THE CLASS OF A FIBRE IN NONCOMMUTATIVE GEOMETRY

HEATH EMERSON

Abstract. This note addresses the K-homology of a C*-algebra crossed product of a discrete group acting smoothly on a manifold, with the goal of better understanding its noncommutative geometry. The Baum-Connes apparatus is the main tool. Examples suggest that the correct notion of the ‘Dirac class’ of such a noncommutative space is the image under the equivalence determined by Baum-Connes of the fibre of the canonical fibration of the Borel space associated to the action, and a smooth model for the classifying space of the group. We give a systematic study of such fibre, or ‘Dirac classes,’ with applications to the construction of interesting spectral triples, and computation of their K-theory functionals, and we prove in particular that both the well-known deformation of the Dolbeault operator on the noncommutative torus, and the class of the boundary extension of a hyperbolic group, are both Dirac classes in this sense and therefore can be treated topologically in the same way.

1. Introduction

The purpose of this article is to use the Baum-Connes apparatus to shed some light on the noncommutative geometry of some examples of C*-algebras that probably deserve to be thought of as ‘noncommutative manifolds,’ since they are canonically KK-equivalent to classical manifolds.

We do this by fixing a definition of a class in the K-homology of a crossed-product \( C_0(X) \rtimes \Gamma \) of a smooth action by a discrete group which we call the Dirac class of the action, and which is determined by the K-homology class of a fibre in the natural fibration \( p: ET \times_{\Gamma} X \to B\Gamma \) and the Dirac map involved in the Baum-Connes apparatus. This makes the Dirac class dependent on not only the action, but on aspects of the group itself including, in a certain sense, its coarse geometry. Our class differs from the transverse Dirac classes studied by A. Connes and others, which is, roughly speaking, invariant under the whole diffeomorphism group of the manifold, and doesn’t really involve the group as such.

We use this set-up to prove that the boundary extension of a classical hyperbolic group acting on its sphere at infinity, and the deformed Dolbeault spectral triple over the irrational rotation algebra of Connes, are, at the level of K-homology, instances of the same same construction: they are each Dirac classes for the respective actions.

We also deduce an index theorem for Dirac classes, which computes the K-theory functional determined by a Dirac class, in terms of topological data (the intersection index of a Baum-Douglas cycle with a fibre.) When specialized to either the boundary extension of a hyperbolic group, where it computes the boundary map on K-theory, or the irrational rotation situation, the resulting index formulas seem quite promising.

We now explain of all of this in more detail.

The Baum-Connes conjecture [3] seeks to reduce the analytic problem of computing the K-theory groups of a crossed-product \( C_0(X) \rtimes \Gamma \) to topology (by and large we work with the max crossed-product in this paper, as it is functorial, and since most of the actions we consider specifically are amenable.) In the work of Meyer and Nest, following a tradition initiated by Kasparov, Lusztig, Higson and others, it is shown that to \( \Gamma \) one can associate a proper \( \Gamma \)-C*-algebra \( \mathcal{P} \) and a Kasparov morphism \( D \in KK^\Gamma(\mathcal{P}, \mathbb{C}) \) (the ‘Dirac morphism’) with the property that the forgetful map \( KK^\Gamma \to KK^H \) maps \( D \) to an equivalence, for any finite subgroup \( H \) of \( \Gamma \). This condition determines \( D \). External product in \( KK^\Gamma \) gives a map

\[
KK^\Gamma(A, B) \to KK^\Gamma(\mathcal{P} \otimes A, B)
\]

for any \( \Gamma \)-C*-algebras \( A, B \), and the co-domain of this map is of a purely topological nature because it is isomorphic to \( RKK^\Gamma(\mathcal{E}\Gamma; A, B) \) by an important Poincaré duality theorem of Kasparov [33].

The C*-algebra \( \mathcal{P} \) and the morphism \( D \) are not always easy to represent concretely. In this paper, we assume that \( \mathcal{E}\Gamma \) can be modelled by a smooth, co-compact, equivariantly K-oriented manifold \( Z \). This covers the case of \( \mathbb{Z}^d \) actions, and most actions of discrete subgroups of semisimple Lie groups. The hypothesis implies that we can take \( \mathcal{P} := C_0(Z) \) and \( D := [Z] \in KK^\Gamma_{-d}(C_0(Z), \mathbb{C}) \) the class of the \( \Gamma \)-equivariant Dirac operator on \( Z \). The assumptions are satisfied by, for example, fundamental groups \( \Gamma = \pi_1(M) \) of compact, oriented, aspherical, spinc-manifolds, taking \( Z := M \) with its lifted \( \Gamma \)-equivariant K-orientation.
The geometric content of the Dirac map starts to appear if one puts $A = B = \mathbb{C}$ and $\Gamma = \mathbb{Z}^d$. The domain of the Dirac map is $KK^2_{\mathbb{C}}(\mathbb{C}, \mathbb{C}) \cong KK_*(C(T^d), \mathbb{C})$ and the co-domain is $KK^2_{\mathbb{C}}(C_0(\mathbb{R}^d), \mathbb{C}) \cong KK_*(C_0(\mathbb{R}^d/\mathbb{Z}^d), \mathbb{C}) = KK_*(C(T^d), \mathbb{C})$ where $T^d := \mathbb{R}^d/\mathbb{Z}^d$ and $\hat{T}^d$ is by definition the ‘dual’ torus. The Dirac map therefore is a map
\begin{equation}
(1.2) \quad K_*(\hat{T}^d) \to K_{*+d}(T^d),
\end{equation}
and it is not difficult to compute that it is precisely the well-known Fourier-Muñiz transform, implemented by composing cohomology cycles with the smooth correspondence
\[ T^d \leftarrow (T^d \times \hat{T}^d, \beta) \to \hat{T}^d, \]
from $T^d$ to the dual torus $\hat{T}^d$, where $\beta$ is the Mischenko-Poincaré element, and the maps are the projection maps. Furthermore, as we show, it has an interesting effect on Baum-Douglas K-homology, for it interchanges (the K-homology class of) a $j$-dimensional subtorus in $\hat{T}^d$ to (the class of a) certain canonical $d - j$-dimensional ‘dual’ torus in $T^d$. It was this observation that first made the author want to study the Dirac map more closely, and especially for actions.

If $A = C_0(X)$, for a $\Gamma$-space $X$, and $B = \mathbb{C}$, the Dirac map looks like
\[ [Z] \otimes_C \cdot : KK^1_*(C_0(X), \mathbb{C}) \to KK^1_{*-d}(C_0(Z \times X), \mathbb{C}) \]
and the domain is the K-homology of the crossed-product $C_0(X) \rtimes \Gamma$, while the co-domain, if $\Gamma$ is torsion-free, is naturally isomorphic to $K_{d-*}(Z \times_\Gamma X)$ – the K-homology of the ‘Borel space’ $Z \times_\Gamma X$, which fibres over $\Gamma \\backslash Z \cong B\Gamma$, with fibre $X$. The Dirac map shifts degrees by $-d$.

We define a Dirac class for groups with torsion, but in the torsion-free case, the Dirac class is any class in $K^{d-n}_{*}(C_0(X) \rtimes \Gamma)$ mapped by the Dirac map to the Baum-Douglas K-homology class of the fibre $X$: a spin$^c$-manifold mapping (properly) to $Z \times_\Gamma X$, by including it as a fibre.

This definition does not guarantee that a Dirac class exists, nor that it is unique, because the localization map is neither onto nor 1-1 in general. However, if $\Gamma$ has a dual-Dirac morphism, then the Dirac map can be split, yielding a existence result about Dirac classes (although still not uniqueness). It is this method which, when applied to isometric actions of nice discrete groups $\Gamma$ (like $\mathbb{Z}^d$), leads to spectral triple representations of the Dirac class by spectral triples over $C_0(X) \rtimes \Gamma$, whose general format, of the Schrödinger kind, $D + \delta$, with $\delta$ an operator on the group $\Gamma$, $D$ the Dirac operator on $X$, are somewhat similar to the ones appearing [20] (for $\Gamma = \mathbb{Z}^d$). When $\mathbb{Z}$ acts by irrational rotation on the circle, the Dirac class is represented by the famous spectral triple (the deformed Dolbeault operator $\bar{\theta}$ over $A_\theta$ first defined by A. Connes (see [16]).

Actions of discrete (co-compact) groups of Möbius transformations $\Gamma \subset SL_2(\mathbb{R})$ on the circle $\mathbb{T}$ are smooth actions preserving a K-orientation; they are special classes of broader classes of hyperbolic groups acting on their boundaries. These examples cannot be treated like isometric actions as in the previous paragraph, by $\mathbb{Z}^d$: one cannot form an external product of the type $D + \delta$ as in the previous paragraph because there is no $\Gamma$-invariant Dirac operator $D$ on the circle (because there is no $\Gamma$-invariant probability measure) with which one can take external product with.

It turns out that the the Dirac class of such an action can be represented by completely orthogonal methods: probabilistic ones concerning the action of $\Theta$ on probability measures on its boundary (see [16]). These imply that the regular representation of $C(\partial \Gamma) \rtimes \Gamma$ on $L^2(\Gamma, L^2(\partial \Gamma, \mu))$, together with the orthogonal projection $P_{L^2(\Gamma)}$ onto the subspace $L^2(\Gamma)$ of functions constant on the boundary, make up a Fredholm module representing the boundary extension class: the class in $KK^1_*(C(\partial \Gamma) \rtimes \Gamma, \mathbb{C})$ of the boundary extension
\begin{equation}
(1.3) \quad 0 \to C_0(\Gamma) \rtimes \Gamma \to C(\Gamma) \rtimes \Gamma \to C(\partial \Gamma) \rtimes \Gamma \to 0
\end{equation}
with $\bar{\Gamma}$ the compactification of $\Gamma$ obtained by mapping it in as an orbit in the disk $\mathbb{D}$, and compactifying in the closed disk $\overline{\mathbb{D}}$. The Fredholm module described above has finite summability the Hausdorff dimension of $(\partial \Gamma, \mu)$. This appears a step forward in understand the noncommutative geometry of these (Type III) examples, but it is only, in a sense, the noncommutative conformal geometry that is being understood. Whether one can integrate a noncommutative notion of length (or distance) into these examples remains unknown.

We prove here only that the Dirac class is the boundary extension class. The fact of being a Dirac class has, in any case, various topological consequences: it allows a completely topological description of its pairing with K-theory.

In general, what the Dirac class detects, topologically, is a certain intersection number. If one has a Baum-Douglas cycle (or cocyle) for $Z \times \Gamma X$, a higher index construction produces a K-theory class for $C_0(X) \rtimes \Gamma$ which pairs with the Dirac class to give a certain analytic index. The index theorem is that this analytic index is the topological intersection number of the Baum-Douglas cycle (or cocyle) with the fibre $X \subset Z \times \Gamma X$. The irrational rotation algebra is already an interesting example. In Connes’ work it is shown that $\partial \theta$ can be extended, by constructing a connection, and so on, to act on sections of various ‘noncommutative vector bundles’ over $A_\theta$ – that is, f.g.p. modules $E_{p,q}$. These bundles are parameterized by pairs of relatively prime integers and are higher indices of the 1-dimensional Baum-Douglas cocycles for the ordinary torus given by loops $L_{p,q}$; the content of our index theorem here is that the index of the operator $D_{\theta}$ extended to act on $L^2(E_{p,q})$ is the topological intersection number of the loop with the standard meridian loop of the torus (that is, $q$, in this parameterization.)

The boundary extension class of a hyperbolic group, due to work of the author and Ralf Meyer, is torsion of order $\chi(\Gamma)$ if $\Gamma$ is torsion-free, and $\chi(\Gamma) \neq 0$, and it is non-torsion, nonzero, if $\chi(\Gamma) = 0$. The intersection index computes the boundary map

$$\delta: K_1(C(\partial \Gamma) \rtimes \Gamma) \to K_0(C_0(\Gamma) \rtimes \Gamma) = K_0(C) = \mathbb{Z},$$

and one of the author’s initial interests was in finding K-theory classes in $K_1(C(\partial \Gamma) \rtimes \Gamma)$ in the case $\chi(\Gamma) = 0$ (e.g. for Kleinian groups with nonzero pairing with the boundary extension. We give in fact a direct geometric construction of such a K-theory class, based on a non-vanishing vector field on $Z \setminus \Gamma$, using the intersection index formula to compute its image under $\delta$. We also use our framework and an argument with $\mathbb{Z}/k$-manifolds to explain the torsion of the boundary extension class, in general.

I would like to thank Paul Baum, for all his boundless enthusiasm for the subject of Dirac operators and K-homology has taught me. I would also like to thank Nigel Higson, for several very pertinent remarks, and the referee, for the number of suggestions, whose adoption has greatly improved the layout and content of this article.

2. The Dirac-localization map for K-oriented groups

If $\Gamma$ is a locally compact group acting smoothly on a smooth Riemannian manifold $X$, then a $\Gamma$-equivariant orientation on $X$ consists of

a) A $\Gamma$-invariant Riemannian metric on $X$.

b) A $\Gamma$-equivariant complex vector bundle $S \to X$ (the spinor bundle), equipped with a $\Gamma$-invariant Hermitian metric, and, if $n$ is even, a $\Gamma$-invariant $\mathbb{Z}/2$-grading on $S$.

c) A $\Gamma$-equivariant fibrewise irreducible representation of the Clifford algebra bundle of $X$, on $S$ compatible with the $\mathbb{Z}/2$-gradings if relevant.

Assuming that the action is proper, one can then construct a $\Gamma$-invariant connection on $X$ compatible with the Levi-Civita connection on $TX$, and corresponding $\Gamma$-equivariant Dirac operator on $X$, providing a cycle and corresponding class in $K^\Gamma_{-n}(C_0(X), \mathbb{C})$. The class is canonically associated to the K-oriented) $\Gamma$-manifold $X$, and we will denote it $[X]$. We will call
[X] the *transverse Dirac class* of X, the reason for the word ‘transverse’ and the exact definition given below. A good source for the construction of analytic Dirac cycles is [27]. Another good source involving equivariant Dirac operators is the seminal paper [3].

If X is a smooth, but not necessarily proper Γ-manifold, it is more difficult to directly construct a Dirac class of the above type, since Γ may not even preserve any Riemannian metric on X. But there are several ways of arguing that there still exists a class in KK\(\Gamma_{-n}(C_0(X), \mathbb{C})\) playing the role of the Dirac class, even though a representative cycle is more difficult to describe.

For example, if Γ = Z is the integers, then one of the foundational results of KK-theory is that there is a KK-equivalence between \(C_0(X) \rtimes \mathbb{Z}\) and the C*-algebra of continuous functions on the mapping cylinder \(C_0(\mathbb{R} \times \mathbb{Z} X)\), shifting degrees by +1. With the appropriate orientation hypothesis on X, the mapping cylinder is K-orientable with associated (non-equivariant) Dirac class \([\mathbb{R} \times \mathbb{Z} X] \in KK_{-n-1}(C_0(\mathbb{R} \times \mathbb{Z} X), \mathbb{C})\) and we can uniquely define a class \([X] \in KK_{-n}(C_0(X) \rtimes \mathbb{Z}, \mathbb{C})\) by the requirement that the KK-equivalence

\[
KK_{-n}(C_0(X) \rtimes \mathbb{Z}, \mathbb{C}) \to KK_{-n-1}(C_0(\mathbb{R} \times \mathbb{Z} X), \mathbb{C})
\]

alluded to above, maps \([X]\) to \([\mathbb{R} \times \mathbb{Z} X]\).

Recently, these ideas are often understood in terms of the set-up of Meyer and Nest, which abstracts the earlier work of Connes, Baum, Kasparov, Higson and many others, and interprets the KK-equivalence just discussed as a localisation map.

Localizing a category at a collection of morphisms inverts the morphisms. Meyer and Nest consider the category KK\(\Gamma\) of Γ-C*-algebras, where Γ is a locally compact group, and localize it at the weak equivalences, where

\[
f \in KK\(\Gamma\)(A, B)
\]

is a weak equivalence if, for every compact subgroup \(H \subset \Gamma\), the restriction map

\[
KK\(\Gamma\) \to KK\(H\)
\]

maps \(f\) to an equivalence. They show that to any Γ can be associated a unique Γ-C*-algebra \(P\) and morphism

\[
D \in KK\(\Gamma\)(P, \mathbb{C})
\]

such that the localization of KK\(\Gamma\) at the weak equivalences has morphisms between objects A and B the elements of KK\(\Gamma\)(\(P \otimes A, B\)) and the localization map from KK\(\Gamma\) to its localization, identifies with the map on morphisms given by Kasparov product

\[
KK\(\Gamma\)(A, B) \xrightarrow{D \otimes -} KK\(\Gamma\)(P \otimes A, B).
\]

In most applications, \(P\) is a proper Γ-C*-algebra. In this paper, we will be working with instances of \(G\) where \(P\) is represented by a very specific cycle that of the Dirac operator. This means that the more important of our definitions (like of Dirac class) depend on this structure, and do not apparently make much sense for more general groups, although the map we are going to discuss is a special case of the more general Meyer-Nest localization map.

We are going to be working with discrete groups Γ for which \(P\) can be realized as a smooth, proper, Γ-equivariantly K-oriented Γ-manifold \(Z\). For such \(Z\) we can directly construct an analytic cycle and Dirac class

\[
[Z] \in KK_{-d}(C_0(Z), \mathbb{C})
\]

which is equal to \(D\) if \(d\) is even, and a suspension of \(D\) otherwise. We will then be able to describe the localization map in very concrete geometric terms.

The exact hypotheses on the discrete group Γ we will be using are the following.
Definition 2.1. A K-orientation on the discrete group $\Gamma$ will refer to a smooth, proper $\Gamma$-equivariantly K-oriented co-compact $\Gamma$-compact manifold $Z$ which is $H$-equivariantly contractible for every compact subgroup $H$ of $\Gamma$. We refer to the pair $(\Gamma, Z)$ as a smooth K-oriented group. We let $\lfloor Z \rfloor \in \text{KK}_{\Gamma}^*(C_0(Z), \mathbb{C})$ be the class of the associated $\Gamma$-equivariant Dirac operator on $Z$. We call it the transverse Dirac class of $Z$.

The contractibility assumption means that $Z$ is a model for the classifying space $\mathcal{E}\Gamma$ for proper actions of $\Gamma$, that $Z$ can be identified with the localizing object $\mathcal{P}$ of Meyer and Nest, and that $\lfloor Z \rfloor$ is the Dirac morphism.

Example 2.2. Every compact group admits a smooth K-orientation with $Z$ a point.

The group $Z^d$ admits a smooth K-orientation using $Z := \mathbb{R}^d$ with the smooth action of $\mathbb{R}^d$ by translation; since $Z^d$ is a closed subgroup of $\mathbb{R}^d$, $(Z^d, \mathbb{R}^d)$ is a smooth K-oriented group.

Suppose that $M$ is a compact Riemann surface (a compact two-dimensional manifold equipped with a complex structure). Then it admits a canonical orientation. The universal cover $\tilde{Z} := \tilde{M}$ has a free and proper action of $\Gamma := \pi_1(M)$, and can be equipped with a $\Gamma$-invariant metric and orientation (lifted from $M$, i.e. a complex structure) and metric of constant negative curvature, making it contractible, and more generally, $H$-equivariantly contractible for any compact group of isometries of $Z$.

The Riemannian manifold $Z$ can of course be identified with the hyperbolic plane $\mathbb{H}^2$ with an appropriate proper, isometric action of $\Gamma$.

Thus, $(\Gamma, \mathbb{H}^2)$ is a smooth, oriented group.

Similarly, any orientation-preserving co-compact discrete group of hyperbolic isometries of $\mathbb{H}^3$ admits the structure of a smooth K-oriented group, since any compact oriented 3-manifold also carries a K-orientation.

More generally, if $\Gamma$ is a torsion-free uniform lattice in a semi-simple Lie group with associated symmetric space $Z = G/K$, then K-orientability of $\Gamma \backslash X$ implies $\Gamma$-equivariant K-orientability of $Z$, and hence $(\Gamma, Z)$ admits a canonical structure of a smooth oriented group in this case, from a K-orientation on $\Gamma \backslash Z$.

This amounts to the well-known procedure of ‘lifting’ a K-orientation under a covering map.

Definition 2.3. Let $(\Gamma, Z)$ be a smooth oriented group. The Dirac-localization map is the map

$$L : \text{KK}_{\Gamma}^*(A, B) \otimes_{\mathbb{C}[\lfloor Z \rfloor]} \text{KK}_{\Gamma}^*(C_0(Z) \otimes A, B)$$

induced by external product in $\text{KK}_{\Gamma}^*$, with the class $\lfloor Z \rfloor$ of the transverse Dirac class for $\Gamma$ acting on $Z$.

We will generally just use the term ‘localization map.’

Remark 2.4. Any model for the Dirac morphism of $\mathbb{H}^2$ determines its own corresponding ‘localization map’, as we have already discussed above, localization in this sense makes sense for general locally compact groups, without further assumptions on their classifying spaces. But in this article, we are interested in doing computations. These computations are most easily done when the Dirac morphism has the simple geometric model that it has under our assumptions. For example, dropping the equivariant K-orientation assumption on $Z$ forces one to use a different co-domain for the localization map: $C_0(Z)$ must be replaced by $C_\tau(X)$, the algebra of sections of the Clifford algebra bundle of $Z$, which is noncommutative, and, furthermore, $\mathbb{Z}/2$-graded, or by $C_0(TZ)$, with $TZ$ the tangent bundle, which is no longer $\Gamma$-compact, and has various other disadvantages from a computational point of view.
Remark 2.5. If $B$ is a trivial $\Gamma$-$C^*$-algebra, and $A$ is an arbitrary $\Gamma$-$C^*$-algebra, recalling that $\Gamma$ is discrete, there is a completely canonical isomorphism

$$KK^*_\Gamma(A, B) \cong KK_*(A \rtimes \Gamma, B),$$

due to the standard bijection between $*$-homomorphisms with domain a crossed-product $A \rtimes G$, and covariant pairs.

Taking this into account, the Dirac-localization map for $B = \mathbb{C}$ can be considered as a map

$$K^*(A \rtimes \Gamma) := KK_*(A \rtimes \Gamma, \mathbb{C}) \cong KK^*_\Gamma(A, \mathbb{C}) \to KK^\Gamma_{-d}(C_0(Z) \otimes A, \mathbb{C}) \cong K^{*-n}(C_0(Z) \rtimes \Gamma)$$

for any $\Gamma$-$C^*$-algebra $A$. If $\Gamma$ is torsion-free, $A = C_0(X)$, some $\Gamma$-space $X$, then the target of Dirac-localization is $KK_*(C_0(X \rtimes \Gamma), \mathbb{C}) = K_{-d}(Z \rtimes \Gamma X)$. Using a standard Morita equivalence one can identify this with the $K$-homology of the Borel space $X \rtimes \Gamma Z$, which fibres over $\Gamma \setminus Z$ under the second projection map, with fibre $X$.

For a compact group, the Dirac-localization map is the identity map.

2.1. Factorization of the localization map. We close this section with a review of an important factorization of the localization map.

Let $(\Gamma, Z)$ be a smooth oriented group. Then a result going back to Kasparov shows that there is a Poincaré duality isomorphism

$$KK^\Gamma_{d}(C_0(Z) \otimes A, B) \cong RKK^\Gamma(Z; A, B)$$

(2.6)

shifting degrees by $d$. See [22]. The group $RKK^\Gamma(Z; A, B)$, explained in [33], is identical, by the definitions, to the groupoid-equivariant group $KK^\Gamma_{+d}(C_0(Z) \otimes A, C_0(Z) \otimes B)$ defined by LeGall; this point of view is convenient, because $KK^\Gamma$ is equivalent to the category of $G$-equivariant correspondences, by [21], for proper groupoids $G$.

The way the Poincaré duality map

$$PD : RKK^\Gamma(Z; A, B) \to KK^\Gamma_{-d}(C_0(Z) \otimes A, B)$$

is defined is as follows. It is the composition of the map

$$RKK^\Gamma(Z; A, B) \to KK^\Gamma_{d}(C_0(Z) \otimes A, C_0(Z) \otimes B)$$

which forgets the $\Gamma \times Z$ equivariance on a cycle, remembering only $\Gamma$-equivariance, which we denote by $f \mapsto \tilde{f}$, and the map

$$KK^\Gamma_{d}(C_0(Z) \otimes A, C_0(Z) \otimes B) \xrightarrow{\otimes_{C_0(Z)}[Z]} KK^\Gamma_{-d}(C_0(Z) \otimes A, B).$$

(2.7)

of composition with the Dirac class $[Z] \in KK^\Gamma_{-d}(C_0(Z), \mathbb{C})$.

The main ingredient of the Poincaré duality isomorphism is thus the class $[Z] \in KK^\Gamma_{-d}(C_0(Z), \mathbb{C})$ of the $\Gamma$-equivariant Dirac operator on $Z$ – the transverse Dirac class, in our terminology, for $\Gamma$ acting on $Z$.

The map $PD^{-1}$ inverse to $PD$ described above, is defined using the map, which we call the inflation map, of Kasparov:

$$\text{infl} : KK^\Gamma_{d}(C_0(X), \mathbb{C}) \to RKK^\Gamma(Z; C_0(X), \mathbb{C}).$$

In these terms,

$$PD^{-1}(f) = \Theta \otimes_{C_0(Z)} \text{infl}(f),$$

(2.9)

where

$$\Theta \in RKK^\Gamma_{d}(Z; \mathbb{C}, C_0(Z)) \cong KK^\Gamma_{+d}(C_0(Z), C_0(Z \times Z)),$$
is the class of the $G$-equivariant correspondence

\[ Z \xleftarrow{\text{id}} Z \xrightarrow{\delta} Z \times Z, \]

where the momentum map for the $G$-space $Z \times Z$ is in the first variable, and $\delta_Z : Z \to Z \times Z$ be the diagonal map.

Correspondences and their associated KK-morphisms are discussed in Section 3.1. A cycle representing $\Theta \in \text{RKK}^\Gamma_{+d}(Z; \mathbb{C}, C_0(Z))$ is built by constructing a family of Bott cycles $\Theta_z$ at $z \in Z$. Such a Bott cycle is defined as follows. In each small Riemannian ball $B_z$ around $z$, use the Clifford multiplication and a vector pointing towards $z$, to construct a multiplier of the module of spinors over the ball and KK$_{+d}(\mathbb{C}, C_0(B_z))$ cycle and then a KK$_{+d}(\mathbb{C}, C_0(Z))$ cycle by the map induced by the open inclusion $B_z \subset Z$.

The required cycle for $\text{RKK}^\Gamma_{+d}(Z; \mathbb{C}, C_0(Z))$ is then built from considering $\Theta$ as an operator on the Hilbert module of sections of the field. See [33].

See Section 5 for more on the inflation map and Poincaré duality.

**Proposition 2.10.** Let $(\Gamma, Z)$ be a smooth K-oriented d-dimensional group. Then the localization map factors as

\[
\begin{array}{ccc}
\text{KR}^\Gamma_{+d}(A, B) & \xrightarrow{\text{infl}} & \text{RKK}^\Gamma_{+d}(Z; A, B) \\
\downarrow \mathcal{L} & & \downarrow \text{PD} \\
\text{KK}^\Gamma_{+d}(C_0(Z) \otimes A, B) & & \\
\end{array}
\]

where PD is Poincaré duality.

For the proof, see Theorem 4.34 of [22].

Since PD is always an isomorphism, the inflation map and the Dirac map are equivalent; thus one is an isomorphism if and only if the other is.

If $\Gamma$ is torsion-free, $(\Gamma, Z)$ a smooth K-oriented group, then $\Gamma$ acts freely on $Z$, and the commutative diagram (2.11) becomes

\[
\begin{array}{ccc}
\text{K}^*\Gamma & \xrightarrow{\text{infl}} & \text{K}^*(\Gamma\setminus Z) \\
\downarrow \mathcal{L} & & \downarrow \text{PD} \\
\text{K}_{-d}(\Gamma\setminus Z) & & \\
\end{array}
\]

with PD Poincaré duality for the K-oriented manifold $\Gamma\setminus Z$.

The Dirac-localization map for torsion-free K-oriented groups is therefore is between the K-homology of the C*-algebra $\text{C}^*\Gamma$, and the K-homology of the classifying space $\Gamma\setminus Z \cong B\Gamma$.

3. THE LOCALIZATION MAP FOR FREE ABELIAN GROUPS

In this section we describe Dirac-localization for free abelian groups $\mathbb{Z}^d$ acting on points: that is, we describe the localization map

\[ \mathcal{L} : \text{KK}^{\mathbb{Z}^d}_+(\mathbb{C}, \mathbb{C}) \to \text{KK}^{\mathbb{Z}^d}_{-d}(C_0(\mathbb{R}^d), \mathbb{C}). \]

in geometric terms – it turns out to be essentially a direct K-theory version of the Fourier-Mukai transform of algebraic geometry.
3.1. **Topological correspondences.** A (sometimes called ‘topological\(^1\)) correspondence, is a specification of a certain set of geometric data which produces a class in KK. The concept is due to [10]. A closely related concept plays an important role in algebraic geometry, in which context, correspondences they are sometimes referred to as Fourier-Mukai transforms; they are morphisms in a suitable category between projective varieties.

For purposes of K-theory, if X and Y are smooth manifolds, a correspondence from X to Y is a pair of maps and a K-theory class, usually depicted by a diagram
\[(3.1)\quad X \leftarrow (M, \xi) \rightarrow Y,\]
where \(f\) is a smooth K-oriented normally non-singular map; \(b\) is an ordinary smooth map (not necessarily proper), and the class \(\xi\) lies in the representable K-theory of \(M\) with \(b\)-compact support. If \(b\) is proper, this is just the ordinary K-theory of \(M\). The theory of correspondences is due to Connes and Skandalis [10]. Connes and Skandalis associate to such a correspondence a certain analytic cycle for KK-theory in the following way. We will assume that the K-theory class is in dimension zero and is specified by a vector bundle \(E \rightarrow M\) over \(M\). The most delicate part of the construction invokes map \(f\), to which one wishes to associate an analytically defined morphism
\[f_{an}! \in \text{KK}_{\dim Y - \dim M}(C_0(M), C_0(Y)).\]

If \(f\) is a submersion, then \(f\) gives rise to a bundle of smooth manifolds over \(Y\) with fibre the fibres of \(f\), the K-orientation assumption on \(f\) implies a bundle of K-orientations on the fibres, and by a well-known procedure one can then construct from this data a bundle of Dirac operators on the fibres of \(f\). This gives a cycle and analytically defined class \(D_f\) we we set
\[f_{an}! := D_f \in \text{KK}_{\dim Y - \dim M}(C_0(M), C_0(Y)).\]

If \(E\) is a vector bundle over \(M\), \(D_f\) can be twisted by the vector bundle, giving a twisted version \(D_{f,E}\) of \(D_f\) in the same group. Finally, \(b\) induces a map \(b^* : \text{KK}_*(C_0(M), C_0(Y)) \rightarrow \text{KK}_*(C_0(X), C_0(Y))\), and now the analytic class in KK defined by the correspondence is by definition
\[b^*(D_{f,E}) \in \text{KK}_{\dim Y - \dim M}(C_0(M), C_0(Y)).\]

If \(f\) is merely assumed a smooth map, then it can be factored into a submersion and an immersion, and an analytically defined morphism
\[f_{an}! \in \text{KK}_{\dim Y - \dim M}(C_0(M), C_0(Y))\]
is defined by composing the two Kasparov morphisms obtained from the factorization: the submersion determines an element of KK as just described; and a K-oriented immersion \(f : M \rightarrow Y\) defines a KK-morphism in the following way. The immersion has a K-oriented normal bundle \(\nu\), with a tubular neighbourhood embedding
\[\varphi : \nu \rightarrow C_0(Y),\]
on onto an open subset of \(Y\). Combining the Thom isomorphism class
\[\xi_{\nu} \in \text{KK}_{\dim Y - \dim M}(C_0(M), C_0(\nu))\]
and the open embedding
\[\varphi! \in \text{KK}_0(C_0(\nu), C_0(Y))\]
gives a purely topologically-defined morphism in \(\text{KK}_{\dim M - \dim Y}(C_0(M), C_0(Y))\) associated to the immersion.

There is another way of building a natural KK-element from the data \((3.1)\). Part of the recipe above was in fact purely topological: if the map \(f\) was an immersion, then \(f!\) is defined purely
in terms of Thom modification in K-theory (by the normal bundle of \( f \)). The idea behind the topological index (of an elliptic operator) of Atiyah and Singer was as follows. Since we are only really concerned about submersions, let
\[
f : M \to Y,
\]
with K-oriented fibres. We have defined \( f_{an!} \) above using the bundle of Dirac operators along the fibres of \( f \). Instead, let \( \zeta : M \to \mathbb{R}^n \) be a smooth embedding, for some \( n \). Then
\[
M \to Y \times \mathbb{R}^n, \quad \tilde{f}(x) = (\zeta(x), f(x))
\]
is a smooth embedding. We obtain by the procedure above an element
\[
\tilde{f}! \in KK_{\dim Y - \dim M + n}(C_0(M), C_0(Y \times \mathbb{R}^n)) \cong KK_{\dim Y - \dim M}(C_0(M), C_0(Y)).
\]
where the second equality is by the Bott Periodicity KK-equivalence \( C_0(\mathbb{R}^n) \cong \mathbb{C} \), which shifts degrees by \(-n\). If \( f! \) is defined as \( \tilde{f} \) then the Atiyah-Singer Index Theorem in KK-theory is the statement that
\[
f_{an!} = f!
\]
for any smooth K-oriented map \( f \).

The most important feature of correspondences is that they can be composed in a purely geometric manner: the composition
\[
X \leftarrow M \overset{b}{\to} Y \overset{b'}{\to} M' \overset{f'}{\to} Z
\]
if the maps \( f \) and \( b' \) are transverse, is represented by the correspondence
\[
X \leftarrow M \times_Y M' \to Z,
\]
with \( M \times_Y M' \) having its canonical smooth manifold structure, and where the map \( M \times_Y M' \to Z \) (the composition of the projection \( M \times_Y M \to M' \) and the map \( f' : M' \to Z \)) carries a certain K-orientation induced by the K-orientations on \( f \) and \( f' \). The left map \( M \times_Y M' \to X \) is similarly the composition of the first coordinate projection and the map \( b \). It is easy to integrate the K-theory data into this recipe.

This efficient recipe of composing correspondences (KK-elements) will be used later in this article.

The dimension of the correspondence \((3.1)\) is \( \dim Y - \dim M + \deg \xi \). If \( \xi \) is the class of the trivial line bundle, so that all the information in the correspondence lies in the maps and the K-orientations, then the dimension is \( \dim Y - \dim M \). With this notion of dimension, correspondences composed by the transversality recipe described above, do so additively with respect to dimension.

### 3.2. Localization and Fourier-Mukai duality

We now describe a correspondence which encodes the localization map. The main ingredient will be the K-theory class \( P_d \in K^0(T^d \times \widehat{T^d}) \) of the Poincaré bundle, defined to be the class of the f.g.p. module over \( C(T^d \times \widehat{T^d}) \) consisting of all continuous functions \( f \) on \( \mathbb{R}^d \times \widehat{T^d} \) such that
\[
f(x + v, \chi) = \chi(v)f(x), \quad x \in \mathbb{R}^d, \quad \chi \in \widehat{T^d} := \widehat{\mathbb{Z}^d}.
\]
The bimodule structure over \( C(T^d \times \widehat{T^d}) \) is given by
\[
(f \cdot h)(x, \chi) = f(x, \chi)h(x, \chi),
\]
where \( T^d \) is understood as \( \mathbb{R}^d / \mathbb{Z}^d \) so \( h \) in this formula is to be interpreted as a continuous function on \( \mathbb{R}^d \times \widehat{T^d} \) which is \( \mathbb{Z}^d \)-periodic in the first variable.

If \( \chi : \mathbb{Z}^d \to T \) is a character, it induces a complex line bundle \( L_\chi \) over \( \mathbb{R}^d / \mathbb{Z}^d = T^d \), and this is precisely the restriction of \( \beta \) to a the slice \( T^d \times \{ \chi \} \cong T^d \) is the induced vector bundle \( L_\chi \).
The total family of these bundles makes up the space of the Poincaré bundle. More exactly, the space \( \mathbb{R} \times \widehat{T} \times \mathbb{C} \) where \((x - n, \chi, \lambda) \sim (x, \chi(n), \lambda)\), which projects to \( T \times \widehat{T} \) with fibres \( \mathbb{C} \), forms a rank-one complex vector bundle over \( T^d \times \widehat{T}^d \) whose module of sections is as described above.

The Poincaré bundle is the Fourier transform of a finitely generated projective module over \( C(T^d) \otimes C^*(\mathbb{Z}^d) \), which is defined for general discrete groups \( \Gamma \), and in this more general context called the Mischenko bundle, figuring in a common formulation of the Baum-Connes assembly map involving only non-equivariant KK-theory and not the equivariant flavour.

**Definition 3.3.** The Fourier-Mukai correspondence is given by the topological correspondence of degree \(-d\)

\[
T^d \xrightarrow{pr_1} (T^d \times \widehat{T}^d, \mathcal{P}) \xrightarrow{pr_2} \widehat{T}^d,
\]

from \( T^d \) to \( \widehat{T}^d \). The coordinate projection is given its standard K-orientations.

**Remark 3.5.** The class in \( \text{KK}_{-d}(C(T^d), C(\widehat{T}^d)) \) of the Fourier-Mukai correspondence, given our general remarks earlier on wrong-way maps from submersions, is the class of the following analytically defined cycle.

To each \( \chi \in \widehat{T}^d \), we associate the flat Hermitian induced vector bundle \( L_\chi := \mathbb{R}^d \times_{\chi, \chi} \mathbb{C} \) over \( T^d \) and form the corresponding twisted Dirac operator \( D_\chi \); then the ensemble \( \{D_\chi\}_{\chi \in \widehat{T}^d} \) makes up a bundle of elliptic operators along the fibres of the coordinate projection \( T^d \times \widehat{T}^d \to \widehat{T}^d \), and a cycle for for \( \text{KK}_{-d}(C(T^d), C(\widehat{T}^d)) \).

**Theorem 3.6.** Under the identification

\[
\text{KK}_{-d}(C(\mathbb{R}^d) \times \mathbb{Z}^d, C^*(\mathbb{Z}^d)) \cong \text{KK}_{-d}(C(T^d)), C(\widehat{T}^d))
\]

by Morita equivalence in the first variable, Fourier transform in the second, the image \( j_{\mathbb{Z}^d}([\mathbb{R}^d]) \) of the Dirac class of \( (\mathbb{Z}^d, \mathbb{R}^d) \) under descent, is the class of the Fourier-Mukai correspondence \( \mathcal{J}_{\Gamma} \).

In particular, the Dirac map \( K_{-d}(\widehat{T}^d) \to K_{+d}(T^d) \) for \( \mathbb{Z}^d \) acting on a point is the Fourier-Mukai transform, given by the map on Baum-Douglas cycles of composition with the smooth correspondence

\[
T^d \xrightarrow{pr_1} (T^d \times \widehat{T}^d, \mathcal{P}_d) \xrightarrow{pr_2} \widehat{T}^d,
\]

where \( \mathcal{P}_d \) is the (class of the) Poincaré bundle.

**Proof.** We start with reviewing the descent map, and work in the generality of a general K-oriented group \( \Gamma \) as above (though the orientation plays no role).

Cycles for \( \text{KK}_{-d}^i(C_0(Z), C) \) are given by Hilbert spaces \( H \) equipped with a unitary action of \( \Gamma \), a \( \Gamma \)-equivariant representation \( \pi: C_0(Z) \to \mathcal{L}(H) \), and an operator, which is almost \( \Gamma \)-equivariant in the appropriate sense. Descent, applied to this data, setting aside the operator for the moment, produces the right \( C^*(\Gamma) \)-module \( j_\Gamma(H) \), which is the completion of \( C_*(\Gamma, H) \), elements of which we write in group-algebra style

\[
\sum_{g \in \Gamma} \xi_g[g],
\]

under the inner product

\[
\langle \xi, \xi' \rangle_{C^*(\Gamma)} = \sum_{g_1, g_2 \in \Gamma} \langle \xi_{g_1}, \xi'_{g_2} \rangle |g_1^{-1}g_2|,
\]
which of course can be re-written as a convolution. The right $C^*(\Gamma)$-module structure on $j_\Gamma(H)$ is

$$\left(\sum_{g \in \Gamma} \xi_g[g]\right) \cdot [h] = \sum_{g \in \Gamma} \xi_g[gh].$$

The left action of $C_0(Z) \rtimes \Gamma$ is given by the covariant pair

$$f(\sum_{g \in \Gamma} \xi_g[g]) = \sum_{g \in \Gamma} \pi(f) \xi_g[g], \quad h(\sum_{g \in \Gamma} \xi_g[g]) = \sum_{g \in \Gamma} h(\xi_g)[hg].$$

The standard Morita equivalence $C(\Gamma \backslash Z)-C_0(Z) \rtimes \Gamma$-bimodule Of Rieffel and others is the completion $\mathcal{E}_\Gamma$ of $C_c(Z)$ under the inner product

$$\langle f_1, f_2 \rangle_{C_0(X) \rtimes \Gamma} = \sum_{g \in \Gamma} f_1^* g^{-1}(f_2)$$

and the right module structure by the (anti-) covariant pair

$$f \cdot [h] := h^{-1}(f), \quad f \cdot f' := ff'.$$

In computing descent at the level of cycles, we therefore need to describe the right Hilbert $C^*(\Gamma)$-module

$$(3.8) \quad \mathcal{M}(H) := \mathcal{E}_\Gamma \otimes_{C_0(Z) \rtimes \Gamma} j_\Gamma(H).$$

We will focus on describing this tensor product module when $H$ is of the form $L^2(Z)$, for a $\Gamma$-invariant measure on $Z$. Exactly the same arguments go through to compute $\mathcal{M}(H)$ when $H = L^2(S)$ is the space of spinors for the Dirac operator on $Z$.

Let $\otimes$ in the following denote the algebraic tensor product. We work with simple tensors in the tensor product $\mathcal{M}(X)$, which we can denote $f \otimes_{C_0(X)} \xi[g]$, where $f, \xi \in C_c(Z)$, and $\xi$ thought of as an element of the Hilbert space $L^2(Z)$. The null vectors are spanned by the $C^*(\Gamma)$-invariant submodule spanned over $\mathbb{C}$ by the vectors

$$(3.9) \quad f' f \otimes_{C_0(X)} \xi[g] - f' \otimes_{C_0(X)} f \xi[g], \quad h^{-1}(f) \otimes_{C_0(X)} \xi[g] - f \otimes_{C_0(X)} h(\xi)[hg].$$

Using the first relation, one sees that we are describing the quotient of $H \otimes \mathbb{C}\Gamma$ by the span of the vectors

$$(3.10) \quad h(\xi) \otimes [hg] - \xi \otimes [g],$$

i.e., the tensor product module amounts to forming the quotient module, by the diagonal left action of $\Gamma$ (by right $C^*(\Gamma)$-module maps) and then completing under the inner product

$$(3.11) \quad \langle \xi_1 \otimes [g_1], \xi_2 \otimes [g_2] \rangle_{C^*(\Gamma)} := \langle \xi_1, \xi_2 \rangle_{C^*(\Gamma)} \cdot [g_1^{-1} g_2].$$

Now we will use the special structure of $Z$. Let $F \subset Z$ be a fundamental domain for the $\Gamma$-action. We define a map, somewhat formally, on elementary tensors by

$$\Phi(\xi \otimes [g]) := \sum_{k \in \Gamma} k(\xi|_F) \otimes [kg].$$

Here we start with $\xi \in C_c(Z) \subset L^2(Z)$, restrict it to $F$, and then move this restricted function on $F$ periodically over $Z$, giving the functions $k(\xi|_F)$.

We can take the co-domain of $\xi$ to be the space of bounded, measurable maps

$$\xi : Z \to \mathbb{C}\Gamma, \quad \text{s.t.} \quad \xi(gx) = [g]\xi(x) \forall x \in Z.$$

With this interpretation, $\Phi$ sends null-vectors (3.10) to zero. We define an inner product on such functions by

$$\langle \xi_1, \xi_2 \rangle_{C^*(\Gamma)} := \int_F \xi_1^* \xi_2,$$

with $\xi^*(x) := \xi(x)^* \in \mathbb{C}\Gamma$. 

Then for $\xi_i \in L^2(Z)$, $g_i \in \Gamma$,
\[
\langle \Phi(\xi_1 \otimes [g_1]), \Phi(\xi_2 \otimes [g_2]) \rangle_{C^* (\Gamma)} = \int_F \langle \xi_1 | g_1 \rangle \xi_2 [g_2] = \int_F \xi_1 \xi_2 \cdot [g_1^{-1} g_2] \in \mathbb{C} \Gamma,
\]
which matches (3.11), so that $\Phi$ is an isometry.

To summarize, we have proved the following,

**Lemma 3.12.** Descent and strong Morita equivalence maps the $\Gamma \rtimes Z$-Hilbert space $L^2(Z)$ to the right $C^* (\Gamma)$-module of maps $\xi: Z \to C^* (\Gamma)$ such that $\xi(gx) = [g] \xi(x)$ for all $x \in Z$, with inner product, module structure
\[
\langle \xi_1, \xi_2 \rangle_{C^* (\Gamma)} := \int_F \xi_1^* \xi_2 \quad \xi[g](x) := \xi(x)[g].
\]

Very little change needs to be made to the above argument when $H$ is generalized to be $L^2(S)$ for a spinor bundle $S$ over $Z$, equipped with a unitary $\Gamma$-action by bundle maps. Furthermore, if $D$ is a $\Gamma$-equivariant Dirac operator on $L^2(S)$, it descends to a densely defined operator on the right $C^* (\Gamma)$-module $j_\Gamma (L^2(S))$ by the obvious formula
\[
D \left( \sum \xi_g [g] \right) := \sum D \xi_g \otimes [g].
\]
The class $(j_\Gamma (L^2(S)), \hat{D})$ of this spectral triple represents $j_\Gamma ([Z])$ in $KK_{-d} (C_0 (Z) \rtimes \Gamma, C^* (\Gamma))$.

The Kasparov product
\[
[E] \otimes_{C_0 (Z) \rtimes \Gamma} \lambda_T ([Z])
\]
in the case $Z = \mathbb{R}^d$, $\mathbb{F} = \mathbb{Z}^d$ can now be described in the following way. By our work above, the right $C^* (\mathbb{Z}^d)$-module $E \otimes_{C_0 (\mathbb{R}^d) \rtimes \mathbb{Z}^d} j_\mathbb{Z}^d (L^2(Z))$ is isomorphic to the right $C^* (\mathbb{Z}^d)$-module of maps $\xi: \mathbb{R}^d \to C^* (\mathbb{Z}^d)$ such that $\xi(x + n) = [n] \xi(x)$, $\forall x \in \mathbb{R}^d$, $n \in \mathbb{Z}^d$, with the $C^* (\mathbb{Z}^d)$-valued inner product defined above. Under Fourier transform $C^* (\mathbb{Z}^d) \cong C(\hat{\mathbb{T}}^d)$ these correspond to maps on $T^d \times \hat{T}^d$ satisfying the conditions described in (3.13). That is, the right $C(\hat{T})$-module we are describing is the module of sections of the Miscenko-Poincaré module $L$. A small elaboration of the computations just given integrates a spinor bundle, and the discussion in Remark 3.12 shows that this space carries a natural bundle of Dirac operators on it, because we can twist by flat connections.

The axioms of the Kasparov product proves the result.

For the second statement, note that for any discrete group, the standard identification (at the level of cycles) $KK^o_\Gamma (A, \mathbb{C}) \cong KK_* (A \rtimes \Gamma, \mathbb{C})$ factors through the composition of the descent functor and the map $\epsilon_* : KK_* (A \rtimes \Gamma, C^* (\Gamma)) \to KK_* (A \rtimes \Gamma, \mathbb{C})$ induced by the trivial representation $C^* (\Gamma) \to \mathbb{C}$. It follows from a quick calculation that if $(\Gamma, Z)$ is $K$-oriented, then the Dirac map interpreted as a map
\[
KK_* (C^* (\Gamma), \mathbb{C}) \to KK_{-d} (C_0 (Z) \rtimes \Gamma, \mathbb{C})
\]
is given by Kasparov composition with the image $j_\Gamma ([Z]) \in KK_{-d} (C_0 (Z) \rtimes \Gamma, C^* (\Gamma))$ of the Dirac class $[Z] \in KK_{-d} (C_0 (Z), \mathbb{C})$ under descent. We have computed this class above and showed that it is that of the Fourier-Mukai correspondence. This proves the other assertion.

\[\square\]

**Remark 3.13.** Taking its index of the correspondence (3.11), that is, composing it with the correspondence
\[
\cdot \leftarrow T^d \xrightarrow{id} T^d,
\]
gives the correspondence
\[
(3.14) \quad \cdot \leftarrow (T^d \times \hat{T}^d, \mathcal{P}) \xrightarrow{\mathcal{P}^g} \hat{T}^d,
\]
The corresponding analytic cycle for $\text{KK}_{-d}(C, C(\hat{T}^d))$ is sometimes described as a kind of Hilbert module index: twisting in a suitable sense the Dirac operator on $T^d$ by the Poincaré bundle over $T^d \times \hat{T}^d$ gives a Fredholm operator on a $C(\hat{T}^d)$-module whose $C(\hat{T}^d)$- index gives a class in $K_{-d}(C^*(\hat{T}^d))$. After Fourier transform, what we are describing is the application of the Baum-Connes analytic assembly map

$$
\mu: \text{KK}_*(C(T^d), C) \rightarrow \text{KK}_{-d}(C, C^*(Z^d))
$$

to the class $[T^d]$ of the Dirac operator on $T^d$.

The Theorem above implies that application of descent

$$
\text{KK}^d_{-d}(C_0(\mathbb{R}^d), C) \rightarrow \text{KK}_*(C_0(\mathbb{R}^d) \times \mathbb{Z}^d, C^*(\mathbb{Z}^d))
$$

and Morita equivalence $C_0(\mathbb{R}^d) \times \mathbb{Z}^d \sim C(T^d)$ to the $\mathbb{Z}^d$-equivariant Dirac class $[\mathbb{R}^d]$ gives the class of the Fourier-Mukai correspondence, but from this it follows that after taking the index, as just discussed, we obtain the class $\mu([\mathbb{R}^d]) \in \text{KK}_{-d}(C^*(\mathbb{Z}^d))$.

This equality of classes in $K_*(C^*(\mathbb{Z}^d))$ has a more general version, equating two apparently two slightly different methods of defining the Baum-Connes assembly map for torsion-free discrete groups. The paper [36] of Land shows that they are the same. There is therefore some connection between our statement and Land’s, at least in this special case of the group $\mathbb{Z}^d$, and only after taking the index; our statement involving the Fourier-Mukai correspondence is slightly more ‘bivariant’ in nature. But some of the arguments in the proof above rather similar to some of those of Land.

We now return to the localization map for $G = \mathbb{Z}^d$. We are going to describe it geometrically.

3.3. Computation of the localization map for free abelian groups. If $\Gamma = \mathbb{Z}^d$, $T^d$ the torus $T^d := \mathbb{R}^d/\mathbb{Z}^d$, and $\hat{T}^d := \hat{\mathbb{Z}}^d$ the dual torus then $\text{KK}_{-d}^d(C, C) \cong \text{KK}_*(C^*(\mathbb{Z}^d), C)$ and by Fourier transform $\text{KK}_*(C^*(\mathbb{Z}^d), C) \cong \text{KK}_*(C(\hat{T}^d), C)$, while Morita invariance implies that $\text{KK}_{-d}^d(C_0(\mathbb{R}^d), C) \cong \text{KK}_*(C(\mathbb{R}^d/\mathbb{Z}^d), C) = \text{KK}_*(C(T^d), C)$.

The Dirac-localization map therefore identifies with a map

$$
(3.15) \quad \text{K}_{-d}(\hat{T}^d) \rightarrow \text{K}_{*+d}(T^d).
$$

Now fixing a basis and dual basis, the groups $\text{K}_*(T^d)$ and $\text{K}_*(\hat{T}^d)$ can each be identified, by the Künneth Theorem, with the graded tensor product

$$
\text{K}_*(T) \otimes \mathbb{Z} \cdots \otimes \mathbb{Z} \text{K}_*(T).
$$

This blurs a little the difference between $T^d$ and $\hat{T}^d$ but we will return to a coordinate free perspective below.

The group $\text{K}_*(T)$ has two generating K-homology classes: the $K_0(\mathbb{T})$-class $[\cdot]$ of a point $p$ in $T$, and the $K_1(\mathbb{T})$-class $[\mathbb{T}]$ of the Dirac operator on the circle. Now for an $r$-tuple $k = k_1 < \cdots < k_r$ of integers from $\{1, \ldots, n\}$ we associate the $l$-dimensional correspondence (or Baum-Douglas cycle)

$$
(3.16) \quad T^l \leftarrow T^j \rightarrow T^d,
$$

with $T^j$ carrying its standard (product) K-orientation, and the left map $T^l \rightarrow T^d$ sending the $j$th coordinate circle of $T^l$ into the $k_j$th coordinate of $T^d$, and putting the point $p$ into the other coordinates. We call this a standard coordinate embedding of an $l$-torus in $T^d$. Let $[k] \in \text{K}_r(T^d)$ be its Baum-Douglas class.

Obviously, every standard coordinate embedding $T^l \rightarrow T^d$ comes along with a `dual’ coordinate embedding $T^{d-l} \rightarrow T^d$, mapping circles into the complementary coordinates, and putting $p$’s in the other coordinate spots. Let $[k^\perp] \in \text{K}_{*+d}(T^d)$ be its class.
Theorem 3.17. Let
\[ \mathcal{L} : K_*(T^d) \cong KK_{-d}^Z(C, C) \to KK_{-d}^Z(C_0(\mathbb{R}^d), C) \cong K_{-d}(T^d) \]
be the localization map for \( Z^d \).

If \( |k| = k_1 < \cdots < k_r \) is the class of a standard coordinate embedding, then
\[ \mathcal{L}(k) = (-1)^{d r + \frac{k(k - 1)}{2}} \cdot [k^\perp], \]
with \( [k^\perp] \) the class of the dual coordinate embedding.

In particular, the Dirac map, that is, composition with \( (3.7) \), interchanges the K-homology
classes of a point in the dual torus \( \hat{T}^d \), and the class of the Dirac operator on the torus \( T^d \).

Proof. Given the Künneth theorem, and taking products, it suffices to verify the
assertion for \( Z \), since the K-homology classes we are considering are all external products of K-homology classes
for \( T \).

The Dirac map is thus
\begin{align*}
(3.18) \quad K_* (\hat{\mathbb{Z}}) & \cong K_* (C^* (\mathbb{Z}), C) = KK_1^\mathbb{Z} (C, C) \xrightarrow{\mathcal{R} \otimes} KK_{0}^\mathbb{Z} (C_0(\mathbb{R}), C) \\
& \cong K_{-1} (C(\mathbb{R}/Z), C).
\end{align*}

The K-homology class of a point in \( \hat{\mathbb{Z}} \) maps to the class of the trivial representation in \( KK_1^\mathbb{Z} (C, C) \),
which acts as a unit, so the image under the next map is the \( Z \)-equivariant Dirac class \( \mathcal{R} \in KK_{-1}^\mathbb{Z} (C_0(\mathbb{R}), C) \), i.e. the Dirac class for the circle in \( KK_{-1} (C(\mathbb{R}/Z), C) \).

Hence the Dirac map sends a point class \([\cdot]\) in \( K_0 (\hat{T}) \) to the Dirac class \([\cdot]\) in \( K_{-1} (T) \). It remains to show that it maps \([\hat{T}]\) to the class \([\cdot]\) of a point in \( K_0 (T) \).

Under the identification \( K_0 (T) \cong KK_1^\mathbb{Z} (C_0(\mathbb{R}), C) \), the point homology class for \( T \) corresponds to the class \([ev] \in KK_1^\mathbb{Z} (C_0(\mathbb{R}), C) \) of the \( Z \)-equivariant representation \( C_0(\mathbb{R}) \to C_0(\mathbb{Z}) \subset \mathcal{K}(\mathbb{Z}) \)
due to the inclusion \( \mathbb{Z} \to \mathbb{R} \). We need to prove that \([\hat{T}] \otimes_C [\mathcal{R}] = [ev] \in KK_1^\mathbb{Z} (C_0(\mathbb{R}), C) \). To do
so we employ the fact that \( [\mathcal{R}] \in KK_{-1}^\mathbb{Z} (C_0(\mathbb{R}), C) \) is invertible in \( KK^\mathbb{Z} \). Let \( \eta \in KK_1^\mathbb{Z} (C, C_0(\mathbb{R})) \) be the class of the self-adjoint unbounded multiplier \( \delta(x) = x \) of \( C_0(\mathbb{R}) \). Then
\[ \eta \otimes_{C_0(\mathbb{R})} [\mathcal{R}] \otimes_C [\mathcal{R}] = [ev] \in KK_0^\mathbb{Z} (C_0(\mathbb{R}), C, C_0(\mathbb{R})) \]
is the content of the Dirac-dual-Dirac method for \( Z \).

Therefore the equation \([\hat{T}] \otimes_C [\mathcal{R}] = [ev] \in KK_0^\mathbb{Z} (C_0(\mathbb{R}), C) \) we want to prove is equivalent to the equation
\[ \eta \otimes_{C_0(\mathbb{R})} [ev] = [\hat{T}] \in KK_{-1}^\mathbb{Z} (C, C). \]
But the composition on the left is clearly represented by the spectral triple with Hilbert space \( \ell^2 (\mathbb{Z}) \), and operator the densely defined operator of multiplication by \( n \). It’s Fourier transform
is therefore the Dirac operator on the circle \( \hat{T} \). This completes the proof.

\[ \square \]

Remark 3.19. Naturally, one can try to prove that the Dirac map, say, for \( Z \), interchanges the
point class and the Dirac classes for \( T \) and \( \hat{T} \), using the correspondence \( (3.7) \) rather directly.

Composition of the correspondences
\[ (3.20) \quad \mathbb{T} \leftarrow (T \times \hat{T}, \beta) \to \hat{T} \leftarrow \cdots \]
gives by transversality
\[ (3.21) \quad \mathbb{T} \leftarrow (T, \beta |_{\mathbb{T}}) \to \cdots \]
where we understand \( \mathbb{T} \) as a subset of \( T \times \hat{T} \) by \( T \times \{ p \} \), the point we have picked. Taking \( p = 0 \), the zero character of \( Z \), is convenient. The inclusion \( T \to T \times T \) of the slice pulls back
the f.g.p. $C(T \times T)$-module defining $\beta$ to the module of continuous functions on $\mathbb{R} \times \{0\}$ such that $f(x + n, 0) = f(x, 0)$, i.e. periodic functions, and hence the restricted module is precisely $C(\mathbb{T})$. Hence the restriction of $\beta$ to $\mathbb{T}$ is the class of the trivial line bundle, proving that the Dirac map sends the point K-homology class to the correspondence

$$\mathbb{T} \xrightarrow{id} \mathbb{T} \to \ast,$$

which describes the Dirac class $[\mathbb{T}]$.

Things do not run so smoothly if one starts with the class $[\mathbb{T}]$. The resulting correspondence involves a manifold of dimension 2 which then must be Thom, or Bott un-modified, to a manifold of dimension zero (a point), and one has to take care of the bundle as well. It is easier to use the dual-Dirac method to do the calculation, as we did in the proof of Theorem 3.17, since then the cycle one begins the calculation with is a point.

With some labour, the following result can be deduced from Theorem 3.17 but we will prove it more geometrically in a forthcoming note with D. Hudson [14].

Suppose $T \subset T^d$ is a $j$-dimensional torus subgroup. It lifts to a $j$-dimensional linear subspace $L \subset \mathbb{R}^d$.

Let $L^\bot$ be all characters of $\mathbb{R}^d$ which vanish on $L$, $(\mathbb{Z}^d)^\bot$ all $\chi \in \hat{\mathbb{T}}$ that vanish on $\mathbb{Z}^d$ and $T^\bot$ the projection to $\hat{\mathbb{T}} \cap (\mathbb{Z}^d)^\bot \cong \hat{\mathbb{T}} = \hat{T}$ of $L^\bot$. It is a $d - j$-dimensional subtorus of $T^d$. It can be suitably K-oriented in order to make the following result true.

**Theorem 3.22.** Let $T \subset T^d$ be a $j$-dimensional linear torus, $T^\bot \subset T^d$ its $d - j$-dimensional dual torus. Then the Dirac-Fourier-Mukai transform

$$K_j(T^d) \to K_{j+d}(\hat{T}^d)$$

maps the cycle $[T]$ to the cycle $[T^\bot]$.

Finally, we note that just as application of descent and the Fourier transform to the Dirac class of $(\mathbb{R}^d, \mathbb{Z}^d)$ produced the Fourier-Mukai correspondence

$$F_d \in KK_d(C(T^d), C(\hat{T}^d)),$$

when we do the same with the dual-Dirac element

$$\eta \in KK^{d - j}_d(\mathbb{R}^d, C(\mathbb{R}^d))$$

we obtain the class $F_d' \in KK_d(C(\hat{T}^d), C(T^d))$ of the ‘reversed’ Fourier-Mukai correspondence

$$\hat{T}^d \xleftarrow{pr_2} (\hat{T}^d \times T^d, \beta) \xrightarrow{pr_1} T^d,$$

**Corollary 3.24.** Application of the composition of functors

$$KK^d_d(\mathbb{R}^d, C(\mathbb{R}^d)) \to KK_d(C^*(\mathbb{Z}^d), C(\mathbb{R}^d)) \cong KK_d(C(\hat{T}^d), C(T^d))$$

to the dual-Dirac element $\eta$ for $\mathbb{R}^d$ gives the class of the dual Fourier-Mukai correspondence $F_d'$ of (3.23).

In particular,

$$F_d' \circ F_d = id, \quad F_d \circ F_d' = id,$$

as morphisms in the category $KK$.

The fact that the Dirac map descends to the Fourier-Mukai transform seems to be one of the ‘well-known to experts’ kind, but has not apparently been written down anywhere as far as the author has been able to determine. The physics literature, however, is extensive on the matter, as Fourier-Mukai duality is a form of T-duality (see for example [38]). The recent paper [4] treats Fourier-Mukai duality in terms of K-theory as well, but the context is slightly different.
4. The Dirac class of a discrete group

Motivated by the calculations with $\mathbb{Z}^d$ of the previous section, we now proceed to a notion of the Dirac class on the ‘noncommutative manifold’ underlying the $C^*$-algebra $C^*(\Gamma)$ for possibly non-abelian discrete groups $\Gamma$.

4.1. Point classes and Dirac classes. We will continue to assume that $\Gamma$ admit a smooth orientation $(\Gamma, Z)$. The group $C^*$-algebra in this case may be considered – at least at the level of homology – as a ‘noncommutative compact smooth oriented manifold’ of dimension $d$ with the ‘Dirac class’ $[\hat{\Gamma}] \in KK^d_0(\mathbb{C}, \mathbb{C}) \cong K^d(C^*(\Gamma))$ defined below, playing the role of the class of the associated Dirac operator.

Choose a point $x_0 \in Z$. The group $\Gamma$ acts on $l^2\Gamma$ by the regular representation. The composition

$$
(4.1) \quad \text{ev} : C_0(Z) \xrightarrow{\text{restr}} C_0(\Gamma x_0) \to C_0(\Gamma) \xrightarrow{\text{mult}} K(l^2\Gamma)
$$

is a $\Gamma$-equivariant $*$-homomorphism and determines a class

$$
(4.2) \quad [\text{ev}] \in KK^0_0(C_0(Z), \mathbb{C}).
$$

Since $Z$ is a classifying space, it is path-connected and $[\text{ev}]$ is independent of the choice of point.

Definition 4.3. Let $(\Gamma, Z)$ be a smooth oriented group of dimension $d$. A Dirac class for $\Gamma$ is any class

$$
[\hat{\Gamma}] \in K^d(C^*(\Gamma)) = KK^d_0(\mathbb{C}, \mathbb{C})
$$

such that

$$
L([\hat{\Gamma}]) = [\text{ev}] \in KK^0_0(C_0(Z), \mathbb{C}),
$$

where $L$ is the localization map (Definition 2.3).

The definition is of course largely motivated by Theorem 3.17.

Remark 4.4. One could make a variant of the definition involving the reduced $C^*$-algebra of the group. The projection $C^*(\Gamma) \to C^*_r(\Gamma)$ induces a pullback map $K^*(C^*_r(\Gamma)) \to K^*(C^*(\Gamma))$ so there is an associated (reduced) localization map

$$
(4.5) \quad K^*(C^*_r(\Gamma)) \to K^*(C^*(\Gamma)) \cong KK^*_0(\mathbb{C}, \mathbb{C}) \xrightarrow{\otimes [Z_d]} KK_{d+d}^*(C_0(Z), \mathbb{C}).
$$

Occasionally we will call a class in $KK_{d+d}(C^*_r G, \mathbb{C})$ mapping to $[\text{ev}] \in KK^0_0(C_0(Z), \mathbb{C})$ under the reduced localization map a reduced Dirac class; note that the projection $C^*_r(\Gamma) \to C^*(\Gamma)$ pulls a reduced Dirac class back to a Dirac class, so the existence of a reduced class is stronger.

Example 4.6. If $\Gamma$ is finite, so $Z$ is a point, the localization map is the identity map and the Dirac class for $\Gamma$ is represented by the homomorphism

$$
\lambda : C^*(\Gamma) \to K(l^2\Gamma),
$$

induced by the regular representation. In particular, if $\Gamma$ is finite abelian, so that $C^*(G) \cong C(\hat{G})$, the Dirac class of $G$ is the sum of the point K-homology classes of $\hat{G}$. More generally, the Dirac class of a finite group is the sum of the point K-homology classes of the points of $G$, each with multiplicity given by its dimension.

Proposition 4.7. The Dirac class $[\hat{\mathbb{Z}^d}] \in KK^d_0(\mathbb{C}, \mathbb{C}) \cong K^d(C^*(\mathbb{Z}^d))$ of the smooth oriented group $(\mathbb{Z}^d, \mathbb{R}^d)$ is the Fourier transform of the transverse Dirac class $[\mathbb{Z}^d]$ of its Pontryagin dual.
4.2. The Dirac class is non-torsion. The following proves that $\hat{[\Gamma]}$ is always nonzero and non-torsion in $K^d(C^*(\Gamma))$. The result will be refined later.

**Proposition 4.8.** Let $(\Gamma, Z)$ be a smooth, $K$-oriented group, and $[\hat{\Gamma}] \in K^d(C^*(\Gamma))$ a Dirac class. Let

$$\mu: KK^\Gamma_*(C_0(Z), \mathbb{C}) \to K_*(C^*(\Gamma))$$

be the Baum-Connes assembly map. Then

$$\langle \mu([Z]), [\hat{\Gamma}] \rangle := \mu([Z]) \otimes_{C^*(\Gamma)} [\hat{\Gamma}] = 1 \in KK(C, \mathbb{C}) \cong \mathbb{Z}.$$  

In particular, the Dirac class $[\hat{\Gamma}]$ of any smooth $K$-oriented group induces a surjection $K_*(C^*(\Gamma)) \to \mathbb{Z}$, and is never zero in $K$-homology, nor torsion.

The analogous statement holds for a reduced Dirac class.

**Proof.** Denote by $f \mapsto \overline{f}$ the descent map $KK^\Gamma_*(A, B) \to KK_*(A \rtimes \Gamma, B \rtimes \Gamma)$. If $(\Gamma, Z)$ is a smooth oriented group, then $\pi \Gamma = Z$ and the Baum-Connes assembly map with coefficients $B$ is, by definition, $\mu(f) = [P_\varphi] \otimes_{C_\Gamma(\mathcal{Z}) \rtimes \Gamma} [\overline{f}]$ for any $f \in KK^\Gamma_*(C_0(\mathcal{Z}), B)$, and any cut-off function $\varphi \in C_\Gamma(\mathcal{Z})$, $0 \leq \varphi \leq 1$ and $\sum_{g \in \Gamma} g(\varphi) = 1$. The space of cut-off functions is convex and nonempty, and $P_\varphi := \sum_{g \in \Gamma} g(\varphi)[g] \in C_0(\mathcal{Z}) \rtimes \Gamma$ is a projection whose homotopy-class does not depend on the choice of cut-off function. For the element $[\text{ev}] \in KK^\Gamma_*(C_0(\mathcal{Z}), \mathbb{C})$ and the element $[P_\varphi] \in K_0(C_0(\mathcal{Z}) \rtimes \Gamma)$, observe that the map $C_0(\mathcal{Z}) \rtimes \Gamma \to C_0(\mathcal{Z}) \rtimes \Gamma \cong C_0(\Gamma) \rtimes \Gamma = K(\ell^2\Gamma)$ maps $P_\varphi$ to a projection homotopic through projections to a rank-one projection. Hence

$$\langle [\text{ev}], [P_\varphi] \rangle = 1.$$  

On the other hand, descent maps the Dirac class $[Z] \in KK^\Gamma_{-d}(C_0(Z), \mathbb{C})$ to a class $[Z] \in KK_{-d}(C_0(\mathcal{Z}) \rtimes \Gamma, C^*(\Gamma))$, and identifying $KK^\Gamma_{*}(C_0(Z), \mathbb{C}) \cong KK^\Gamma_{*}(C_0(Z) \rtimes \Gamma, \mathbb{C})$, the Dirac map can be identified with the map

$$KK_*(C^*(\Gamma), \mathbb{C}) \to KK_{-d}(C_0(Z) \rtimes \Gamma, \mathbb{C})$$

of composition with $[Z]$. Hence

$$\langle \mu([Z]), [\hat{\Gamma}] \rangle = [P_\varphi] \otimes_{C_0(Z) \rtimes \Gamma} [\overline{[Z]}] \otimes_{C^*(\Gamma)} [\hat{\Gamma}] = [P_\varphi] \otimes_{C_0(\mathcal{Z}) \rtimes \Gamma} [\mathcal{C}(\overline{[\hat{\Gamma}]}))] = [P_\varphi] \otimes_{C_0(\mathcal{Z}) \rtimes \Gamma} [\text{ev}] = 1 \in \mathbb{Z} \cong KK_0(C, \mathbb{C})$$

as claimed. \hfill $\square$

4.3. Dirac classes and the dual-Dirac method. If $(\Gamma, Z)$ is a smooth, oriented group, then a dual-Dirac class for $\Gamma$ is a class

$$\eta \in KK^\Gamma_0(C, C_0(Z))$$

such that $[Z] \otimes_{C} \eta = 1_{C_0(Z)} \in KK^\Gamma_0(C_0(Z), C_0(Z))$. The existence or non-existence question of such $\eta$ is determined by a certain coarse co-assembly map (see [23]), and so is a question about the large-scale geometry of $\Gamma$. The fact that the two coordinate projections $Z \times Z \to Z$ are $\Gamma$-equivariantly homotopy implies by an easy exercise that $[Z] \otimes_{C} \eta = 1_{C_0(Z)}$ as well.

If $Z$ admits a $\Gamma$-invariant Riemannian metric of nonpositive curvature, then a dual-Dirac class exists and is described in detail below. More generally, a dual-Dirac morphism $\eta$ exists if $\Gamma$ admits a uniform embedding in Hilbert space (this theorem appears as Theorem 9.2 in [17] but it is a consequence of assembling results of many others, like [30], [11], or [12]). This is the case if $G$ is linear, or hyperbolic, for example.
Proposition 4.11. If $(\Gamma, Z)$ is a smooth oriented, group with a dual-Dirac morphism $\eta \in \text{KK}^1_{\mathbb{Z}}(\mathbb{C}; C_0(Z))$, then
\[ \eta \otimes_{C_0(Z)} [\text{ev}] \in \text{KK}^1_{\mathbb{Z}}(\mathbb{C}, \mathbb{C}) \cong \mathbb{K}^d(\mathbb{C}^*(\Gamma)) \]
is a Dirac class for $\Gamma$.

Proof. $[Z] \otimes_{\mathbb{C}} (\eta \otimes_{C_0(Z)} [\text{ev}]) = ([Z] \otimes_{\mathbb{C}} \eta) \otimes_{C_0(Z)} [\text{ev}] = [\text{ev}]$ since $[Z] \otimes_{\mathbb{C}} \eta = 1_{C_0(Z)}$. \hfill $\Box$

Let $\Gamma$ be torsion-free, so $K_\ast(C_0(Z) \times \Gamma) \cong K^\ast(\Gamma \setminus Z) \cong K^\ast(B\Gamma)$ and a class $a$ in this ring yields a higher signature, associating to any compact manifold $M$ with fundamental group $\Gamma$ the index $(D^M_\Gamma \cdot \chi^a)$ of the signature operator on $M$ twisted by the K-theory class $\chi^a$, where $\chi: M \rightarrow B\Gamma$ is the classifying map for $M$.

By a theorem of Kaminker and Miller [41], building on work of many others, such classes are homotopy-invariant when they are in the range of the inflation map
\begin{equation}
\text{inflate}: \text{KK}^1_{\mathbb{Z}}(\mathbb{C}, \mathbb{C}) \rightarrow \text{RKK}^1_{\mathbb{Z}}(Z; \mathbb{C}, \mathbb{C}) \cong K^\ast(\Gamma \setminus Z) \cong K^\ast(B\Gamma).
\end{equation}
see (2.8).

Since the composition of the inflation map and Poincaré duality
\[ \text{KK}^1_{\mathbb{Z}}(\mathbb{C}, \mathbb{C}) \xrightarrow{\text{infl}} \text{RKK}^1_{\mathbb{Z}}(Z; \mathbb{C}, \mathbb{C}) \cong K^\ast(\Gamma \setminus Z) \xrightarrow{\text{PD}} K^\ast_{-\ast}(\Gamma \setminus Z) \cong K^\ast_{-\ast}(B\Gamma) \]
is exactly the Dirac map, it follows that the higher signature associated to the Poincaré dual of any class in the range of the Dirac map, is homotopy-invariant.

This applies in particular to the point class $[\cdot] \in K_0(\Gamma \setminus Z)$ (or $[\text{ev}] \in \text{KK}^0_{\mathbb{Z}}(C_0(Z), \mathbb{C})$, as we have been denoting it above.)

Corollary 4.13. Let $(\Gamma, Z)$ be a smooth oriented, torsion-free group. Then a Dirac class for $\Gamma$ is a pre-image in $\text{KK}^1_{\mathbb{Z}}(\mathbb{C}, \mathbb{C})$ of the Poincaré dual of a point in $K^{\ast-d}(\Gamma \setminus Z) \cong K^{\ast-d}(B\Gamma)$, under the inflation map.

In particular, the higher signature associated to the Poincaré dual of a point in $\Gamma \setminus Z \cong B\Gamma$ is homotopy-invariant as soon as a Dirac class exists for $\Gamma$.

The Poincaré dual of a point, and the question of the homotopy-invariance of the higher signature associated to it, is studied in [9] by Connes, Gromov and Moscovici. In their paper, they analyze geometric conditions one can put on a group under which one can write down a `Dirac class’, thus guaranteeing homotopy-invariance (for a single cohomology class). The procedure they use to build such `Dirac cycles’ (they build more general ones as well), is based on the non-positive curvature idea we exploit below.

Assume that $(\Gamma, Z)$ is a smooth oriented group such that $Z$ admits a $\Gamma$-invariant metric of nonpositive curvature. For example, $\Gamma$ could be a discrete subgroup of a connected and semisimple Lie group $G$; if $K \subset G$ is the maximal compact subgroup, then $G/K$ is a symmetric space of nonpositive curvature admitting a $G$-invariant (and hence $\Gamma$-invariant) orientation.

The hypotheses say that there is a $\Gamma$-equivariant spinor bundle $S$ on $Z$, and a $\Gamma$-equivariant bundle map
\[ \text{Cliff}(TZ) \otimes S \rightarrow S \]
specifying the Clifford multiplication on $S$. We denote Clifford multiplication by a tangent vector $\xi$ by $c(\xi)$, so if $z \in Z$ and $\xi \in T_zZ$ is a unit tangent vector then $c(\xi)$ is a certain self-adjoint endomorphism of $S_z$ with square 1.

For $z \in Z$ let $\exp: T_zZ \rightarrow Z$ be the exponential map, a diffeomorphism, and $\log_z: Z \rightarrow T_zZ$ its inverse. Then nonpositive curvature implies that $\log$ is a Lipschitz map, that is, $|\log_z(x) - \log_z(y)| \leq d(x, y)$, where $d$ is the metric on $Z$ induced by the Riemannian metric on $Z$. Let
\[ \delta \in \text{End}(S) \]
be the (unbounded) bundle endomorphism of the spinor bundle given by
\[ \delta(z, \xi) = c(\log_z(z_0)) \]

The group \( \Gamma \) acts by unitary bundle maps of \( S \), giving the module \( C_0(Z, S) \) of sections the structure of a \( \Gamma \)-Hilbert module. Moreover, the multiplier \( \delta \) almost-commutes with \( \Gamma \), because \( \log_z \) is Lipschitz.

The cycle consisting of the \( C_0(Z) \)-module \( C_0(Z, S) \) of sections of \( S \), together with the unbounded endomorphism \( \delta \), represents the dual-Dirac morphism
\[ \eta \in KK_{\Gamma}^*(C_0(Z)). \]

Restricting it to an orbit gives a concrete model for the composition
\[ \delta \otimes C_0(Z) [ev] \in KK_{\Gamma}^*(C_0(Z)). \]

The Hilbert space is \( l^2(\Gamma, S) \), the unitary group action is induced from the initial action on \( S \), and the operator is the restriction of \( \delta \) above to the orbit, a Clifford multiplication operator on \( l^2(\Gamma, S) \).

It defines a spectral triple \( (l^2(\Gamma, V), \pi, \delta) \) for \( C^* (\Gamma) \) (not finitely summable in general, see Remark 4.15).

**Theorem 4.14.** If \( (\Gamma, Z) \) is a smooth oriented group and \( Z \) is equipped with a \( \Gamma \)-invariant metric of nonpositive curvature, then the spectral triple \( (l^2(\Gamma, S), \delta) \) defined above represents a Dirac class \([\hat{\Gamma}]\) for \( \Gamma \).

Furthermore, it is defined over the reduced \( C^* \)-algebra of \( \Gamma \) and hence there is a reduced Dirac class for \( \Gamma \) in this case, given by the same cycle but regarded as defined over \( C^* (\Gamma) \).

**Proof.** This follows from Proposition 4.11 and the discussion prior to the statement. \( \square \)

**Remark 4.15.** The Fredholm module (defined over \( C^* (\Gamma) \)), its class is a reduced Dirac class just described is finitely summable if \( \Gamma \) has polynomial growth. By a result of Connes, the existence of a finitely summable spectral triple representing a nonzero class in \( KK_{\Gamma}^0(C_0(Z)) \) implies amenability of \( \Gamma \) (see [7]).

**Remark 4.16.** A. Connes has described Dirac cycles for discrete groups – representatives, in our terminology, of the Dirac class \([\hat{\Gamma}]\) – in his book [7], and again, these are the same cycles we describe below.

5. **Transverse Dirac classes for smooth actions**

In Section 2 we discussed the transverse Dirac class \([Z] \in KK_{\Gamma}^d(C_0(Z), C)\) when \( (\Gamma, Z) \) is a K-oriented group, also pointed out that one can similarly define the transverse Dirac class \([X] \in KK_{\Gamma}^d(C_0(X), C)\) for a smooth manifold admitting a proper and K-orientation-preserving action of \( \Gamma \), in the form of a direct construction of an analytic cycle for KK in the form of the Dirac operator on \( X \) associated to the K-orientation.

In this section we are going to extend the definition of such transverse Dirac classes to non-proper actions, some of which, like the action of a surface group \( \Gamma \) on the boundary circle of the hyperbolic plane, leave no Riemannian metric invariant, which makes it difficult to construct a \( \Gamma \)-equivariant Dirac operator directly. Our main goal in this section is to define the problem, in terms of the localization map.

For any locally compact group with classifying space \( \mathcal{E} \Gamma \) for proper actions, the transformation groupoid \( \mathcal{G}_\Gamma := \Gamma \times \mathcal{E} \Gamma \) is a proper groupoid. A proper groupoid with a one-point unit space is a compact group. So proper groupoids generalize compact groups. The \( \mathcal{G} \)-equivariant Kasparov category \( KK_{\mathcal{G}}^* \) is defined by Le Gall in [37] for any locally compact groupoid. It is functorial in
the groupoid, so the homomorphism of groupoids $\mathcal{G}_\Gamma \to \Gamma$ by mapping $\mathcal{E}\Gamma$ to a point induces a natural map
\begin{equation}
\text{inflate} : KK_\chi^\Gamma(A, B) \to KK_\chi^\mathcal{G}_\Gamma(C_0(\mathcal{E}\Gamma) \otimes A, C_0(\mathcal{E}\Gamma) \otimes B)
\end{equation}

This is Kasparov’s inflation map [28], after identifying $KK_\chi^\mathcal{G}_\Gamma(C_0(\mathcal{E}\Gamma) \otimes A, C_0(\mathcal{E}\Gamma) \otimes B)$ with Kasparov’s $KK_\chi^\Gamma(\mathcal{E}\Gamma; A, B)$ defined in [33].

\begin{remark}
Isomorphism of the inflation map for a given $\Gamma$ and arbitrary $A, B$ is implied by the $\gamma = 1$ version of the Baum-Connes conjecture (see [39]). If $\Gamma$ acts amenably on $X$ and $A = \mathcal{C}_0(X)$ then (5.1) is an isomorphism by the Higson-Kasparov-Tu theorem (28, 42) (these authors prove that $\gamma = 1$).
\end{remark}

It is generally easier to direct analytic cycles for $KK_\Gamma^\gamma$, representing for example wrong-way maps $f^!$, than it is in $KK_\Gamma$, as the following example illustrates – it is because inflation results in a significant weakening of the equivariance condition on cycles.

\begin{example}
Let $\Gamma$ be any countable group of diffeomorphisms of the circle $\mathbb{T}$. Then the action is $KK$-orientable, as we show below, and we construct an analytic cycle in $KK_\Gamma^\mathbb{T,0}(\mathcal{E}\Gamma; C(\mathbb{T}), \mathbb{C})$ representing for example the wrong-way map $f^!$

Assume for simplicity that $\mathcal{E}\Gamma$ is $\Gamma$-compact and can be $\Gamma$-equivariant triangulated, fix such a triangulation.

Identify $\mathbb{T} = \mathbb{R}/\mathbb{Z}$ with coordinate $x$. Let $dx^2$ denote the usual Riemannian metric on the circle. Suppose we change the metric by multiplying by a smooth, positive function $h \in C^\infty(\mathbb{T})_+$. The new metric is $h(x) \cdot dx^2$, it assigns length $\sqrt{h(x)}$ to the tangent vector $\frac{\partial}{\partial x}$ at $x \in \mathbb{T}$. The Dirac operator associated to this Riemannian metric and the standard orientation on the circle is then
\begin{equation}
D_h := h(x)^{-\frac{1}{2}} \cdot D, \quad \text{where} \quad D = -i \frac{\partial}{\partial x},
\end{equation}

$D_h$ is a self-adjoint elliptic operator on $L^2(\mathbb{T}, \mu_h)$ where $\mu_h$ is the measure $\sqrt{h} \cdot dx$.

The group $G$ of diffeomorphisms of $\mathbb{T}$ acts on the space of Riemannian metrics on $\mathbb{T}$, and $g \in G$ pulls the Riemannian metric $h(x) \cdot dx^2$ to the Riemannian metric $h(g^{-1}x)g'(g^{-1}x) \cdot dx^2$.

Let
\begin{equation}
(U_g \xi)(x) = \xi(g^{-1}x).
\end{equation}

Then, for any $h$, $U$ extends to a unitary isomorphism $U : L^2(\mathbb{T}, \mu_h) \rightarrow L^2(\mathbb{T}, \mu_{g(h)})$, and $U_g D_h U_g^* = D_{g(h)}$, where
\begin{equation}
g(h)(x) = h(g^{-1}x) \cdot g'(g^{-1}x),
\end{equation}

corresponding to the pulled-back metric (discussed above), $\mu$ is Lebesgue measure.

We have described, for every $h \in C^\infty(\mathbb{T})_+$, an odd spectral triple
\begin{equation}
(L^2(\mathbb{T}, \mu_h), \pi, D_h),
\end{equation}

where $\pi : C(\mathbb{T}) \rightarrow \mathcal{L}(L^2(\mathbb{T}, \mu_h))$ is the representation by multiplication operators. Furthermore, as observed above, $U_g : L^2(\mathbb{T}, \mu_h) \rightarrow L^2(\mathbb{T}, \mu_{g(h)})$ is a unitary isomorphism conjugating $D_h$ to $D_{g(h)}$.

We now return to the simplicial space $\mathcal{E}\Gamma$. We aim to build a $\Gamma$-equivariant bundle of spectral triples (for $C(\mathbb{T})$ over $\mathcal{E}\Gamma$). Start with the vertices $\mathcal{E}\Gamma^0$. It is a discrete and $G$-finite discrete space, and divides into $G$-orbits. An orbit identifies with $G/H$ where $H \subset G$ is a finite subgroup of $G$. Choose any $h \in C^\infty(\mathbb{T})_+$, determining a Riemannian metric on $\mathbb{T}$, and average it over $H$ to get an $H$-invariant Riemannian metric; in this way we can assume $h \in C^\infty(\mathbb{T})$ gives an $H$-invariant metric to begin with. This implies that the Dirac operator $D_h$ is $H$-fixed under the translation action of $H$ on $\mathbb{T}$. We then obtain the family $\{D_{g(h)}\}_{g \in G/H}$ of spectral triples over $\mathbb{T}$, so that the unitary maps $U_g$ given by elements of $g \in G$ intertwine them exactly.
In this way we define our bundle over the vertex set $\mathcal{E}\Gamma^{(0)}$. As we have discussed, the spectral triple at any point is determined completely by the Riemannian metric corresponding to that point, and the conjugation action of $G$ corresponds to the usual action of $G$ on Riemannian metrics. The space of metrics (or, equivalently, $C^\infty(\mathbb{T})_+$), is convex. Hence Using barycentric coordinates over a simplex whose vertices are assigned points in a convex space, one can map the simplex into the space. In this way, we obtain a $G$-equivariant map $\mathcal{E}\Gamma \to C^\infty(\mathbb{T}),_+$ (where the latter convex space has the $G$-action described above,) and hence a family $\{D_p\}_{p \in \mathcal{E}\Gamma}$ of spectral triples over $C(\mathbb{T})$, which, as a family, is $G$-equivariant.

This cycle represents

$$pr_{T,\mathcal{E}\Gamma}! \in \text{KK}_{*}(\mathcal{E}\Gamma; C(\mathbb{T}), \mathbb{C})$$

– see Definition 5.6 below.

Note that if a point of $\mathcal{E}\Gamma$ is fixed, corresponding to a given $h \in C^\infty(\mathbb{T})_+$, the associated spectral triple with operator $D_h$, is homotopic in an obvious sense, to the ordinary Dirac operator $D$ on $\mathbb{T}$. Along the same lines, if the group $\Gamma$ acts from the beginning by Riemannian isometries of the circle, then one could just form the constant family; this would give a homotopic cycle to the one just discussed.

The papers [20] and [21], formalize the constructions of wrong-way morphisms $f!$ in $\text{KK}^G$, where $G$ is any proper groupoid, one of the main motivations being to apply it to the current situation. The morphism we have denoted

$$pr_{T,\mathcal{E}\Gamma}! \in \text{KK}_{*}(\mathcal{E}\Gamma; C(\mathbb{T}), \mathbb{C}) = \text{KK}^G_0(C_0(\mathcal{E}\Gamma \times \mathbb{T}), C_0(\mathcal{E}\Gamma))$$

in the above Example is an instance.

The groupoid-equivariant theory of wrong-way maps and correspondences is a bundle version, roughly speaking, of the usual theory. A smooth $\mathcal{G}$-manifold $X$ is, by definition, a bundle of smooth manifolds over the base $\mathcal{G}^0$ of $\Gamma$. Morephisms in $\mathcal{G}$ act by diffeomorphisms between fibres. There is a natural notion of smooth $\mathcal{G}$-equivariant map between two $\mathcal{G}$-manifolds, meaning that it is fibrewise smooth (and equivariant). One may similarly define $\mathcal{G}$-equivariant K-orientations, prove the $\mathcal{G}_t$-equivariant Thom Isomorphism ([37]) and [20, 21] develop a purely topological category of $\mathcal{G}$-equivariant correspondences based on these $\mathcal{G}$-manifolds, and smooth $\mathcal{G}$-maps between them.

The wrong way elements $f! \in \text{KK}^G_{\dim Y - \dim(X)}(C_0(X), C_0(Y))$, for smooth $K$-oriented $\mathcal{G}$-maps $f$ between $\mathcal{G}$-manifolds $X$ and $Y$, that we describe in this theory, are based on Atiyah’s topological index, and use only equivariant (fibrewise, equivariant ) Thom isomorphisms and (fibrewise, equivariant) open embeddings; the corresponding analytic constructions of such morphisms have been studied in the literature for a long time, of course, going back to [10]. The reference [22] discusses analytic construction of shriek maps in some detail, especially in the groupoid-equivariant setting. The last section of [21] discusses analytic shriek maps and the comparison to topological ones, also in the equivariant setting.

Remark 5.4. In the theory of topological correspondences, in order to define wrong-way elements $f! \in \text{KK}^G_{\dim Y - \dim(X)}(C_0(X), C_0(Y))$ where $\mathcal{G}$ is a proper groupoid, we need more in the way of hypotheses. What is needed is that $X$ embeds equivariantly into the total space of a $\mathcal{G}$-equivariant vector bundle over $\mathcal{G}^0$. This is analogous to the existence of an embedding of any manifold in a Euclidean space, but the equivariance condition in the groupoid-equivariant context is quite strong. There are simple examples of proper groupoids which do not embed equivariantly in a vector bundle in this sense. (See [20].) However, such embeddings are guaranteed if $\mathcal{G}$ has a ‘full vector bundle’ over it’s base (see [20]) and this is the case if $\mathcal{G} = \Gamma \ltimes \mathcal{E}\Gamma$ for a discrete group $\Gamma$ with co-compact $\mathcal{E}\Gamma$, the classifying space for proper actions, by a result of Lück and Oliver. More generally, it is proved in [21] that with the hypothesis, that $Z$ has a full
equivariant vector bundle over its base, all three theories: that of $G$-equivariant correspondences using normally non-singular maps, smooth $G$-equivariant correspondences (without requiring normal data), and the analytically defined theory $KK^G$ of LeGall all give the same theory, for smooth $G$-manifolds.

In order to avoid any pathologies, then, we will put a blanket assumption on the discrete groups $\Gamma$ studied in this paper, that $\Gamma \times \mathcal{E} \Gamma$ is compact. As above, then, the transformation groupoid $G_T := \Gamma \times \mathcal{E} \Gamma$ is proper and has a full vector bundle on its base, and the above results apply.

**Definition 5.5.** Let $X$ a locally compact space with a continuous action of the discrete group $\Gamma$ with $\Gamma$-compact $\mathcal{E} \Gamma$. Let $G_T := \mathcal{E} \Gamma \times \Gamma$ the corresponding (proper) transformation groupoid, a $KK$-orientation on the $\Gamma$-action on $X$, is an endowment of the $G_T$-space $\mathcal{E} \Gamma \times \Gamma$ with the structure of a smooth, $G_T$-equivariantly $K$-orientable $\mathcal{G}_T$-manifold.

The $K$-orientation assumption posits a $G_T$-equivariant bundle of $K$-orientations on the vertical tangent bundle of the projection $\mathcal{E} \Gamma \times X \rightarrow \mathcal{E} \Gamma$. Thus, a $KK$-orientation in our sense is not a single fixed $K$-orientation, but an equivariant bundle of them, over $\mathcal{E} \Gamma$.

The smoothness assumption means that we are given a bundle, parameterized by the points of $\mathcal{E} \Gamma$, of smooth structures on $X$, such that a group element $g \in \Gamma$ acts as a diffeomorphism between $X$ with the smooth structure assigned to $p \in \mathcal{E} \Gamma$, to $X$ with the smooth structure assigned to $g(p)$.

In particular, this structure endows $X$ with a manifold structure by including it as a fibre in $\mathcal{E} \Gamma \times X$; however, it is not necessarily true that this smooth structure is constant as one moves from one fibre to another. This is because the $\Gamma$-action on $X$ can actually fail to be smooth, even if the bundle is smooth (boundary actions of hyperbolic groups provide an example, see Lemma 7.3 and discussion around it).

If one excludes these examples, there is no reason for purposes of this paper not to assume that the $\Gamma$-action on $X$ was smooth to begin with; then one can of course given $\mathcal{E} \Gamma \times X$ the constant fibrewise smooth structure.

For compact groups, $\mathcal{E} \Gamma$ can be taken to be a point, and Definition 5.5 reduces to the standard definition of a smooth, equivariantly ($K$-)oriented manifold $X$.

**Definition 5.6.** Let $\Gamma$ be a discrete group and $X$ a $\Gamma$-equivariantly $KK$-orientable manifold (Definition 5.5)

A **transverse Dirac class** for $X, \Gamma$ is a class

$$[X] \in KK_{-n}(C_0(X), C)$$

such that

$$\text{inflate}([X]) = \text{pr}_{X, \mathcal{E} \Gamma}! \in KK^G_n(C_0(X \times \mathcal{E} \Gamma), C_0(\mathcal{E} \Gamma)),$$

where $\text{pr}_{X, \mathcal{E} \Gamma}! \in KK^G_n(C_0(X \times \mathcal{E} \Gamma), C_0(\mathcal{E} \Gamma))$ is the class of the $G$-equivariant fibrewise smooth and $G$-equivariantly $K$-oriented non-singular map $\text{pr}_{X, \mathcal{E} \Gamma} : X \times \mathcal{E} \Gamma \rightarrow \mathcal{E} \Gamma$ discussed above, and inflate is as in (6.1).

**Example 5.7.** If $\Gamma$ is the trivial group, then the class $[X] \in KK_{-n}(C_0(X), C) = K_n(X)$ of the Dirac operator on $X$ is a transverse Dirac class.

If $X$ is a point, $\Gamma$ an arbitrary locally compact group, then the class $1 \in KK^G_n(C, C)$ of the trivial representation of $\Gamma$ is a transverse Dirac class for the action of $\Gamma$ on a point.

**Example 5.8.** If $\Gamma$ is compact, so $\mathcal{E} \Gamma$ is a point, then one definition of a $KK$-orientable action of $\Gamma$ on $X$ boils down to the usual assumption of a $\Gamma$-equivariantly $K$-oriented manifold, and the transverse Dirac class $[X] \in KK^G_{-\dim X}(C_0(X), C)$ is represented by the usual Dirac cycle discussed in the first paragraph of this paper.
More generally, if $\Gamma$ acts smoothly and properly on $X$, preserving a $K$-orientation in the sense of the discussion at the beginning of the paper, then as remarked there one can directly construct a $\Gamma$-equivariant Dirac operator and class $[D_X] \in KK_{n}^{\Gamma}(C_0(X), \mathbb{C})$. Inflating this class gives the cycle for $RKK_{n}^{\Gamma}(\mathcal{E}\Gamma; C_0(X), \mathbb{C})$ consisting of the (constant) bundle of Dirac operators along the fibres of $X$ with respect to the (constant) bundle of $K$-orientations.

The equality
\[ \text{inflate}([D_X]) = p_{\mathcal{E}\Gamma, X}! \]
and the consequent one that $[D_X]$ is the transverse Dirac class, follows from the basic index theorem of Kasparov theory (that the analytically and topologically defined shriek maps coincide.)

Note that in the case of a proper action, the inflation map
\[ \text{inflate}: KK_{0}^{\Gamma}(C_0(X), \mathbb{C}) \to KK_{0}^{\Gamma}(C_0(X \times \mathcal{E}\Gamma), C_0(\mathcal{E}\Gamma)) = RKK_{0}^{\Gamma}(\mathcal{E}\Gamma; C_0(X), \mathbb{C}) \]
is an isomorphism. Therefore, transverse Dirac classes exist and are unique in these cases. The same holds if the action is merely amenable.

**Remark 5.9.** Hilsum and Skandalis in [11] define equivariant $K$-orientability of a smooth but potentially non-isometric group $\Gamma$ action on a smooth manifold $X$, using the metaplectic group in place of the spin group, and they construct a corresponding analytic morphism
\[ [X] \in KK_{\dim X}^{\Gamma}(C_0(X), \mathbb{C}) \]
using hypo-elliptic operator theory and a frame bundle construction. It would see to us almost certainly true that Hilsum-Skandalis $K$-orientability (of a smooth action) implies $K$-orientability in our sense, but we do not address the proof in this article, since it is not particularly material for us; we leave it as an open question as to whether transverse Dirac classes exist in full generality for smooth actions.

If $\Gamma$ has property $T$ and a $\gamma$-element, then the class in $KK_{0}^{\Gamma}(\mathbb{C}, \mathbb{C})$ of the $\gamma$-element maps to $1 \in RKK_{0}^{\Gamma}(\mathcal{E}\Gamma; \mathbb{C}, \mathbb{C})$ under the inflation map, and hence the $\gamma$-element is a transverse Dirac class for $\Gamma$ acting on a point; however, it is not equal to the class $[\epsilon] \in KK_{0}^{\Gamma}(\mathbb{C}, \mathbb{C})$ of the class of the trivial representation of $\Gamma$. Thus there is more than one transverse Dirac class for a property $T$ group $\Gamma$ acting on a point.

**Lemma 5.10.** Let $X$ carry a $KK$-orientable action of $\Gamma$. Then the $\Gamma$-action on $X \times Z$ acquires an induced $KK$-orientation, $X \times Z$ has a transverse Dirac class $[X \times Z]$, and
\[ \text{PD}(\text{pr}_{Z,X}!) = [X \times Z] \in KK_{n-d}^{\Gamma}(C_0(X \times Z), \mathbb{C}), \]
where $\text{PD}$ is Kasparov’s Poincaré duality.

This follows from the description of $\text{PD}$ given in the discussion preceding Proposition 2.10.

**Proposition 5.11.** If $(\Gamma, Z)$ is a smooth, oriented group, and $\Gamma$ acts $KK$-orientably on $X$, and if $[X] \in KK_{-n}^{\Gamma}(C_0(X), \mathbb{C})$ is a transverse Dirac class for $X$ and $[X \times Z]$ the transverse Dirac class for the $\Gamma$-manifold $X \times Z$, then
\[ \mathcal{L}([X]) = [X \times Z] \in KK_{n-d}^{\Gamma}(C_0(X \times Z), \mathbb{C}), \]
where $\mathcal{L}$ is the localization map.

Moreover, if $\Gamma$ is torsion-free, then $KK_{0}^{\Gamma}(C_0(X \times Z), \mathbb{C}) \cong K_{*}(X \times_{\Gamma} Z)$ and with this identification
\[ \mathcal{L}([X]) = [X \times_{\Gamma} Z] \in K_{n+d}(X \times_{\Gamma} Z), \]
where $[X \times_{\Gamma} Z]$ is the class of the Dirac operator on $X \times_{\Gamma} Z$ (the transverse Dirac class of the trivial group acting on $X \times_{\Gamma} Z$.)
Since $\mathcal{L}([X]) = [X] \otimes_C [Z]$, the external product in $\text{KK}^\Gamma$, the Proposition is the multiplicativity statement for transverse Dirac classes

\[(5.12) \quad [X] \otimes_C [Z] = [X \times Z]\]

when $X$ has a transverse Dirac class.

**Proof.** We use the inflation map

\[
\text{inflate} : \text{KK}^\Gamma(\mathbb{C}^0(X \times Z), \cdot) \rightarrow \text{RKK}^\Gamma(\mathbb{E}, \mathbb{C}^0(X \times Z), \mathbb{C}^0(X \times Z), \mathbb{C}) \cong \text{KK}^\Gamma(\mathbb{E} \times \mathbb{W}, \mathbb{C}^0(\mathbb{E} \times \mathbb{W}), \mathbb{C}^0(\mathbb{E} \times \mathbb{W}))
\]

in this argument, which is an isomorphism since $X \times Z$ is proper.

By the discussion in Example 5.8, the Dirac class we always denoted $[Z] \in \text{KK}^\Gamma_n(\mathbb{C}^0(Z), \mathbb{C})$, is the same as the transverse Dirac class, thus inflate([Z]) = $\text{pr}_{\mathbb{E} \times \mathbb{W}}!$, while inflate([X]) = $\text{pr}_{\mathbb{E} \times \mathbb{W}}!$ for any transverse Dirac class $[X]$. Since inflation is an isomorphism respecting external products, (5.12) is equivalent to the identity

\[\text{pr}_{\mathbb{E} \times \mathbb{W}}! \otimes_C \text{pr}_{\mathbb{E} \times \mathbb{W}}! = \text{pr}_{\mathbb{E} \times \mathbb{W}}!,\]

which is the basic multiplicativity property of shriek maps.

The converse holds as well, which is sometimes useful for identifying when a given construction has produced a transverse Dirac class $[X]$, since in practical terms, external products like $[X] \otimes_C [Z]$ can be described concretely if the constituents are described as unbounded cycles.

**Proposition 5.13.** A class $[X] \in \text{KK}^\Gamma_n(\mathbb{C}^0(X), \mathbb{C})$ is a transverse Dirac class if and only if

\[ [X] \otimes_C [Z] = [X \times Z] \in \text{KK}^\Gamma_{n-d}(\mathbb{C}^0(X \times Z), \mathbb{C}). \]

where $[X \times Z]$ is the transverse Dirac class of the proper space $X \times Z$ (and the left-hand side is the external product in $\text{KK}^\Gamma$).

**Proof.** Suppose $[X] \in \text{KK}^\Gamma_n(\mathbb{C}^0(X), \mathbb{C})$ satisfies

\[ [X] \otimes_C [Z] = [X \times Z], \]

that is, suppose that $\mathcal{L}([X]) = [X \times Z]$. I claim that inflate([X]) = $\text{pr}_{\mathbb{E} \times \mathbb{W}}!$. Applying Poincaré duality to both sides of this and using the commutative diagram (2.11) we see that what a wish to prove is equivalent to the statement that

\[ [X \times Z] = \text{PD}(\text{pr}_{\mathbb{E} \times \mathbb{W}}!) \in \text{KK}_{n-d}(\mathbb{C}^0(X \times Z), \mathbb{C}). \]

which is the content of Lemma 5.10.

\[\square\]

6. **Dirac classes for actions**

In this section we simultaneously generalize transverse Dirac classes for manifolds and Dirac classes for discrete groups, to define Dirac classes for a certain class of smooth discrete actions, by requiring that they are constituted in a certain sense by splicing together a Dirac class for the group, and a transverse direct class for the manifold.
6.1. Definition of the Dirac class. The following is the main definition of this paper.

**Definition 6.1.** Let \((\Gamma, Z)\) be a smooth, \(d\)-dimensional \(K\)-oriented group, and let \(\Gamma\) act \(KK\)-orientably on the smooth compact oriented \(n\)-dimensional manifold \(X\).

Let \([X] \in KK_{\Gamma}^n(C(X), \mathbb{C})\) be a transverse Dirac class for the action.

Then a *Dirac class* for \(\Gamma \times X\) is any class
\[
[\Gamma \times X] \in KK_{\Gamma \times \mathbb{Z}}^n(C_0(X), \mathbb{C})
\]
such that
\[
\mathcal{L}([\Gamma \times X]) = [ev] \otimes \mathcal{L}([X]) \in KK_{\Gamma}^n(C_0(Z \times X), \mathbb{C}),
\]
where \(\mathcal{L}\) is the localization map, \([ev]\) as in \((\ref{ev})\).

A *reduced* Dirac class is a class \([\Gamma \times X] \in KK_{\Gamma \times \mathbb{Z}}^d(C(X), \mathbb{C})\) which pulls back to a Dirac class under the map on \(K\)-homology induced by the projection \(C(X) \times \Gamma \to C(X) \times \Gamma\).

If \(\Gamma\) is torsion-free, \(KK_{\Gamma}^n(C_0(Z \times X), \mathbb{C}) \cong K_n(Z \times \Gamma X)\), where \(Z \times \Gamma X\) denotes the quotient of \(Z \times X\) by the diagonal action of \(\Gamma\). The smooth manifold \(Z \times \Gamma X\) is foliated into the images of the slices \(Z \times \{x\}\), for \(x \in X\), and, \(Z \times \Gamma X\) is also a bundle of compact manifolds over \(\Gamma \setminus Z\) under the coordinate projection
\[
p : Z \times \Gamma X \to \Gamma \setminus Z.
\]
The submanifold \(p^{-1}(\Gamma z_0)\) is a closed transversal \(X_{z_0}\) for the foliation, naturally diffeomorphic to \(X\), for any \(z_0 \in Z\).

Let \(i_{z_0, X} : X \to Z \times \Gamma X\) be the corresponding embedding. The class
\[
[ev] \otimes C [X] \in KK_{\Gamma}^n(C_0(Z \times X), \mathbb{C}) \cong K_n(Z \times \Gamma X)
\]
is, by the definitions, equal to the class of the Baum-Douglas cycle
\[
Z \times \Gamma X \xrightarrow{i_{z_0, X}} X \to .
\]
from \(Z \times \Gamma X\) to a point, obtained by mapping the \(K\)-oriented compact manifold \(X\) into \(Z \times \Gamma X\) as a transversal to the foliation described above.

**Proposition 6.3.** Suppose that \(\Gamma\) is torsion-free, and \(X\) is smooth and \(\Gamma\)-equivariantly \(K\)-orientable. Let \(i_{z_0, X} \in KK_0(C(Z \times \Gamma X), C(X))\) be the class of the \(*\)-homomorphism Gelfand dual to the inclusion of \(X\) into \(Z \times \Gamma X\) as a fibre of \(Z \times \Gamma X \to \Gamma \setminus Z\). Let \([X] \in KK_{\Gamma}^n(X)\) be a transverse Dirac class of \(X\) and \([X]' \in KK_{\Gamma}^n(C_0(X), \mathbb{C})\) the ordinary Dirac class of \(X\), obtained by forgetting the \(G\)-action.

Then a Dirac class for \(\Gamma \times X\) is any class mapping to
\[
i_{z_0, X} \otimes_{C(X)} [X]' \in KK_{\Gamma}^n(C_0(Z \times \Gamma X), \mathbb{C}) = K_n(Z \times \Gamma X),
\]
under the composition of the localization map and the natural isomorphism \(KK_{\Gamma}^n(C_0(Z \times \Gamma X), \mathbb{C}) \cong K_n(Z \times \Gamma X)\).

**Proof.** Since \(\Gamma\) itself is a zero-dimensional, equivariantly \(K\)-oriented \(\Gamma\)-manifold, it has a transverse Dirac class \([\Gamma] \in KK_0(C(\Gamma), \mathbb{C})\), and if \(o_{z_0} : \Gamma \to Z\) is the orbit map at \(z_0\), then
\[
[ev] = o_{z_0}([\Gamma]) \in KK_0(C_0(Z), \mathbb{C}),
\]
is clear. By an obvious case of multiplicativity of transverse Dirac classes,
\[
[ev] \otimes C [X] = (o_{z_0} \times id_X)^*([\Gamma \times X]) \in KK_{\Gamma}^n(C_0(Z \times X), \mathbb{C}),
\]
where \([\Gamma \times X]\) is the transverse Dirac classes of the (proper, equivariantly \(K\)-oriented) manifold \(\Gamma \times X\). Applying the descent functor gives the result, since \(o_{z_0} : \Gamma \to Z\) descends to the inclusion of the point \(\Gamma z_0\) in \(\Gamma \setminus Z\).
The analogue of proposition 6.11 holds for groupoids as well. Namely, if \((\Gamma, Z)\) is a smooth oriented group, \(X\) an equivariantly oriented \(\Gamma\)-manifold, then a Dirac class \(\hat{\eta} \in KK_{\Gamma}^\Gamma(X)\) exists as soon as the groupoid \(\Gamma \ltimes X\) has a dual-Dirac morphism \(\eta \in KK_{\Gamma}^{\Gamma \ltimes X}(C_0(X), C_0(Z \times X))\); this is the case if \(\Gamma\) itself has one. If the groupoid \(\Gamma \ltimes X\) has a dual-Dirac morphism, then the Dirac class for \(\Gamma \ltimes X\) is unique if \(\gamma_{\Gamma \ltimes X} \equiv 1 \in KK_{\Gamma}^{\Gamma \ltimes X}(C_0(X), C_0(X))\), where \(\gamma_{\Gamma \ltimes X}\) is the corresponding \(\gamma\)-element for the groupoid \(\Gamma \ltimes X\). This occurs if \(X\) is a proper, or more generally, an amenable \(\Gamma\)-space.

In the latter case, if \(X\) is also compact, then \(\Gamma\) itself has a \(\gamma\)-element (and not just the groupoid \(\Gamma \ltimes X\)). More generally, if \((\Gamma, Z)\) is a smooth, oriented group, \(X\) a smooth oriented \(\Gamma\)-manifold, and if \(\eta \in KK_{\Gamma}^Z(C, C_0(Z))\) is a dual-Dirac morphism for \(\Gamma\), then the groupoid \(\Gamma \ltimes X\) also has a dual-Dirac morphism and corresponding Dirac class, given by the formula

\[
\hat{\eta}(\Gamma \ltimes X) = (\eta \otimes C \mathbb{1}_C(X)) \otimes C_0[Z \times X] \langle [\text{ev}] \otimes C [X] \rangle.
\]

More generally, existence of a Dirac class for \(\Gamma\) implies one for any action.

**Proposition 6.5.** If \((\Gamma, Z)\) is a smooth oriented group, \(\hat{\Gamma} \in KK_{\Gamma,d}(C, C)\) is a Dirac class for \(\Gamma\), and if \([X] \in KK_{\Gamma,n}(C_0(X), C)\) is a transverse Dirac class then

\[
\hat{\Gamma} \otimes C [X] \in KK_{\Gamma,d-n}(C_0(X), C)
\]

is a Dirac class for \(\Gamma \ltimes X\), where the Kasparov product is the external product in \(KK^\Gamma\).

**Proof.** The proof is a trivial consequence of associativity of the Kasparov product.

\[\square\]

6.2. **Groups of nonpositive curvature acting by Riemannian isometries.** Suppose \((\Gamma, Z)\) is a smooth \(K\)-oriented group with \(Z\) carrying a \(\Gamma\)-invariant metric of nonpositive curvature, and suppose that \(\Gamma\) acts by Riemannian isometries of \(X\) preserving a \(K\)-orientation. The Dirac class of \(\Gamma\) is represented by the spectral triple \((L^2(\Gamma, V), \pi, \delta)\) of Theorem 4.14. It is finitely summable if \(\Gamma\) has polynomial group (not otherwise).

Since the \(\Gamma\)-action is assumed isometric on \(X\), the transverse Dirac class is also represented by a spectral triple, of the type \((L^2(S), \pi, DX)\), where \(DX\) is the \(\Gamma\)-equivariant Dirac operator associated to the equivariant metric and \(K\)-orientation.

**Corollary 6.6.** If \((\Gamma, Z)\) is a smooth \(K\)-oriented group with \(Z\) carrying a metric of nonpositive curvature, and if \(\Gamma\) acts isometrically and preserving \(\Gamma\)-orientation on a Riemannian manifold \(X\), then, in the notation above, the Dirac class for \(\Gamma \ltimes X\) is represented by the spectral triple \((L^2(S) \otimes L^2(\Gamma, V), DX \otimes 1 + 1 \otimes \delta)\).

In particular, if \(\Gamma\) has polynomial growth \(\sim n^d\) then the (reduced) Dirac class \([\Gamma \ltimes X]\) is represented by \(\dim(X) + d\)-summable spectral triple over \(C_0(X) \rtimes \Gamma\).

**Proof.** The proof is an immediate consequence of Proposition 6.12 and the standard recipe for taking external products of unbounded cycles in \(KK^\Gamma\). [** include reference ]

\[\square\]

**Example 6.7.** The Dirac class of a \(K\)-orientation preserving action of a finite group \(\Gamma\) on \(X\) is represented by a spectral triple first described by A. Connes: let \(\tau: \mathbb{C} \to \mathbb{C}\) be the standard
trace, $L^2(A_\theta)$ the GNS Hilbert space associated to $\tau$. The algebra $A_\theta$ is represented on $L^2(A_\theta)$ by left multiplication, and the two densely defined derivations

$$\delta_1(\sum_{n\in\mathbb{Z}} f_n[n]) := \sum_{n\in\mathbb{Z}} f'_n[n], \quad \delta_2(\sum_{n\in\mathbb{Z}} f_n[n]) := \sum_{n\in\mathbb{Z}} n f_n[n],$$

using group-algebra notation. They assemble to a densely defined self-adjoint operator

$$\overline{\mathcal{D}}_\theta := \begin{bmatrix} 0 & \delta_1 - i\delta_2 \\ \delta_1 + i\delta_2 & 0 \end{bmatrix},$$

on $L^2(A_\theta) \oplus L^2(A_\theta)$, a deformation of the Dolbeault operator $\overline{\mathcal{D}}_{\mathbb{T}^2}$ on $\mathbb{T}^2$.

Note that, as a (unbounded) operator on a Hilbert space, $\overline{\mathcal{D}}_\theta$ is absolutely identical to the ordinary Dolbeault operator $\overline{\mathcal{D}}_{\mathbb{T}^2}$ operating with its usual initial domain of smooth functions in the graded Hilbert space $L^2(\mathbb{T}^2) \oplus L^2(\mathbb{T}^2)$. Thus as far as the operator is concerned, we are dealing with a classical operator. However, the dynamics is encoded by the representation of $A_\theta$, so that the noncommutative aspect of this spectral triple lies entirely in the representation of $A_\theta$ involved in it by the GNS procedure. To be explicit, identifying $L^2(A_\theta)$ with $L^2(\mathbb{T}^2) \otimes l^2(\mathbb{Z})$ then the representation of $\pi: A_\theta = C(\mathbb{T}) \rtimes \mathbb{Z} \to \mathcal{L}(L^2(\mathbb{T}^2) \oplus L^2(\mathbb{T}^2))$, is the one determined by the covariant pair

$$\pi(f)(x, y) = f(x)\xi(x, y), \quad (n \cdot \xi)(x, y) = e^{2\pi i n y} \xi(R_{\theta}^{-n}(x), y).$$

**Remark 6.8.** (Z-actions.) More generally, suppose that $\mathbb{Z}$ acts on a complete Riemannian manifold $X$, isometrically, and preserving a K-orientation in the sense that there is a Hermitian $\mathbb{Z}$-equivariant spinor bundle $S_X$ over $X$, graded or ungraded or $p$-multigraded (if one is working over the reals), and a $\mathbb{Z}$-equivariant connection on $S_X$ and associated $\mathbb{Z}$-equivariant Dirac operator

$$D_X: L^2(S_X) \to L^2(S_X)$$

determining the transverse Dirac class $[X] \in \text{KK}^2_{\mathbb{Z}}(C_0(X), \mathbb{C})$.

Following the recipe of Corollary 6.6 we form an external product and get the following explicit representative of $[\mathbb{Z} \rtimes X] \in \text{KK}^n_{\mathbb{Z}^{n+1}}(C_0(X) \rtimes \mathbb{Z}, \mathbb{C})$. We assume for simplicity that dim $X$ is odd, and that $S_X$ is ungraded, $D_X$ self-adjoint. Then the Hilbert space of our spectral triple consists of two copies of $L^2(S_X) \otimes l^2(\mathbb{Z})$ with standard even grading, and the operator

$$\begin{bmatrix} 0 & D_X \otimes 1 + i(1 \otimes \delta) \\ D_X \otimes 1 - i(1 \otimes \delta) & 0 \end{bmatrix}$$

where $\delta$ is the number operator on $l^2(\mathbb{Z})$. The representation of $C(X) \rtimes \mathbb{Z}$ on this Hilbert space is by

$$f(\xi \otimes e_k) := f\xi \otimes e_k, \quad m(\xi \otimes e_k) := m(\xi) \otimes e_{k+m}.$$ 

This of course directly generalizes the irrational rotation example.

We next consider an action of $\mathbb{Z}^2$ preserving a K-orientation on the compact manifold $X$ of dimension $n$.

If $n$ is odd, the spinor bundle $S_X$ for $X$ is ungraded; let $D_X$ be the corresponding Dirac operator. Let $\overline{\mathcal{D}}$ be the Dolbeault operator on the $\mathbb{Z}/2$-graded Hilbert space $L^2(\mathbb{T}^2) \oplus L^2(\mathbb{T}^2)$. Then the Dirac class of the action is represented by the following odd-dimensional spectral triple over $C(X) \rtimes \mathbb{Z}^2$. The Hilbert space is $L^2(\mathbb{T}^2) \otimes L^2(S_X) \oplus L^2(\mathbb{T}^2) \otimes L^2(S_X)$ with no grading, and the operator with respect to this decomposition is

$$(6.9) \quad \begin{bmatrix} 0 & \overline{\mathcal{D}}_{\mathbb{T}^2} \otimes 1 + i(1 \otimes D_X) \\ \overline{\mathcal{D}}_{\mathbb{T}^2} \otimes 1 - i(1 \otimes D_X) & 0 \end{bmatrix}.$$
The action of $C(X)$ is by letting $f \in C(X)$ act by a multiplication operator in the $L^2(S_X)$ factor. The group $\mathbb{Z}^2$ acts diagonally, with the implicitly assumed unitary action on sections of the spinor bundle $S_X$, and the action of $\mathbb{Z}^2$ on $L^2(T^2)$ given by the Fourier transform

$$(g \cdot \xi)(\chi) := \chi(g)\xi(\chi), \quad \chi \in \mathbb{Z}^2 \cong T^2.$$ 

This spectral triple is clearly $2 + n$-summable.

If $n$ is even, $S_X$ graded into $S_X^0 \oplus S_X^1$, then the Dirac class is represented by the odd operator

$$D_X := X^0_{\text{even}} \otimes L^2(T^2) \otimes L^2(S_X^1)$$

on the $\mathbb{Z}/2$-graded Hilbert space with even part

$$L^2(T^2) \otimes L^2(S_X^0) \oplus L^2(T^2) \otimes L^2(S_X^1)$$

and odd part

$$L^2(T^2) \otimes L^2(S_X^1) \oplus L^2(T^2) \otimes L^2(S_X^0).$$

Here $D_X := D_X|_{L^2(S_X^0)}: L^2(S_X^0) \to L^2(S_X^0)$, and $D_X := D_X|_{L^2(S_X^1)}: L^2(S_X^1) \to L^2(S_X^1)$.

The action of $C(X) \times \mathbb{Z}^2$ is as before.

This Dirac spectral triple is $n + 2$-summable, of course.

6.4. Dirac classes and inflation. We aim to compute

$$\text{infl}(\Gamma \times X) \in \text{RKK}^{\text{G}_{\text{r}}}_{d-n}(Z; C_0(X), \mathbb{C}),$$

equivalently, of PD$^{-1}(\{ev\} \otimes X)$ where, as usual, $(\Gamma, Z)$ is a K-oriented group, acting KK-orientably on $X$. Assume $X$ is a transverse Dirac class for the action, and $[\Gamma \times X]$ a Dirac class. Recall that

$$\text{RKK}^{\text{G}_{\text{r}}}_{d-n}(Z; C_0(X), \mathbb{C}) \cong \text{KK}^{\text{G}_{\text{r}}}_{d}(C_0(Z \times X), C_0(Z)),$$

so that we might expect a description of $\text{infl}(\Gamma \times X)$ in the form of a $\text{G}_{\text{r}}$-equivariant correspondence from $Z \times X$ to $Z$ — that is, a bundle of Baum-Douglas cycles for $X$, parameterized by the points of $Z$. As it turns out, $\text{infl}(\Gamma \times X)$ is represented by a piece of geometric data which generalizes slightly the data involved in a $\text{G}_{\text{r}}$-equivariant correspondence in the sense of [21]. We will call it a ‘(smooth, $\text{G}_{\text{r}}$-equivariant...) correspondence with singular support.’

Suppose that $i_M: M \to Z$ is a closed, smooth, $\Gamma$-invariant, co-dimension $d$ submanifold of $Z$ with $\Gamma$-equivariantly K-oriented normal bundle $\pi: \nu \to Z$. Let $\varphi: \nu \to Z$ the associated tubular neighbourhood embedding onto an open $\Gamma$-invariant neighbourhood $U$ of $M$. The $\Gamma$-equivariant K-orientation on $\nu$ determines a Thom class

$$\xi_\nu \in \text{KK}^{\text{G}_{\text{r}}}_{d-n}(C_0(Z), C_0(Z)) \cong \text{RKK}^{\text{G}_{\text{r}}}_{d-n}(Z; \mathbb{C}, \mathbb{C}).$$

The corresponding cycle has Hilbert $C_0(Z)$-module sections $C_0(U, S')$, where $S'$ is the bundle over $U$ defined by pulling back the the spinor bundle $S \to M$ for $\nu$, to a bundle over $\nu \cong U$, and operator a Clifford multiplier $F$ such that $f(F^2 - 1)$ is a $C_0$-bundle endomorphism of $S'$. In terms of correspondences, this is the class of the smooth, $\text{G}_{\text{r}}$-equivariant correspondence

$$(6.11) \quad \text{Z} \leftarrow (U, \varphi!(\xi_\nu)) \to \text{Z},$$

from $Z$ to $Z$, where the arrows designate the open inclusion.

Since, however, the construction only depends on the $\Gamma$-equivariant K-oriented embedding $i_M: M \to Z$, we will define

$$(6.12) \quad i^* \otimes_M i! \in \text{KK}^{\text{G}_{\text{r}}}_{d-n}(C_0(Z), C_0(Z)) = \text{RKK}^{\text{G}_{\text{r}}}_{d-n}(Z; \mathbb{C}, \mathbb{C})$$
to be the class of the correspondence \((6.11)\), and refer to it as a correspondence with singular support. We will also therefore also refer to a diagram

\[
Z \xleftarrow{i_M} M \xrightarrow{i_M} Z
\]

a ‘correspondence with singular support’; the corresponding class is given by \((6.12)\).

The entire discussion goes through if \(i_M: M \to Z\) is merely assumed a \(\Gamma\)-equivariant, equivariantly \(K\)-oriented immersion, as the reader may easily confirm.

The main reason we want to discuss correspondences with singular support is that the class we aim to describe has this form.

Choose \(z_0 \in Z\), let \(o_{z_0}: \Gamma \to Z\) be the orbit map at \(z_0\). It is a smooth, \(\Gamma\)-equivariantly \(K\)-oriented immersion. The normal bundle is \(\cong o_{z_0}^*(TZ)\), using the usual tubular neighbourhood embedding of the form

\[
\varphi(g,\xi) := \exp_{gz_0}(\epsilon'\xi),
\]

where \(\xi \mapsto \xi'\) is an appropriate re-scaling of tangent vectors (e.g. by \(\xi' := \frac{\epsilon\xi}{(1+|\xi|^2)^{\frac{1}{2}}}\)) into an open disk sub bundle of the tangent bundle, on which the Riemannian exponential map is a diffeomorphism.

The \(\Gamma\)-equivariant map \(o_{z_0}: \Gamma \to Z\) gives \(\Gamma\) the structure of a \(G\)-space, where \(G := \Gamma \times Z\) as before, and

\[
(6.13) \quad Z \xleftarrow{o_{z_0}} \Gamma \xrightarrow{o_{z_0}} Z.
\]

is a \(G\)-equivariant correspondence with singular support in the sense discussed above, from \(Z\) to \(Z\), with class

\[
o_{z_0}^* \otimes C_0(\Gamma) \circ o_{z_0}! \in KK^G_{\Gamma}(C_0(Z), C_0(Z)) = RKK^G_{\Gamma}(Z; \mathbb{C}, \mathbb{C})
\]

where \(o_{z_0}^* \in KK^G_{\Gamma}(C_0(Z), C_0(\Gamma))\) is the class of the induced \(\ast\)-homomorphism.

Similarly, if \(X\) is a smooth, compact manifold carrying a \(KK\)-orientation preserving action of \(\Gamma\), then

\[
(6.14) \quad Z \times X \xleftarrow{o_X \times id_X} \Gamma \times X \xrightarrow{o_{z_0} \circ pr_{\Gamma}} Z
\]

is a \(G\)-equivariant correspondence with singular support from \(Z \times X\) to \(Z\), with class

\[
(o_{z_0} \times id_X)^* \otimes C_0(Z) \circ (o_{z_0} \circ pr_{\Gamma})! \in KK^G_{\Gamma}(C_0(Z \times X), C_0(Z)) = RKK^G_{\Gamma}(Z; C_0(X), \mathbb{C}).
\]

**Proposition 6.15.** If \((\Gamma, Z)\) is a smooth oriented group, \(X\) an equivariantly oriented \(\Gamma\)-manifold, \([\Gamma \times X]\) a Dirac class for the action, then inflate([\(\Gamma \times X\)]) = (o_{z_0} \times id_X)^* \otimes C_0(Z) \circ (o_{z_0} \circ pr_{\Gamma})! \in RKK^G_{\Gamma}(Z; C_0(X), \mathbb{C}).

**Proof.** We need to show that \(PD^{-1}([ev] \otimes C_0[Z])\) is the class of the induced \(\ast\)-homomorphism.

\[
PD^{-1}: KK^G_{\Gamma}(C_0(Z \times X), \mathbb{C}) \xrightarrow{\Theta} KK^G_{\Gamma}(C_0(Z \times X), C_0(Z)) \cong RKK^G_{\Gamma}(Z; C_0(X), \mathbb{C})
\]

is Poincaré duality.

The map \(PD^{-1}\) is the composition of inflation

\[
inflate: KK^G_{\Gamma}(C_0(Z) \otimes A, B) \to RKK^G_{\Gamma}(Z; C_0(Z) \otimes A, B),
\]

with Kasparov product in \(RKK^G_{\Gamma}(Z)\) with a class \(\Theta \in RKK^G_{\Gamma}(Z; \mathbb{C}, C_0(Z))\). The class \(\Theta\) is the class of the \(G\)-equivariant correspondence

\[
(6.15) \quad Z \xleftarrow{id} Z \xrightarrow{\delta_Z} Z \times Z,
\]

where the momentum map for the \(G\)-space \(Z \times Z\) is in the first variable, and \(\delta_Z: Z \to Z \times Z\) be the diagonal map.
By definition, \( \text{inflate}([X]) \in \text{RKK}_{G_n}^\Gamma(Z; C(X), \mathbb{C}) \) is represented by the \( G \)-equivariant correspondence
\[
Z \times X \xleftarrow{id} Z \times X \xrightarrow{\text{pr}_Z} Z
\]
and since inflate is compatible with external products,
\[
\text{inflate}([ev] \otimes_C [X]) = \text{inflate}([ev]) \otimes_{Z \times C} \text{inflate}([X]) \in \text{RKK}_{G_n}^\Gamma(Z; C(X), \mathbb{C})
\]
is represented by the \( \Gamma \times Z \)-equivariant correspondence (with singular support)
\[
Z \times Z \times X \xleftarrow{id_x \times \alpha_{z_0} \times id_x} Z \times X \xrightarrow{\text{pr}_Z} Z, \tag{6.17}
\]
where the momentum map for \( Z \times Z \times X \) is projection to the first coordinate, or, more precisely, the class of the ordinary \( \mathcal{G} \times \mathcal{G} \)-equivariant correspondence
\[
Z \times Z \times X \xleftarrow{id_x \times \varphi \times \text{id}_x} (Z \times \nu \times X, \xi_{\nu}) \xrightarrow{\text{pr}_Z} Z \tag{6.18}
\]
with \( \nu \) the normal bundle to the orbit, that is \( \nu = o_{z_0}^*(TZ) \), and \( \varphi: \nu \rightarrow Z \) the tubular neighbourhood embedding. Since \( \varphi \times \text{id}_X \) is a submersion, one can compose \( \text{(6.18)} \) with \( \text{(6.16)} \) by transversality. The result is bordant to
\[
Z \xleftarrow{o_{z_0}^*\circ \pi} (o_{z_0}^*(TZ), o_{z_0}^*(\xi_{TZ})) \xrightarrow{o_{z_0}^*\circ \pi} Z
\]
where \( \pi: o_{z_0}^*(TZ) \rightarrow \Gamma \) is the vector bundle projection, as claimed. \( \square \)

The case where \( \Gamma \) is torsion free and hence acts freely on \( Z \) can be expressed and proved more simply.

Since \( Z \times X \) is a \( \mathcal{G} \)-equivariantly K-oriented bundle of smooth manifolds, by hypothesis, \( \mathcal{G}_\Gamma \)-equivariant Poincaré duality holds and gives an isomorphism
\[
\text{RKK}^\Gamma_\Gamma(Z; C_0(X), \mathbb{C}) \cong \text{RKK}^\Gamma_{+n}(Z; \mathbb{C}, C_0(X)) \tag{6.19}
\]
and composing this with the generalized Green-Julg isomorphism and a standard Morita equivalence identifies \( \text{RKK}^\Gamma_{+n}(Z; \mathbb{C}, C_0(X)) \) with \( K^{-*}(Z \times_\Gamma X) \), the K-theory of the mapping cylinder.

The composition
\[
K^{-*}(Z \times_\Gamma X) = \text{KK}^\Gamma_\Gamma(C_0(Z \times X), \mathbb{C}) \xrightarrow{\text{PD}^{-1}} \text{RKK}^\Gamma_\Gamma(Z; C_0(X), \mathbb{C}) \cong \text{RKK}^\Gamma_{+n}(Z; \mathbb{C}, C_0(X)) \cong K^{-*}(Z \times_\Gamma X) \tag{6.20}
\]
is ordinary Poincaré duality for \( Z \times_\Gamma X \). By Proposition \( \text{6.15} \), we obtain the following.

**Corollary 6.21.** If \( \Gamma \) is torsion-free, then \( \Gamma \times Z \)-equivariant Poincaré duality for \( X \)
\[
\text{RKK}^\Gamma_\Gamma(Z; C_0(X), \mathbb{C}) \rightarrow K^{-*}(Z \times_\Gamma X)
\]
maps inflate([\( \Gamma \times X \)]) to the class in \( K^{-d}(Z \times_\Gamma X) \) of the correspondence
\[
\cdot \xleftarrow{i_{z_0,X}} Z \times_\Gamma X,
\]
where \( i_{z_0,X}: X \rightarrow Z \times_\Gamma X \) is the inclusion of the fibre \( X \) at \( \Gamma z_0 \in \Gamma \backslash Z \).
6.5. Dirac classes for proper actions. Suppose now that $X$ is a smooth, proper $\Gamma$-manifold, $\chi \to Z \cong \mathcal{E}\Gamma$ a smooth classifying map for the proper action of $\Gamma$ on $X$. By Sard’s theorem, $\chi$ has a regular value $z_0$, so $F := \chi^{-1}(z_0)$ is a smooth submanifold of $X$ of dimension $n - d$, carrying a smooth action of the finite group $\text{Stab}_\Gamma(z_0)$. If $\Gamma \backslash X$ is compact, then $F$ is compact.

The fibres $F_g := \chi^{-1}(gz_0)$ as $g$ ranges over $\Gamma$ are isomorphic copies, and come with actions of the corresponding conjugate isotropy groups. We set

$$F_\Gamma := \{(x, g) \in X \times \Gamma \mid \chi(x) = gz_0\}.$$

which is a bundle over $\Gamma z_0 \subset X$ with fibre $F_g \times \text{Stab}_\Gamma(gz_0)$ over $gz_0$. A $\Gamma$-equivariant K-orientation on $X$ induces a canonical $\Gamma$-equivariant K-orientation on $F_\Gamma$.

Set $[F_\Gamma] \in \text{KK}^\mathcal{G}_d(C_0(F_\Gamma), \mathbb{C})$ the transverse Dirac class for $\Gamma$ acting on $F_\Gamma$. Let $i : F_\Gamma \to X$ be the projection to the first factor.

**Theorem 6.23.** Let $(\Gamma, Z)$ be a smooth oriented group, and $X$ is a $\Gamma$-equivariantly $\mathcal{G}$-oriented proper $\Gamma$-manifold, $\chi : X \to Z$ be a smooth $\Gamma$-map, $z_0 \in Z$ a regular orbit, and $F_\Gamma, i : F_\Gamma \to X$ etc as in the discussion above. Then the Dirac class for $\Gamma \times X$ is given by the class of the fibre of $\chi$:

$$[\Gamma \times X] = i_*([F_\Gamma]) \in \text{KK}^\mathcal{G}_{d-n}(C_0(X), \mathbb{C}).$$

In particular, if $n < d$ then the Dirac class vanishes, and otherwise, the Dirac class is represented by a $n - d$-dimensional spectral triple over $C_0(X) \rtimes \Gamma$.

**Proof.** We show that

$$\text{infl} ate(i_*([F_\Gamma])) = \text{PD}^{-1}(\text{ev}) \otimes \mathbb{C}[X]) \in \text{KK}^\mathcal{G}_{d-n}(Z; C_0(Z \times X), \mathbb{C}).$$

The result will follow from Proposition 2.10. As in the proof of Proposition 6.15, PD$^{-1}$ involves composition with the class $\Theta \in \text{KK}^\mathcal{G}_d(Z; \mathbb{C}, C_0(Z))$, where $\Theta = \delta!$ where $\delta : Z \to Z \times Z$ is the diagonal map, canonically K-oriented, and $\mathcal{G}$-equivariant.

Let $\chi : X \to Z$ be the smooth classifying map with regular value $z_0$ discussed above. Set

$$G_\chi : X \to Z \times X$$

the graph of $\chi$: $G_\chi(z, x) := (z, \chi(x))$.

**Lemma 6.25.** The equality

$$\delta \otimes \mathbb{C} \text{id}_X = (\text{id}_Z \otimes \mathbb{C} G_\chi)!$$

holds in

$$\text{KK}^\mathcal{G}_d(Z; C_0(Z \times X), C_0(Z \times Z \times X)) = \text{KK}^\mathcal{G}_d(Z; C_0(X), C_0(Z \times X)).$$

**Proof.** By the universal property of $\mathcal{E}\Gamma \cong Z$, the coordinate projections $Z \times Z \to Z$ are $\Gamma$-equivariantly homotopic. Fix a $\Gamma$-equivariant smooth homotopy

$$F : Z \times Z \times [0, 1] \to Z$$

between the two coordinate maps and pull it back in one coordinate using the map $\chi$ to get

$$\tilde{F} : Z \times X \times [0, 1] \to Z, \quad \tilde{F}(z, x, t) := F(z, \chi(x), t).$$

Then, as is easily checked, $\text{id}_Z \times \tilde{F}$ gives a smooth $\mathcal{G}_\Gamma$-equivariant homotopy between the smooth $\mathcal{K}$-oriented $\mathcal{G}_\Gamma$-equivariant maps $\delta \times \text{id}_X$ and $\text{id}_Z \times G_\chi$, as claimed.

To complete the proof, we need to evaluate the composition of $\mathcal{G}_\Gamma$-equivariant correspondences

$$Z \times X \leftrightarrow Z \times X \xrightarrow{\text{id}_Z \times G_\chi} Z \times X \xleftarrow{\text{id}_Z \times \varepsilon_{z_0} \times \text{id}_X} Z \times \Gamma \times X \to Z.$$
The maps \( G_\chi : X \to Z \times X \) and \( e_{z_0} \times \text{id}_X : \Gamma \times X \to Z \times X \) are transverse since \( z_0 \) is a regular value (and hence so is \( g_{z_0} \) for all \( g \in \Gamma \)) and the associated coincidence manifold
\[
\{(x, g, y) \in X \times \Gamma \times X \mid G_\chi(x) = (g_{z_0}, y)\}
\]
is the smooth K-oriented manifold \( F_1 \) described above in (6.22). Taking the product of everything with \( \text{id}_Z \) gives the identity (6.24) as required.

\[\square\]

**Corollary 6.27.** \([\Gamma \ltimes Z] = [\text{ev}] \in KK_0^\Gamma(C_0(Z), \mathbb{C}).\]

This is the case of Theorem 6.23 where \( Z = X, \chi \) the identity map.

**Remark 6.28.** Corollary 6.27 admits another proof, much easier, for it boils down to the simple statement that
\[
[\text{ev}] \otimes C[Z] = [Z] \otimes [\text{ev}] \in KK_0^\Gamma(C_0(Z) \times Z, \mathbb{C}),
\]
and this follows from the fact that the two coordinate projections \( Z \times Z \to Z \), are equivariantly proper homotopic, because \( Z \) is universal.

Finally, we note that when \( \Gamma \) is finite, acting on \( X \), arbitrary, our description \( i_*([F_1]) \) of the Dirac class for \( C_0(X) \rtimes \Gamma \) just given matches that given in Example 6.7 since then \( Z \) becomes a point, and \( [\text{ev}] \) the class of the regular representation of the finite group.

Theorem 6.23 is quite satisfying, from a certain point of view, as it gives a case where the homological subtraction involved in forming a Dirac class, which lies in dimension \( d - n \), matches precisely the geometric dimension: there is a spectral triple representative of summability dimension \( n - d \).

7. Dirac classes for boundary actions of negative curved groups

Along with the Dirac class for the irrational rotation algebra, and its spectral triple representative, an important example in noncommutative geometry is the action of a co-compact discrete subgroup of \( SL_2(\mathbb{R}) \) acting on the circle by Möbius transformations. This is a special case of a Gromov hyperbolic group \( \Gamma \) acting on its boundary \( \partial \Gamma \).

If \( \Gamma \) is a Gromov hyperbolic group (see [24] for an exposition) hyperbolicity leads to a compact, metrizable, \( \Gamma \)-space \( \overline{\Gamma} \) containing \( \Gamma \) as a dense open \( \Gamma \)-invariant open subset, and complement \( \partial \Gamma \). This produces an exact sequence
\[(7.1) \quad 0 \to C_0(\Gamma) \rtimes \Gamma \to C(\overline{\Gamma}) \rtimes \Gamma \to C(\partial \Gamma) \rtimes r \Gamma \to 0\]
and, using the canonical isomorphism \( C_0(\Gamma) \rtimes \Gamma \cong \mathcal{K}(l^2 \Gamma) \), and amenability of the action, a result due to Adams in [1], we obtain a KK-class \( [\partial_1] \in KK_0^\Gamma(C(\partial \Gamma), \mathbb{C}) = K_1(C(\partial \Gamma) \rtimes r \Gamma). \)
Alternatively, in [10] a \( \Gamma \)-equivariant completely positive splitting of (7.1) is provided, which implies the extension determines a \( KK_1 \)-class.

The main result of this section is that when \( \Gamma \) also fits into the previous framework, the boundary extension class is the Dirac class of the action, with its boundary K-orientation.

Some fine points about the statement are discussed following the Theorem.

**Theorem 7.2.** Let \((\Gamma, Z)\) be a smooth K-oriented group with \( Z \) negatively curved. Then the \( \Gamma \)-action on \( \partial Z \) admits a KK-orientation in the sense of Definition 6.26 and the Dirac class of the action is given by
\[
[\Gamma \ltimes \partial Z] = [\partial_1] \in K_1(C(\partial Z) \rtimes \Gamma) \cong K_1(C(\partial \Gamma) \rtimes \Gamma).
\]
where \([\partial_1]\) is the boundary extension class.

The boundary extension class is represented by a cycle which doesn’t involve any smooth structures, but only, in a sense, on the asymptotic geometric of the group \( \Gamma \), and its action on it.
7.1. KK-orientability of boundary actions. For simplicity, we are going to assume that $\Gamma$ is torsion-free, or, equivalently, that $\Gamma = \pi_1(M)$ for a negatively curved, compact, $d$-dimensional, manifold which we assume, in addition, to be $K$-oriented and on which, therefore, we can assemble a Dirac operator $D$ acting on the spinor bundle.

The metric, $K$-orientation, etc on $M$ lifts to $\Gamma$-equivariant data: spinor bundles on $Z := \tilde{M}$, connection, and so on, and one assembles the ‘lifted,’ $\Gamma$-equivariant Dirac operator representing $[Z] \in \text{KK}^{\Gamma}_*\left(C_0(Z), \mathbb{C}\right)$.

The boundary sphere $\partial Z$ of the negatively curved space $Z$ is the boundary of the usual geodesic compactification of $Z$, and it agrees by a $\Gamma$-equivariant homeomorphism with the Gromov boundary $\partial \Gamma$ of the group $\Gamma$, or of $Z$ itself.

The isometric group action of $\Gamma$ on $Z$ extends to an action of $\Gamma$ on $\partial Z$ by homeomorphisms, due to general properties of hyperbolic groups, and the action in this case can be shown to be by $C^{1+\epsilon}$-diffeomorphisms, but is not smooth in general, even for surface groups. \footnote{The action is smooth when the curvature of $M$ is constant.} We show below that, however, the $\Gamma$-action on the boundary sphere is KK-orientable in our sense.

We first describe the localization map in this situation. We use the same notation as above, with $M = \Gamma \setminus Z$, a negatively curved manifold. Let $SM$ be the sphere bundle of its tangent bundle. Then

$$Z \times_{\Gamma} \partial Z \cong SM,$$

in the following canonical way. Given $z \in Z$, and $(z, \xi)$ a unit tangent vector at $z$, let

$$\text{EXP}_z(z, \xi) := \lim_{t \to \infty} \exp_z(t \xi), \quad \xi \in S_z Z.$$

It follows a geodesic ray beginning at $z$ and ending at a boundary point in $\partial Z$. This construction is clearly equivariant and determines a homeomorphism between the fibre $S_z Z$ of the sphere bundle $SZ \to Z$, and the boundary sphere $\partial Z$. Any such homeomorphism of course then gives $\partial Z$ a smooth structure, identifying it with an ordinary sphere.

In any case, we see that the localization map can be identified with a map

$$K^*(C(\partial Z) \rtimes \Gamma) \to \text{K}^{*-d}(SM),$$

and a Dirac class is one which maps to the class of a single fibre of the bundle projection $\pi: SM \to M$, $K$-oriented as a sphere, and regarded as a Baum-Douglas cycle for $SM$.

Lemma 7.3. In the above notation, the $\Gamma$-action on $\partial Z$ is KK-orientable.

Proof. We show that the bundle $E \Gamma \times \partial Z = Z \times \partial Z$ of smooth manifolds (with fibre $\partial Z$) admits a canonical fibrewise smooth structure, left invariant by $\Gamma$, by noting that the exponential map discussed above gives a $\Gamma$-equivariant homeomorphism

$$\text{EXP}: SZ \to Z \times \partial Z,$$

with $SZ$ the sphere bundle of $Z$, such that the diagram

$$\begin{array}{ccc}
SZ & \xrightarrow{\text{EXP}} & Z \times \partial Z \\
\downarrow \pi & & \downarrow \text{pr}_Z \\
Z & & \\
\end{array}$$

commutes. $SZ$ is a smooth manifold, and $\Gamma$ acts smoothly on it since it acts smoothly on $Z$. The bundle projection $\pi$ is a smooth, $\Gamma$-equivariant submersion. Hence it gives $Z \times \partial Z \cong SZ$ the structure of a $\Gamma$-equivariant bundle of smooth manifolds over $Z$, that is, a $Z \times \Gamma$-manifold.

The above reasoning, replacing the sphere bundle $SM$ by the (closed) disk bundle $DM$, generates a bundle of manifolds-with-boundary (the manifolds are closed disks), carrying by
assumption a bundle of $K$-orientations, equivariant under $\Gamma$, and this bundle generates a bundle of $K$-orientations on the bundle of boundaries by the two-out-of-three Lemma.

\[ \square \]

Remark 7.4. From the foliation point of view, $SM$, in the above notation, admits an Anosov foliation into asymptotic equivalence classes of geodesic rays; this foliation has generic leaf $\cong Z$, or more generally $Z/\Gamma'$ where $\Gamma' \subset \Gamma$ is the isotropy of a boundary point (always a cyclic group, either infinite or trivial). The leaves of this foliation are all smooth, but the foliation is not infinitely differentiable in the transverse direction.

The holonomy groupoid accordingly acts by $C^{1+\tau}$-diffeomorphisms on one of the transversals $S_xM$, and this can be naturally identified with the boundary action of the group $\Gamma$ on $\partial Z$, as in the above argument.

The lack of smoothness of the $\Gamma$ action on its boundary thus corresponds to failure of transverse smoothness of the Anosov foliation. See [32].

7.2. Preparatory remarks on extension theory. Proceeding to the proof of Theorem 7.2, we begin with a discussion of (known) constructions relating to extensions and KK-theory. We will need at some stage equivariant versions of some of the constructions below, with respect to a group, or groupoid, so will deal with the general theory at that level of generality. However, as the referee has pointed out, there are issues with making extension theory equivariant, for example, a continuous group action on a $C^*$-algebra may not extend to a (continuous) action on its multiplier algebra. We will be working strictly with étale groupoids, however, so we will fix $\mathcal{G}$ to be an étale groupoid in the following discussion – in fact, in our applications, it will be either trivial, proper, and of the form $\mathcal{G}_\Gamma = \Gamma \ltimes \mathcal{E}\Gamma$, or $\Gamma$ itself (with $\Gamma$ a hyperbolic group, as per the discussion above.)

Suppose that

\[ 0 \rightarrow J \xrightarrow{\alpha} B \xrightarrow{\beta} A \rightarrow 0 \]

is a $\mathcal{G}$-equivariant exact sequence of $C^*$-algebras. The Busby invariant of the equivariant extension \[(7.5)\] is the $\mathcal{G}$-equivariant $^*$-homomorphism $\tau(a) := \pi(\tilde{a}) \in Q(J) := \mathcal{M}(J)/J$, where $\pi: \mathcal{M}(B) \rightarrow \mathcal{M}(B)/B$ is the quotient map, and where $\tilde{a}$ denotes a lift of $a$ under $\beta$, regarded as a multiplier of $B$.

The Busby invariant is uniquely associated to the strong isomorphism class of the extension: if $\tau: A \rightarrow Q(J)$ is any ($\mathcal{G}$-equivariant) $^*$-homomorphism, then $B := \{(a, m) \in A \oplus \mathcal{M}(J) \mid \pi(m) = \tau(a)\}$ determines an ($\mathcal{G}$-equivariant) extension with of $A$ by $J$ with the given Busby invariant, and if $\tau$ comes from \[(7.5)\] then this procedure determines a strongly isomorphic extension. This procedure puts strong isomorphism classes of $\mathcal{G}$-equivariant extensions in in 1-1 correspondence with $\mathcal{G}$-equivariant $^*$-homomorphisms $A \rightarrow Q(J)$.

Similarly, if $\mathcal{M}^*(B)$ denotes multipliers of $B \otimes \mathcal{K}$ and $Q^*(J) := \mathcal{M}^*(J)/J \otimes \mathcal{K}$ then we obtain a bijective correspondence between strong isomorphism classes of $\mathcal{G}$-equivariant extensions of $A$ by $J \otimes \mathcal{K}$ and $\mathcal{G}$-equivariant $^*$-homomorphisms $A \rightarrow Q^*(J)$.

We generally work with Busby invariants rather than extensions themselves.

Example 7.6. Suppose that $\rho: A \rightarrow \mathcal{L}(J \otimes \ell^2)$ is a $\mathcal{G}$-equivariant representation, and that $P \in \mathcal{L}(J \otimes \ell^2)$ such that

\[ [P, \rho(a)], \quad \rho(a) \cdot (P^2 - P) \quad P(gP - P) \in \mathcal{K}(J \otimes \ell^2) \]

for all $a \in A$, $g \in \mathcal{G}$, then in the usual way this defines a $\mathcal{G}$-equivariant Kasparov triple $(J \otimes \ell^2, \rho, F := 2P - 1)$, that is, cycle for $\text{KK}_\mathcal{G}^\mathcal{G}(A, J)$. The map

$\tau: A \rightarrow Q^*(J), \quad \tau(a) := P\rho(a)P \mod J \otimes \mathcal{K}$.
is a $\mathcal{G}$-equivariant *-homomorphism, and hence is the Busby invariant of some strong isomorphism class of $\mathcal{G}$-equivariant extension of $A$ by $J \otimes K$. It is the $\mathcal{G}$-equivariant extension associated to the Kasparov cycle $(J \otimes I^2, \rho, P)$ for $\text{KK}^G_1(A, J)$.

In typical examples (e.g. where $A$ is unital), the operator $P$ is an essential projection: that is, $P^2 - P$ is compact.

Bott Periodicity can be described conveniently by this set-up.

**Example 7.7.** The Kasparov triple $(C_0(\mathbb{R}), 1, \chi)$ represents the Bott class in $\text{KK}_1(C, C_0(\mathbb{R}))$, if $\chi: \mathbb{R} \to [-1, 1]$ is a normalizing function. Similarly, it represents the Thom class of the trivial 1-dimensional vector bundle $\mathbb{R}$ over a point. Of course $P := \sum_{i=0}^{n-1} t_i$ is then an essential projection.

Say that a $\mathcal{G}$-equivariant Busby invariant $\tau: A \to Q^*(J)$ is equivariantly dilatable if there is a completely positive, contractive and $\mathcal{G}$-equivariant map $s: A \to M^*(J)$ such that $\pi \circ s = \tau$. We say that $s$ is a splitting of $\tau$. It determines an equivariant completely positive splitting of the corresponding extension. The Stinespring construction realizes any dilatable Busby invariant as one of the form $\tau(a) = P \rho(a) P \mod J \otimes K$, i.e. as the Kasparov cycle as in Example 7.6 where $P$ is a projection. Note that this procedure produces not just an essential projection ($P^2 - P$ is compact), but a projection ($P^2 - P = 0$).

**Remark 7.8.** In Kasparov theory, essential projections can be replaced by actual projections at the expense of adding a degenerate to the cycle: suppose that $\mathcal{E} = J \otimes I^2$ is the standard Hilbert $J$-module and $(\mathcal{E}, \pi, P)$ is an odd cycle for $\text{KK}^G_1(A, J)$, where $P$ is a self-adjoint essential-projection in the sense of Definition 7.6 such that $\|P\| \leq 1$, then the triple $(\mathcal{E}, 0, 1 - P)$ is evidently a triple as well, where $0$ denotes the zero representation of the algebra on $\mathcal{E}$, but it is degenerate. Hence the cycles $(\mathcal{E}, \pi, P)$ and $(\mathcal{E} \oplus \mathcal{E}, \pi \oplus 0, P \oplus 1 - P)$ are equivalent in $\text{KK}$. Let $\hat{P} := \begin{bmatrix} P & (P - P^2)^\frac{1}{2} \\ (P - P^2)^\frac{1}{2} & 1 - P \end{bmatrix}$, then $\hat{P}^2 = \hat{P}$, that is, $\hat{P}$ is an actual projection. The operator homotopy with

$$
\hat{P}_t := \begin{bmatrix} P & (tP - t^2P^2)^\frac{1}{2} \\ (tP - t^2P^2)^\frac{1}{2} & 1 - P \end{bmatrix}
$$

gives a homotopy between the Kasparov cycles $(\mathcal{E} \oplus \mathcal{E}, \pi \oplus 0, P \oplus 1 - P)$ and $(\mathcal{E} \oplus \mathcal{E}, \rho \oplus 0, \hat{P})$, so $(\mathcal{E}, \rho, P)$ and $(\mathcal{E} \oplus \mathcal{E}, \rho \oplus 0, \hat{P})$ determine the same class: $P$ has been replaced by an actual projection. This leads to a completely positive map

$$
\hat{s}(a) := \hat{P} \hat{\rho}(a) \hat{P},
$$

for the Busby invariant

$$
\hat{\tau}(a) := \hat{P} \hat{\rho}(a) \hat{P} \mod J \otimes K.
$$

Computing, this equals

$$
\begin{bmatrix}
P \rho(a) P & P \rho(a) \sqrt{P - P^2} \\
P \rho(a) \sqrt{P - P^2} & \sqrt{P - P^2} \rho(a) \sqrt{P - P^2}
\end{bmatrix}
\mod M_2(J)
$$

and as all entries except for the top left corner are zero mod $M_2(J)$, this equals $P \rho(a) P = \tau(a)$, whence $\hat{\tau} = \tau$.

We are primarily interested in the following example of a geometric source.

Let $\overline{M}$ be a compact manifold-with-boundary $\partial M$ and interior $M$. Then we have an extension

$$
0 \to C_0(M) \to C(\overline{M}) \to C(\partial M) \to 0.
$$
With the identification $\mathcal{M}(C_{0}(M)) \cong C_{b}(M)$ we can describe the Busby invariant as the *-homomorphism

$$\tau: C(\partial M) \to C_{b}(M)/C_{0}(M), \quad \tau(f) = \tilde{f} \text{ mod } C_{0}(M)$$

where $\tilde{f}$ is any extension of $f$ to a continuous function on $\overline{\mathcal{M}}$.

It will be convenient to work with another extension rather than $(\mathcal{M}, r)$. Let $\mathcal{M} \subset \overline{\mathcal{M}}$ be a collar of the boundary (collars, even $G$-equivariant collarings, with $G$ a groupoid, are discussed extensively in [22].) Thus $\mathcal{M} \cong \partial M \times [0, 1)$ with the boundary identifying as $M \times \{0\}$. Let $\chi \in C_{b}(\mathcal{M})$ with $0 \leq \chi \leq 1$, $\chi = 1$ on $\partial M$ and $\chi$ has compact support in $\mathcal{M}$. We may take $\chi(x, t) = 1 - t$ for example, defined on $U \cong \partial M \times [0, 1)$ and extended to zero outside $U$, where we have used the identification $\mathcal{M} \cong \partial M \times [0, 1)$ Let

$$\nu := \mathcal{M} \cap M$$

an open subset of $M$ homeomorphic (via the collaring) to $\partial M \times (0, 1)$. Let $r: \mathcal{M} \to \partial M$ be the projection, then dualizing $r$ gives a *-homomorphism

$$\hat{r}: C(\partial M) \to C_{b}(\mathcal{M}) \subset C_{b}(\nu),$$

and since $\chi^{2} - 1 \in C_{0}(\nu)$, we get a Kasparov cycle $(C_{0}(\nu), \hat{r}, \chi)$ for $KK_{1}(C(\partial M), C_{0}(\nu))$. On the other hand, the extension

$$0 \to C_{0}(\nu) \to C_{0}(\mathcal{M}) \to C(\partial M) \to 0 \quad (7.10)$$

admits the following completely positive splitting:

$$s: C(\partial M) \to C_{0}(\mathcal{M}), \quad s(f) := \chi \cdot \hat{r}(f) \cdot \chi,$$

since $\chi \cdot \hat{r}(f) \cdot \chi = f$ on $\partial M$.

Now, carrying out the general procedure discussed above, with $A := C(\partial M)$, $B := C(\mathcal{M})$, $J := C_{0}(\nu)$ and $P := \chi$, and we realize the Busby invariant of the extension $(7.10)$ as the upper left corner of the representation

$$\hat{\rho}(f) := \left[ \begin{array}{cc} \chi \cdot \hat{r}(f) \cdot \chi & \sqrt{\chi - \chi^{2}} \cdot \hat{r}(f) \cdot \sqrt{\chi - \chi^{2}} \\ \sqrt{\chi - \chi^{2}} \cdot \hat{r}(f) \cdot \sqrt{\chi - \chi^{2}} & \chi \cdot \hat{r}(f) \cdot \chi \end{array} \right] \text{ mod } M_{2}(C_{0}(\nu)),$$

This proves that the Kasparov cycle associated to the extension $(7.10)$ is the triple $(C_{0}(\nu), \hat{r}, \chi)$ for $KK_{1}(C(\partial M), C_{0}(\nu))$. (Compare to Example 7.7).

Let $s: \partial M \to M$ the smooth embedding $s(x) = c(x, \frac{1}{2})$, where $c: \partial M \times [0, 1) \to M$ is the collaring ($c$ is a diffeomorphism onto the open collar $\mathcal{M}$) Then $s$ has an evidently trivial normal bundle with total space $\nu$ the same as above, which therefore carries a canonical $K$-orientation and Thom class $s_{t} \in KK_{1}(C(\partial M), C_{0}(\nu))$.

**Lemma 7.11.** 1) The class $[s_{\nu}] \in KK_{1}(C(\partial M), C_{0}(\nu))$ of the extension $(7.10)$ is equal to the Thom class $s_{\nu}$ of the normal bundle to the embedding $s$. 2) Let $[\partial M] \in KK_{1}(C(\partial M), C_{0}(M))$ be the class of the extension $(\mathcal{M})$. Then

$$(\varphi^{1})_{*}([\partial M]) = [\partial M] \in KK_{1}(C(\partial M), C_{0}(M))$$

holds, where $\varphi^{1}: C_{0}(\nu) \to C_{0}(M)$ is the *-homomorphism induced by the open embedding $\varphi: \nu \to M$.

**Remark 7.12.** In the notation of correspondences, this says that

$$s_{!} = [\partial M] \in KK_{1}(C(\partial M), C_{0}(M)).$$

The proofs of the Lemma is straightforward (see Example [21]. See [10] for some rather similar argumentation (which is where the author learned it.)

There is no difficulty whatsoever in making the construction $G$-equivariant, if $G$ is a proper groupoid, acting on a bundle of smooth manifolds. We state the Lemma, and leave details
of the proof to the reader; very similar such Lemmas using similar techniques appear in [22]. Furthermore, we construct equivariant collars in the main example of interest, below.

Lemma 7.13. Let $\mathcal{G}$ be a proper groupoid acting smoothly on a bundle of smooth manifolds-with-boundary $\overline{M}$ with boundary $\partial M$ and interior $M$. Assume there is a $\mathcal{G}$-equivariant collaring $c: \partial M \times [0,1) \to \overline{M}$, i.e. $c$ is a $\mathcal{G}$-equivariant fibrewise diffeomorphism onto an open neighbourhood of $\partial M$ in $\overline{M}$ whose restriction to $\partial M \times \{0\}$ is the inclusion $\partial M \to \overline{M}$. Then the $\mathcal{G}$-equivariant extension $0 \to C_0(M) \to C(\overline{M}) \to C(\partial M) \to 0$ admits a $\mathcal{G}$-equivariant contractive and completely positive splitting, the smooth embedding $\iota: \partial M \to M$, $\iota(x) = c(x, \frac{1}{2})$ admits a canonical $\mathcal{G}$-equivariant orientation, and the equation

$$\iota! = [\partial M] \in \text{KK}^G(C(\partial M), C_0(M))$$

holds.

7.3. Conclusion of the proof. We now return to hyperbolic groups.

Let $(Z, \Gamma)$ be a smooth $K$-oriented group with $Z$ negatively curved, so that it is Gromov hyperbolic with Gromov compactification $\overline{Z}$ and boundary $\partial Z \cong \partial \Gamma$ (noting that $\Gamma$ acts co-compactly and isometrically on $Z$).

The boundary $\partial Z$ can be identified with $S^{n-1}$, if $\dim(Z) = n$, and the group acts by $C^{1+\epsilon}$-diffeomorphisms of this sphere. We have a $\Gamma$-equivariant exact sequence

$$(7.14) \quad 0 \to C_0(Z) \to C(\overline{Z}) \to C(\partial Z) \to 0.$$  

Clearly the boundary does not admit a $\Gamma$-equivariant collaring. For if it did, the image $\iota(\partial Z) \subset Z$ would be $\Gamma$-invariant, which is impossible, since $\partial Z$ is compact and $\Gamma$ acts properly.

However, after inflating this whole situation over $Z \cong \ell \Gamma$ we obtain a $\mathcal{G}$-equivariant bundle of manifolds-with-boundary and corresponding extensions, and now it is possible to find an equivariant collaring

$$c: Z \times \partial Z \times [0,1) \to Z \times \overline{Z}$$

quite explicitly, for example as follows. For a point $(x, a) \in Z \times \partial Z$, the geodesic ray emanating from $x$ and pointing towards the boundary point $a$ determines a canonical (geometrically defined) map $r_{x,a}: [0, \infty) \to Z$ (and endpoint $a$ in $\overline{Z}$), so that

$$r_{g_x, g_a}(t) = g r_{x,a}(t)$$

for any isometry of $Z$. Fix a re-scaling $[0, 1) \overset{\sim}{\to} [0, \infty)$ mapping $1$ to $\infty$. Then combining the re-scaling with the map $r$ just defined gives the required collaring

$$c: Z \times \partial Z \times [0,1) \cong Z \times \partial Z \times [0, \infty) \overset{\iota!}{\to} Z \times \overline{Z},$$

the explicit formula may be taken to be

$$c(x, a, t) = (x, r_{x,a}(\sqrt{1 - t})), \quad \text{if } t \neq 0, \quad \text{and } c(x, a, 0) := a.$$  

Lemma 7.13 now applies. Let

$$\iota: Z \times \partial Z \to Z \times Z, \quad \iota(x, a) := c(x, a, \frac{1}{2}).$$

This is a $\mathcal{G}$-equivariant oriented fibre wise embedding, i.e. a bundle of smooth embeddings $\partial Z \to Z$ parameterized by the points of $Z$, and equivariant, as a bundle of maps, under the $\Gamma$-action. It yields a class

$$(7.15) \quad \iota! \in \text{KK}^G(C_0(Z \times \partial Z), C_0(Z \times Z)) \cong \text{RKK}^G(Z; C(\partial Z), C_0(Z))$$
which, by Lemma 7.13, is the same as the corresponding extension class, that is, the class obtained
via the $\mathcal{G}_\Gamma$-equivariant Stinespring construction from the $\mathcal{G}_\Gamma$-equivariant bundle of extensions
\begin{equation}
0 \to C_0(Z \times Z) \to C_0(Z \times \bar{Z}) \to C_0(Z \times \partial Z) \to 0,
\end{equation}
over $Z$.

For convenience in the argument we are using, we point out that the $\Gamma$-equivariant extension \((7.14)\),
though it doesn’t admit a $\Gamma$-equivariant collar, it does admit a $\Gamma$-equivariant
completely positive splitting of another kind. If $x \in Z$, the exponential map determines a map
$\exp_z : S_x(Z) \to \partial Z$, and pushing forward the volume element on $S_x Z$ determined by the metric,
we obtain a measure $\mu_x \in \text{Prob}(\partial Z)$. The formula
\begin{equation}
(Pf)(z) := \int_{\partial Z} f(\xi) d\mu_x(\xi)
\end{equation}
provides a Poisson-transform in this situation: $Pf$ extends continuously to $\bar{Z}$ and restricts to $f$
on the boundary. The construction is clearly equivariant.

Therefore the extension
\begin{equation}
0 \to C_0(Z) \to C(Z) \to C(\partial Z) \to 0
\end{equation}
determines a class $[\partial Z]$ in $\text{KK}^1(\mathcal{C}(\partial Z), C_0(Z))$.

See [8] for a treatment of measures on the boundaries of hyperbolic spaces.

It is clear from computing with the cycles that
\begin{equation}
[\partial Z] \otimes C_0(Z)[\text{ev}] = [\partial \Gamma] \in \text{KK}^1(\mathcal{C}(\partial \Gamma), C_0(\Gamma)),
\end{equation}
where $[\partial \Gamma]$ is the boundary extension class (the Dirac class, as we aim to prove).

**Lemma 7.17.** The inflation of the boundary extension class $[\partial \Gamma]$ in $\text{KK}^1(\mathcal{C}(\partial \Gamma), C_0(\Gamma))$ factors as
\begin{equation}
\text{inflate}(\partial \Gamma) = \mathfrak{l} ! \otimes C_0(Z \times Z) \text{inflate}(\text{ev}) \in \text{RKK}^1(Z; C(\partial Z), C).
\end{equation}

with $\mathfrak{l}$ as in \((7.18)\).

**Proof.** The class $\text{inflate}(\partial \Gamma)$ is that of an extension \((7.16)\) with two natural $\mathcal{G}_\Gamma$-equivariant
completely positive splittings: one using the product of the identity map on $Z$ and the Poisson
splitting of \((7.14)\) explained above, and the other using the $\mathcal{G}_\Gamma$-equivariant collaring. The space of
$\mathcal{G}_\Gamma$-equivariant completely positive maps is convex, and so the two corresponding cycles are
homotopic. We obtain
\begin{equation}
\mathfrak{l} ! = \text{inflate}(\partial \Gamma) \in \text{RKK}^1(Z; C(\partial Z), C_0(Z)),
\end{equation}
by Lemma 7.13. We get
\begin{equation}
\mathfrak{l} ! \otimes C_0(Z \times Z) \text{inflate}(\text{ev})
= \text{inflate}(\partial \Gamma) \otimes C_0(Z \times Z) \text{inflate}(\text{ev}) = \text{inflate}(\partial \Gamma) \otimes C_0(Z) \text{[ev]} = \text{inflate}(\partial \Gamma)
\end{equation}

We now complete the proof of Theorem 7.2.

We have shown that
\begin{equation}
\text{inflate}(\partial \Gamma) = \mathfrak{l} ! \otimes C_0(Z \times Z) \otimes C_0(Z \times Z)(1c_0(\Gamma) \otimes C \text{[ev]})
\end{equation}
where $\mathfrak{l} : Z \times \partial Z \to Z \times Z$ is
\begin{equation}
\mathfrak{l}(x, a) = (x, c(x, a, \frac{1}{2})).
\end{equation}
This equality holds in $\text{RKK}^1(Z; C(\partial Z), C)$. 
To complete the proof, we show that
\begin{equation}
\mathrm{PD}(\{! \otimes C_0(Z \times Z) \otimes C_0(Z \times Z)(1_{C_0}(Z) \otimes \mathbb{C} [\mathrm{ev}])\}) = [\mathrm{ev}] \otimes \mathbb{C} [\partial Z].
\end{equation}

Using the definition of PD, the left hand side of this equation is
\begin{equation}
\overline{\prod} \otimes C_0(Z \times Z) (1_{C_0}(Z) \otimes [\mathrm{ev}]) \otimes C_0(Z) [Z] = \overline{\prod} \otimes C_0(Z \times Z) ([\mathrm{ev}] \otimes \mathbb{C} [Z])
\end{equation}
By commutativity of the external product \(\otimes\) and the fact that the two coordinate projections \(Z \times Z \rightarrow Z\) are \(\Gamma\)-equivariantly homotopic, this is the same as
\begin{equation}
\overline{\prod} \otimes C_0(Z \times Z) ([Z] \otimes \mathbb{C} [\mathrm{ev}]) = \overline{\prod} \otimes C_0(Z \times Z) ([Z] \otimes \mathbb{C} 1_{C_0}(Z) \otimes C_0(Z) [\mathrm{ev}])
\end{equation}
Now we claim that
\begin{equation}
\overline{\prod} \otimes C_0(Z \times Z) ([Z] \otimes \mathbb{C} 1_{C_0}(Z)) = 1_{C_0}(Z) \otimes \mathbb{C} [\partial Z]
\end{equation}
with \([\partial Z]\) the transverse Dirac class on \(\partial Z\).
The class \(\overline{\prod} \in \lim_{\rightarrow} \mathbb{K} \Gamma^\ast\) is represented by the wrong-warp map\n\[ r : Z \times \partial Z \rightarrow Z, r(x, a) := (x, c(x, a, \frac{1}{2})), \]
or, more precisely, by the smooth correspondence \(Z \times \partial Z \stackrel{\mathrm{id}}{\longleftarrow} Z \times \partial Z \rightarrow Z \times Z\).
And \([Z] \otimes \mathbb{C} 1_{C_0}(Z)\) is of course represented by the correspondence \(Z \times Z \stackrel{\mathrm{id}}{\longleftarrow} Z \times Z \stackrel{\mathrm{pr}_2}{\longrightarrow} Z\).
These correspondences are transverse (the left map of the second is a submersion) so can be composed using transversality and coincidence spaces and the outcome is easily computed to be the correspondence \(Z \times \partial Z \stackrel{\mathrm{id}}{\longleftarrow} Z \times \partial Z \rightarrow Z, \)
with \(r'(z, a) := c(z, a, \frac{1}{2})\).
But moving \(c(z, a, \frac{1}{2})\) along the ray \([z, a)\) from \(c(z, a, \frac{1}{2})\) to \(z = \lim_{t \rightarrow 1} c(z, a, t)\) gives a homotopy between \(r'\) and the projection \(\mathrm{pr}_Z : Z \times \partial Z \rightarrow Z\).
Now given the claim \((7.24)\), plug it into \((7.23)\), to give that the left hand side of \((7.21)\) equals
\(1_{C_0(Z) \otimes \mathbb{C} [\partial Z]} \otimes C_0(Z) [\mathrm{ev}] = [\partial Z] \otimes \mathbb{C} [\mathrm{ev}]\),
as required.

8. The intersection index formula

The procedure followed by Connes, Gromov and Moscovici say in their paper \([9]\), amounts to, as they put it, a sort of reverse index theorem. It builds an analytic object (a \(\mathbb{K}\)-class) from to a given topological one (group cohomology class). In their case, the purpose was to prove homotopy-invariance of the topological object (the higher signature determined by the cohomology class).

We are doing something similar. The class of a fibre in \(Z \times \Gamma X \rightarrow \Gamma \backslash X\) may or may not admit an analytic representative (as a cycle representing the Dirac class). But any time this is done, an automatic topological formula for its induced K-theory pairing is determined.

Let \((Z, \Gamma)\) be a smooth, \(d\)-dimensional, K-oriented group, and let \(X\) be a smooth equivariantly K-oriented \(\Gamma\)-manifold of dimension \(n\). Assume that a Dirac class \([\Gamma \times \overline{X}] \in \lim_{\rightarrow} \mathbb{K} \Gamma(X) \times \Gamma, \mathbb{C} \) exists, then it determines a pairing and corresponding map\n\[ K_{n-d}(C_0(X) \times \Gamma) \rightarrow \mathbb{Z}. \]
We are going to compute this map geometrically on the range of the Baum-Connes assembly map
\[ \mu: KK_{n-d}^\Gamma(C_0(Z), C_0(X)) \to K_{n-d}(C_0(X) \times \Gamma). \]
This is possible due to the topological definition of Dirac class.

To simplify matters, we will assume that \( \Gamma \) is torsion-free in the rest of this section. As before we let \( i_{0,X}: X \to Z \times \Gamma X \) the inclusion of \( X \) as a fibre in \( p: Z \times \Gamma X \to \Gamma \setminus Z \).

Using inverse of the Poincaré duality from Proposition 2.10
\[ PD^{-1}: KK^\Gamma(C_0(Z), C_0(X)) \cong RRK^\Gamma(Z; C, C_0(X)) \]
and the generalized Green-Julg Theorem,
\[ \text{RKK}^\Gamma(Z; C, C_0(X)) \cong KK_*(C, C_0(Z \times X) \times \Gamma) \cong K^*(-(Z \times \Gamma X)), \]
we may re-cast the Baum-Connes assembly map as a map
\[ (8.1) \quad \hat{\mu}: K^{-*}(Z \times \Gamma X) \to K_{*-d}(C_0(X) \times \Gamma) \]
shifting degrees by \(-d\). The relevant dimension for purposes of pairing with the Dirac class, is then \( * = n \). The domain of \( \hat{\mu} \) may be described in terms of geometric equivalence classes of smooth correspondences
\[ (8.2) \quad \cdot \leftarrow (M, \xi) \xrightarrow{f} Z \times \Gamma X. \]
with \( \xi \) a compactly supported K-theory class on \( M, f \) K-oriented. Since \( Z \times \Gamma X \) is already endowed with a fixed K-orientation, by the 2-out-of-3 result for K-oriented vector bundles, K-orientations on \( f \), that is, on the vector bundle \( f^*(T(Z \times \Gamma X)) \oplus TM \), are in 1-1 correspondence with K-orientations on \( M \), so that we may regard the data of a geometric cycle for the domain of \( \hat{\mu} \) as being a smooth, K-oriented manifold \( M \), a smooth map \( f: M \to Z \times \Gamma X \), and a compactly supported K-theory class \( \xi \in K^{-i}(M) \) on \( M \).

The dimension of the corresponding class in \( K^*(Z \times \Gamma X) \) is \(-i - n - d + \text{dim } M \), and after Poincaré dualizing it we obtain thus a class in \( \text{KK}^\Gamma_{1-n-\text{dim } M}(C_0(Z), C_0(X)) \), so that in order to get a \( n - d \)-dimensional K-theory class, the right dimension to pair with the Dirac class, for \( C_0(X) \times \Gamma \), we need \( i = \text{dim } M - d \) (mod 2, of course).

In particular, if \( M \) is compact, and \( \xi = 1 \) is the class of the trivial line bundle, the case of most immediate geometric interest, and the one we will focus on, then this shows that we should be interested in examples when \( \text{dim } M = d \), the dimension of \( Z \).

**Definition 8.3.** A \( d \)-dimensional geometric cocycle for the \( \Gamma \) action on \( X \) is a pair consisting of a compact, \( d \)-dimensional K-oriented manifold \( M \) and a smooth map \( f: M \to Z \times \Gamma X \).

Its class in \( K^{-d}(Z \times \Gamma X) \) is denoted \( \text{Index}(f)! \).

**Example 8.4.** If the integers \( \mathbb{Z} \) acts on a compact manifold \( X \) of dimension \( n \), then \( d = 1 \) and geometric 1-cocycles correspond roughly to (homotopy classes of) loops in the mapping cylinder \( \mathbb{R} \times_X Z \).

**Example 8.5.** Let \( \mathbb{Z}^2 \) act on a torus \( T^n \) by a pair of group translations, so that \( \mathbb{R}^2 \times \mathbb{Z}^2 T^n \cong T^{2+n} \).

Let \( \mathcal{L} \) be a plane in \( \mathbb{R}^{2+n} \) specified by a set of \( n \) equations
\[ a_{ij} x + b_{ij} y + u_{i1} t_1 + \cdots + u_{in} t_n = 0, \quad i = 1, \ldots, n \]
with integer coefficients with the \( n \)-by-\( n \) matrix \( U := (u_{ij}) \) invertible over \( \mathbb{Q} \).

Then \( \mathcal{L}/\mathbb{Z}^{n+2} \) is a 2-dimensional torus which maps canonically to \( T^{2+n} \). We get a 2-dimensional geometric cocycle
\[ p: T^2 \to \mathbb{R}^2 \times \mathbb{Z}^2 T^n. \]
Example 8.6. Let $M$ be a negatively curved compact $d$-dimensional $K$-oriented manifold and $\Gamma = \pi_1(M)$ acting on the universal cover $Z := \tilde{M}$. Then

$$Z \times_\Gamma \partial Z \cong SM,$$

where $SM$ is the sphere bundle of the tangent bundle of $M$. If the Euler characteristic $\chi(M)$ is zero, then there is a non-vanishing vector field on $M$ and hence a smooth map

$$\xi : M \to SM,$$

and, $K$-orienting $\xi$ by the $K$-orientations on its domain and range, we get a $d$-dimensional geometric cocycle $\text{Index}(\xi)$ for $\Gamma$ acting on $\partial Z$.

Let $(M, f)$ be a (slightly inapted named) $d$-dimensional geometric cycle, as it determines a smooth $n$-dimensional correspondence as in [8.2] with class $[M, f] \in \text{KK}_n(C, C(Z \times_\Gamma X))$. The dualized version of the assembly map of [8.1] shifts degrees by $-d$ and so

$$\hat{\mu}([M, f]) \in \text{KK}_{n-d}(C, C_0(X) \times \Gamma) = \text{KK}_{n-d}(C_0(X) \times \Gamma)$$

can be paired with the Dirac class $[\Gamma \times \hat{X}] \in \text{KK}_{d-n}(C_0(X) \times \Gamma, C)$ to give an integer. We call this integer the Dirac index of the cocycle. It is an analytic invariant.

We now define a topological invariant of a cocycle $f : M \to Z \times_\Gamma X$. Consider the inclusion $i_{z_0, X} : Z \to Z \times_\Gamma X$ of the fibre $X_{z_0}$. By perturbing $f$ through a homotopy if necessary, we may assume that $f$ and $i_{z_0, X}$ are transverse. Therefore we can compose the correspondences

$$\cdot \leftarrow M \to Z \times_\Gamma X \xleftarrow{i_{z_0, X}} X \to \cdot$$

by transversality, yielding the $K$-oriented smooth, 0-dimensional manifold $f^{-1}(X_{z_0})$, where $X_{z_0}$ is the fibre. This inverse image is is a finite set of points, suitably $K$-oriented.

We call the algebraic sum of these $K$-oriented (e.g. signed) points the intersection index of the cocycle.

Example 8.7. In the case of integer actions as in Example [8.3] the intersection index of a loop in $\mathbb{R} \times_{\mathbb{Z}} X$ is the algebraic number of times the loop crosses the hypersurface $X \cong F \subset \mathbb{R} \times_{\mathbb{Z}} X$.

Example 8.8. The intersection index of the 2-dimensional geometric cocycles for a $\mathbb{Z}^2$-action on $\mathbb{T}^n$ as in Example [8.3] is given by the cardinality of the finite group $U(\mathbb{Z}^n)/\mathbb{Z}^n$ with $U \in M_n(\mathbb{Z}) \cap \text{GL}_n(\mathbb{Q})$ the integer matrix used to define the plane.

Remark 8.9. Given that $\Gamma$ is torsion-free, the long exact sequence of the fibration $p : Z \times_\Gamma X \to \Gamma \backslash Z$ (with fibre $X$) gives that the inclusion of the fibre $X$ in $Z \times_\Gamma X$ induces an isomorphism $\pi_d(X) \to \pi_d(Z \times_\Gamma X)$ on homotopy groups as long as $d \geq 2$, since $\Gamma \backslash Z$ is aspherical.

This shows that for $d > 1$, one cannot achieve geometric cocycles with nonzero intersection indices by mapping spheres $S^d \to Z \times_\Gamma X$, since they factor through the fibre inclusion, and up to obvious homotopy one can alter one of any two fibre inclusions to make them have disjoint range.

The main point of Dirac classes for actions is the following result, which can be considered a kind of ‘black box’ index theorem. It applies automatically every time one constructs a representative of the Dirac class. The result below is a special case of a more general one, Theorem [8.17].

Theorem 8.10. If $f : M \to Z \times_\Gamma X$ is a $d$-dimensional geometric cocycle for $\Gamma$ acting on $X$, then it’s Dirac (analytic) index equals its (topological) intersection index.

This result is a formal consequence of functorial properties of the Dirac method and is discussed following the examples below.
8.1. **Integer actions.** In the case of integer actions, say of \( \mathbb{Z} \) acting on \( X \) smoothly by a \( \varphi: X \rightarrow X \), the Dirac class \([\mathbb{Z} \ltimes X] \in KK_{1-n}(C(X) \rtimes \mathbb{Z}, \mathbb{C})\) always is non-vanishing and non-torsion in K-homology. This follows from Theorem 8.10 and the following construction of a 1-cocycle.

Choose a point \( x_0 \) of \( X \) and let \( \gamma: [0, 1] \rightarrow X \) be a smooth path from \( x_0 \) to \( \varphi(x_0) \) with \( \gamma'(0) \neq 0 \). Let \( f: [0, 1] \rightarrow \mathbb{R} \times \mathbb{Z} \) be the loop \( f(t) := [(t, \gamma(t))] \). It’s intersection index is clearly \(+1\).

If the action is isometric, then we may represent the Dirac class by the spectral triple(s) described in Example 8.10.

Suppose \( X = T \) with \( \mathbb{Z} \) acting by irrational rotation. The Dirac class is represented by the deformed Dolbeault operator \( D_\theta \) acting on \( L^2(A_\theta) \), while \( \mathbb{R} \times \mathbb{Z} T \cong T^2 \) can be identified with the 2-torus. If \( L_{p,q} \subset \mathbb{R}^2 \) is a line through the origin of rational slope \( \frac{p}{q} \), then it projects to a loop \( f_{p,q}: T \rightarrow T^2 \), that is, a geometric 1-cocycle, whose intersection index is \(+q\).

The analytic counterpart of the index theorem is as follows.

Let \( L_\theta \) be a line in \( T^2 \) of slope \( \theta \). The real line acts by Kronecker flow on \( T^2 \) and the loops \( f_{p,q} \) are transverse to the flow. Restricting the groupoid \( \mathbb{R} \times \mathbb{R}^2 \) to the transversals \( f_{p,q} \) and identifying the transversals with \( T \) yields, as one computes, the groupoid \( \mathbb{Z} \ltimes \theta' T \) of irrational rotation by \( \theta' := \frac{p\theta + qr}{s} \). Forgetting the left action of \( A_\theta' \) on these modules gives (since \( A_\theta' \) is unital and acts by compact operators) a family of \( E_{p,q} \) of finitely generated projective modules over \( A_\theta \) (studied by Rieffel.)

The Dirac index computes the Kasparov pairing

\[ \langle [E_{p,q}], [D_\theta] \rangle. \]

Intuitively, this is the index of the Dirac operator on \( T^2 \) ‘twisted by’ the ‘bundle’ \( E_{p,q} \), and by choosing a suitable connection one can represent it quite concretely as a deformed Dolbeault operator, acting on sections of the relevant bundle. The Dirac index (the Fredholm index of this operator) is thus \(+q\).

8.2. **Vanishing of the Fredholm index.** The intersection index formula allows us to dispose rapidly of the problem of computing the ordinary Fredholm index of a Dirac class, for an action of \( \Gamma \) on \( X \) compact, that is, the pairing

\[ \langle [1], [\Gamma \ltimes \overline{X}] \rangle \in KK_{d-n}(\mathbb{C}, \mathbb{C}) = \mathbb{Z}, \]

which, of course, is only potentially nonzero when \( d - n = 0 \mod 2 \).

**Theorem 8.11.** The Fredholm index of the Dirac class \([\Gamma \ltimes \overline{X}]\) of any action is zero.

For example, the ordinary Fredholm index of the deformed Dolbeault operator \( D_\theta \) on \( T_0^2 \) is zero.

The proof is based on the following simple Lemma, whose proof already follows from the discussion in the proof of Proposition 4.8.

**Lemma 8.12.** \( \mu([ev]) = [1_{C^*\Gamma}] \in K_0(C^*\Gamma) \) where \( 1_{C^*\Gamma} \) is the unit in \( C^*\Gamma \).

**Proof.** (of Theorem 8.11). We lift the class \([1] \in K_0(C_0(X) \rtimes \Gamma)\) under \( \hat{\mu} \) to a geometric cocycle with zero intersection index.
Let $u: \mathbb{C} \to C(X)$ be the $\Gamma$-equivariant inclusion, $u \times \Gamma: C^*(\Gamma) \to C(X) \times \Gamma$ the induced map. The diagram
\[
\begin{array}{c}
\KK_{\Gamma}^0(C_0(Z), \mathbb{C}) \xrightarrow{\mu} \KK_0(\C^* \Gamma) \\
u_*, \quad (u \times \Gamma)_* \\
\KK_{\Gamma}^0(C_0(Z), C(X)) \xrightarrow{\mu_X} \KK_0(\C^* \Gamma (u \times \Gamma))
\end{array}
\]
commutes and thus $\mu_X(u_*([\text{ev}]) \in \KK_{\Gamma}^0(C_0(Z), C(X))) = [1_{C^*(X) \times \Gamma}]$ by the Lemma. To show this has zero pairing with the Dirac class, it suffices to compute the Poincaré dual of $u_*([\text{ev}]) \in \RKK_{\Gamma+}(Z; \C, C(X)) \cong K^{-d}(Z \times_\Gamma X)$, and show that it’s intersection index is zero. As the proof is similar to that of Proposition 6.15, we merely sketch it. The class $u_*([\text{ev}])$ is represented (analytically) by the $\Gamma$-equivariant correspondence obtained by composing
\[
Z \xrightarrow{\alpha_{z_0}} \Gamma \xrightarrow{\cdot} X \xrightarrow{id} X,
\]
where $\alpha_{z_0}$ is the orbit map at $z_0$.

The composition gives
\[
Z \xrightarrow{\alpha_{z_0} \circ \text{pr}_\Gamma} \Gamma \times X \xrightarrow{\text{pr}_X} X
\]
from $Z$ to $X$. Poincaré dualizing as in the proof of Proposition 6.15 and taking $\Gamma$-invariants gives the smooth correspondence
\[
\cdot \xleftarrow{\alpha_{z_0}} X \xrightarrow{i_{z_0,X}} Z \times_\Gamma X.
\]
Finally, replacing the point $\Gamma z_0$ to any different point $\Gamma z_1$, we obtain the equivalent (because the two points can be connected by a path) correspondence
\[
\cdot \xleftarrow{\alpha_{z_1}} X \xrightarrow{e_{z_1,X}} Z \times_\Gamma X
\]
and the map $e_{z_1,X}$ now has disjoint image from the image of $i_{z_0,X}$. Hence the intersection index is zero as claimed.

\[\square\]

8.3. Boundary actions of hyperbolic groups.

**Corollary 8.13.** Let $\Gamma$ be the fundamental group of a negatively curved odd-dimensional compact $d$-dimensional manifold $M$ with universal cover $Z$ and Gromov boundary $\partial Z \cong \partial \Gamma$. Then the boundary extension class
\[
[\partial \Gamma] \in \KK_1(C(\partial \Gamma) \times \Gamma)
\]
is a non-torsion, nonzero class in K-homology, and the Dirac index of the $d$-dimensional geometric cocycle of Example 8.6 determined by a non-vanishing vector field on $M$, is $+1$.

**Remark 8.14.** We have implicitly K-oriented $\xi: M \to SM$ by the separate K-orientations on $M$ and on $SM$ given to us. One could also K-orient it differently, by switching the K-orientation on $M$. This would result in an intersection index of $-1$.

In the case of isometry groups of classical (say, real), hyperbolic space, where $M = \Gamma \backslash Z$ where $Z$ is classical hyperbolic space, the sphere bundle $SM$ identifies with $G/\Gamma$, where $G$ is the full group of orientation-preserving isometries. If now $\Gamma' \subset \Gamma$ is a lattice of finite index, and $\xi: M' \to SM' \cong G/\Gamma'$ is a non-vanishing vector field, then
\[
\cdot \xleftarrow{M' \xi} G/\Gamma' \to G/\Gamma
\]
also gives a geometric $d$-cocycle with intersection index $[\Gamma; \Gamma']$, as the reader can easily check.
Of course the existence of a non-vanishing vector field $\xi$ in order to make a positive index is equivalent to vanishing of the Euler characteristic $\chi(M)$. For surface groups $\Gamma = \pi_1(M^g)$, this is not the case, and in fact the boundary extension class, that is, the Dirac class, is torsion of order $\chi(M^g) = 2 - 2g$.

There is a very natural, geometric way of studying torsion in geometric K-homology, however, and this gives some information on, for example, the torsion degree of, for instance, the boundary extension class. We give a brief description of this now.

Let $k$ be any positive integer. The Bockstein sequence for K-homology with $\mathbb{Z}/k$-coefficients is

$$ (8.15) \quad \cdots \to K_*( SM ) \xrightarrow{k} K_*( SM ) \to K_*( SM )_{\mathbb{Z}/k} \xrightarrow{\delta} K_{*-1}( SM ) \to \cdots $$

where $K_*( SM )_{\mathbb{Z}/k}$ is the K-homology of $SM$ with $\mathbb{Z}/k$-coefficients. The Bockstein sequence describes $k$-torsion in K-homology.

R. Deeley in [12,13] describes this group using a modification of the usual Baum-Douglas style, using (K-oriented) $\mathbb{Z}/k$-manifolds in the style of Sullivan, which map to $SM$, and a vector bundle datum. With this description, the Bockstein connecting map in (8.15) has a simple geometric description in terms of Baum-Douglas cycles: if $f : W \to SM$ is a map from a K-oriented $\mathbb{Z}/k$-manifold $W$ to $SM$, then $f$ restricts to a map $\partial W \to SM$, giving an ordinary Baum-Douglas cycle for $SM$ and corresponding $k$-torsion class (since $k$-copies of it is, manifestly, a boundary). One deals with a bundle datum by restriction as well.

Let now $i : S^{d-1} \to SM$ be the inclusion of a fibre in $\pi : SM \to M$, with class $i_*([S^{d-1}]) \in K_{1-d}( SM )$. Choose a smooth vector field $\xi : M \to TM$ transverse to the zero section. The vector field has zeros $p_1, p_2, \ldots$ and an index $\pm 1$ at each of these zeros, and the sum of the indices is equal to $k := \chi(M)$.

The Riemannian exponential map identifies the fibres $S_{p_i}(M)$ with the boundaries $\partial B_j$ of Riemannian balls around $p_i$. Remove these open balls from $M$. This results in a manifold-with-boundary $W$. Using a parallel transport argument, for example, one can produce diffeomorphisms

$$ f_{ij} : \partial B_i \to \partial B_j $$

which are orientation-reversing if $\xi$ has the same index at $p_i$ and $p_j$, and are orientation-preserving otherwise.

Now identify any two $\partial B_i$’s, using the relevant diffeomorphism, if the vector field has the same index at each of their centres. This results in a new manifold-with-boundary $W$, whose remaining boundary components come with a collection of orientation-preserving diffeomorphisms between them. We thus have a $\mathbb{Z}/k$-manifold, where $k$ is the Euler characteristic. Finally, the vector field $\xi$ is non-vanishing on the complement of $\cup_i B_i$, can be arranged compatible with the diffeomorphisms $f_{ij}$, and hence determines a map $\xi' : W \to SM$.

Thus we obtain a cycle $(W, \xi')$ for $K_0(M)_{\mathbb{Z}/k}$.

**Theorem 8.16.** The Bockstein map $\delta : K_0(SM)_{\mathbb{Z}/k} \to K_1(SM)$ maps the class of $\xi' : W \to SM$ to the class $i_*([S^{d-1}]) \in K_1(SM)$.

In particular, the fibre class $i_*([S^{d-1}])$, and hence the boundary extension class $[\partial W] \in K^1(C(\partial \Gamma ) \rtimes \Gamma )$, is $\chi(M)$-torsion in $K^1(C(\partial \Gamma ) \rtimes \Gamma )$.

We conclude with the proof of the intersection index formula, which is essentially a formal consequence of functoriality results in equivariant KK-theory.

**Theorem 8.17.** If $\cdot \rightsquigarrow (M, \xi \bigcup Z \times \Gamma X$ is a smooth correspondence from a point to $Z \times \Gamma X$, $\text{Index}(f!, \xi) \in KK_*(\mathbb{C}, C_0(Z \times \Gamma X))$ its class, $[\text{ev}] \otimes \mathbb{C} [X] \in KK_{-d}(Z \times \Gamma X, \mathbb{C})$ the K-homology
class of a fibre of $Z \times_\Gamma X \to \Gamma \backslash X$ then

$$\langle \hat{\mu}( \text{Index}(f!, \xi)), [\Gamma \ltimes X] \rangle = \langle \text{Index}(f!, \xi), [\text{ev}] \otimes_\mathbb{C} [X] \rangle,$$

with in both cases the pairings between between Kasparov K-theory and K-homology.

\textit{Proof.} The work of Meyer and Nest, part of which was extended in \cite{22}, on formalizing and abstracting the Dirac method, show that in a rather more general context, the Baum-Connes assembly map

\begin{equation}
\text{KK}_*^\Gamma(C_0(\mathcal{E}\Gamma), B) \xrightarrow{\mu} \text{KK}_*^\Gamma(\mathbb{C}, B \rtimes \Gamma)
\end{equation}

agrees with the following map, supposing that one has a suitable dual (see \cite{22} Theorem 6.9 and environmental discussion). The dual involves various data, including a proper $\Gamma$-C*-algebra $\mathcal{P}$ which in the present case of interest is $C_0(Z)$. Duality identifies the domain of (8.18) with the group

$$\mathcal{R}\text{KK}_*^{\Gamma+d}(\mathcal{E}\Gamma; C_0(\mathcal{E}\Gamma), \mathcal{P} \otimes C_0(X)).$$

The generalized Green-Julg Theorem identifies this group with

$$\text{KK}_*^{\Gamma+d}(\mathbb{C}, \mathcal{P} \otimes C_0(X) \rtimes \Gamma).$$

Hence assembly is equivalent to a map

\begin{equation}
\text{KK}(\mathbb{C}, \mathcal{P} \otimes C_0(X) \rtimes \Gamma) \to \text{KK}_*^{\Gamma+d}(\mathbb{C}, C_0(X) \rtimes \Gamma).
\end{equation}

The map in question is induced by Kasparov product with with the Dirac morphism $D \in \text{KK}_*^{\Gamma}(\mathbb{C}),$. $C_0(X) \rtimes \Gamma$).

Translating this into the present context, where $\mathcal{P} = C_0(Z)$, $D = [Z] \in \text{KK}_*^{\Gamma+d}(C_0(Z), \mathbb{C})$, gives the following Lemma, from which the Theorem follows immediately from putting $\psi := [\Gamma \ltimes X]$ to be the Dirac class in equivariant theory.

\textbf{Lemma 8.20.} Let $\varphi \in \text{KK}_*^\Gamma(C_0(Z), C_0(X))$ and $\check{\varphi} \in K^{-s-d}(Z \times_\Gamma X)$ it’s Poincaré dual. Let $\psi \in \text{KK}_*^{\Gamma+d}(C_0(X), \mathbb{C})$ and $L(\psi) \in \text{KK}_*^{\Gamma+d}(C_0(Z \times_\Gamma X), \mathbb{C}) = K_{s+d}(Z \times_\Gamma X)$ it’s image under the localization map. Then

\begin{equation}
\langle \mu(\varphi), \psi \rangle = \langle \check{\varphi}, L(\psi) \rangle \in \mathbb{Z},
\end{equation}

where the pairing is that between K-theory and K-homology of $Z \times_\Gamma X$.

This concludes the proof of the intersection index formula. \hfill \Box

Finally, we note that the more general statement of the Intersection Index Formula specializes to a topological formula for computing the boundary map of the boundary extension of a hyperbolic group. We record it here, by way of conclusion.

\textbf{Corollary 8.22.} The boundary map

$$\delta: K_1(C(\partial Z) \rtimes \Gamma) \to \mathbb{Z}$$

associated to the boundary extension admits the following topological description. Let

$$\hat{\mu}: K^{-s}(SM) \to K_{s+d}(C(\partial Z) \rtimes \Gamma)$$

be the Baum-Connes assembly map. Then if $\cdot \longmapsto (W, \xi) \overset{\delta \omega}{\longmapsto} SM$ is a Baum-Douglas cocycle for $SM$, with class $\text{Index}(f!, \xi)$, and $f: W \to SM$ transverse to the fibre $S_{z_0}M$, then

$$\langle \delta \circ \hat{\mu} \rangle(\text{Index}(f!, \xi)) = \text{Index}(\left[f^{-1}(S_{z_0}M)\right] \cdot \xi)$$

is the index of the Dirac operator on the spin$^c$-manifold $f^{-1}(S_{z_0}M)$, twisted by $\xi$.
