{\text{success}}$ with the normalized discriminability, i.e. $(N D(\Phi_\eta) - 1)/(N - 1)$.

A. Two pure states

For the case with two pure states, using Eq. (18), one can obtain

$$\rho_T = \begin{pmatrix} \eta_1 (1 - |\gamma|^2) & -\gamma \eta_1 \sqrt{1 - |\gamma|^2} \\ -\gamma^* \eta_1 \sqrt{1 - |\gamma|^2} & \eta_1 |\gamma|^2 + \eta_2 \end{pmatrix},$$

In this case using $F(\rho_1, \rho_2) = \text{Tr} \rho_1 \rho_2 + 2 \sqrt{\det \rho_1 \det \rho_2}$ we get $F(\rho_T, \eta_p) = \eta_1^2 + \eta_2^2 + 2 \eta_1 \eta_2 \sqrt{1 - |\gamma|^2}$, we arrive at the following relation for the discriminability of two pure states

$$D(\Phi_\eta) = \eta_1^2 + \eta_2^2 + 2 \eta_1 \eta_2 \sqrt{1 - |\gamma|^2}$$

where $\eta_{\text{min}} = \min \{ \eta_1, \eta_2 \}$. For the case with equal prior probabilities $\eta_1 = \eta_2 = \frac{1}{2}$, this quantity becomes

$$D(\Phi_\eta = \frac{1}{2}) = \frac{1}{2} (1 + \sqrt{1 - |\gamma|^2}).$$
ties reach to their common lowest value at the same point in minimum-error discrimination. As a result, two quanti-
tication in minimum-error discrimination [2]. Figure 1 compares the plot of (2
which is, surprisingly, equal to the probability of cor-
rect in minimum-error discrimination [2]. Figure 1 compares the plot of (2D(\Phi_\eta) - 1) with IDP limit [1]. For general case with unequal probabilities, we compare
discriminability D(\Phi_\eta) with probability of correction in minimum-error discrimination. As a result, two quanti-
ties reach to their common lowest value at the same point \eta = \frac{1}{2}. Moreover, discriminability has been decreased by
increasing the overlap parameter \gamma (Fig 2).

B. Three Pure States

In order to further proceed with an example of three pure states, let us first present a procedure to find the
matrix T^N_{\eta_p} for an arbitrary N pure states. For simplicity, we temporary change our notation and use
T^N(\Phi_\eta) as a linear invertible transformation that construct
the orthonormal set \{|e_i\} from a priori nonorthogonal linearly independent set \{|\phi_i\}, via the Gram-Schmidt
procedure

\[ T^N(\phi_i) = |e_i\rangle, \quad \text{for} \ i = 1, \cdots, N. \]  

(26)

Let \( a_{ni}, \) for \( i = 1, \cdots, n \) and \( n = 1, \cdots, N, \) denote the coefficients of the expansion of \(|\phi_n\rangle\) in terms of the above
orthonormal basis, i.e. \( |\phi_n\rangle = \sum_{i=1}^{n} a_{ni} |e_i\rangle, \) where \( a_{nn} = \sqrt{1 - \sum_{i=1}^{n-1} |a_{ni}|^2} \) guaranties the normalization of \(|\phi_n\rangle\). We then have an explicit relation for \( T^N(\Phi_\eta) \) in terms of
\( T^{N-1}(\Phi_\eta) \) as

\[ T^{(N)} = \begin{pmatrix} T^{(N-1)} & O \\ O^t & 1/a_{NN} \end{pmatrix}, \]  

(27)

Here, \( O = (0, \cdots, 0)^t \) denotes an \( (N-1) \)-components zero vector, \( O^t \) is its transpose, and \( 1_{N-1} \) is the unit matrix with dimension \( N-1 \). Moreover \( A^{(N-1)} \) is an \( (N-1) \)-components vector defined by
\( A^{(N-1)} = (-a_{N,1}, -a_{N,2}, \cdots, -a_{N,N-1})^t/a_{N,N} \). Recalling that for \( N = 2 \) we have

\[ T^{(2)} = \begin{pmatrix} 1 & -\gamma_{12} \sqrt{1-|\gamma_{12}|^2} \\ 0 & \sqrt{1-|\gamma_{12}|^2} \end{pmatrix}, \]  

(28)

with \( \gamma_{12} = \langle \phi_1 | \phi_2 \rangle \), the above equation allows us to obtain
\( T^{(N)} \) for an arbitrary value of \( N \). Now, having \( T^{(N)} \) for an arbitrary \( N \), one can simply obtain the matrix \( T^{p^*}_{\eta_p} \) by
\( T^{p^*}_{\eta_p} = \eta_p T^{(N)}. \)

Turning our attention to the case of three pure states, i.e. \( N = 3 \), we get

\[ T^{(3)} = \begin{pmatrix} 1 & \gamma_{12} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \\ 0 & \gamma_{21} \gamma_{23} - \gamma_{21} \gamma_{13} \sqrt{1-|\gamma_{21}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \\ 0 & \gamma_{23} \gamma_{21} \gamma_{13} \sqrt{1-|\gamma_{23}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \gamma_{23} - \gamma_{13} \sqrt{1-|\gamma_{12}|^2} \end{pmatrix}, \]  

(29)

where \( a_{23} = (\gamma_{23} - \gamma_{21} \gamma_{13})/\sqrt{1-|\gamma_{23}|^2}. \) We continue with our three pure states for the particular case that all
\( \gamma_{ij} \) are real, so that \( \gamma_{12} = \cos \alpha, \gamma_{13} = \cos \phi \sin \theta, \) and
\( \gamma_{23} = \sin \theta \cos (\alpha - \phi). \) By setting \( \alpha = \pi/3 \) and \( \phi = \pi/4, \) we can provide a comparison between the discriminabil-
ity and the probability of success [25] for the case with equal prior probabilities. This comparison shows a great
consistency between two quantities (Fig. 3).
V. CONCLUSION

By starting from a given set of linearly independent nonorthogonal states \( \{|\phi_i\rangle\} \), with the corresponding prior probabilities \( \{\eta_i\} \), we could obtain a set of orthogonal states \( \{|e_i\rangle\} \). To this aim, we define the invertible transformation matrix \( T_{\eta p} \) which is not unique in the sense that it defines the orthonormal basis \( \{|e_i\rangle\} \) up to a unitary transformation. Moreover, it is also far from uniqueness to the extent of a permutation of the prior probabilities \( \{\eta_i\} \). However, this transformation allows us to associate to each nonorthogonal set \( \{|\phi_i\rangle\} \) and the corresponding prior probabilities \( \{\eta_i\} \) a unique pair of density matrices \( \rho_r \) and \( \eta_p \) up to a permutation over the probabilities \( \{\eta_i\} \). This pair of density matrices inherits all the information about the nonorthogonal states \( \{|\phi_i\rangle\} \) and their corresponding probabilities \( \{\eta_i\} \). In particular, the fidelity \( F(\rho_r, \eta_p) \) can be used to measure in what extent the states are distinguishable, taking into account their relative probabilities. We use this notion and define a quantity called discriminability which shows the possibility of discrimination among a set of quantum states.

The existence of nonorthogonal states could be responsible for some nonclassicalities such as quantum discord \([26, 27]\), no-cloning theorem \([28, 29]\) and no-local-broadcasting \([30]\) which have widespread applications in quantum information theory. The approach presented in this paper associates a distinguishability problem to each discrimination problem. We hope the method presented in this work should shed some light on the similar situations which we deal with quantum properties arising from nonorthogonality.
