Quantum Mechanics with Contextually Labeled Observables

Abstract

In the Contextuality-by-Default theory random variables representing measurement outcomes are labeled contextually, i.e., not only by what they measure but also under what conditions (in what contexts) the measurements are made, including but not reducible to what other measurements are made “together” with the given one. We propose in this paper that the quantum observables generating these random variables be labeled contextually as well, making the sets of the observables in different contexts disjoint. A quantum observable is defined as a pair consisting of the observable’s label and a self-adjoint operator in a Hilbert space. If a system is consistently connected (i.e., obeys “non-disturbance,” “non-invasiveness,” or “non-signaling” conditions), the observables measuring the same property in different contexts have the same operator. A set of random variables possessing a joint distribution is represented by commuting observables. The reverse, however, is not true: random variables from different contexts do not have a joint distribution irrespective of whether the corresponding observables commute. We illustrate this view of observables by deriving the Tsirelson bound for consistently connected cyclic systems of rank 3.

1 Contextually Labeled Random Variables

Throughout this paper we use the example of a rank-3 cyclic system of binary random variables [1-3]. This system involves three properties \{q_1, q_2, q_3\} measured two at a time, with the jointly measured pairs forming a single cycle:

\[ c^1 = (q_1, q_2), c^2 = (q_2, q_3), c^3 = (q_3, q_1). \]  

(1)

The pairs \(c^j\) define (or, simply, are) contexts. The result of measuring property \(q_i\) in context \(c^j\) is a random variable \(R_i^j\). All six random variables are assumed to be binary, \(\pm 1\). We see that these random variables are contextually labeled: e.g., \(R_1^1\) and \(R_1^3\) are distinct even though they measure the same property, \(q_1\), and even if their distributions are the same. This contextual labeling is the departure point of the analysis of any system of measurements (referred to as
a context-content system of random variables) in the Contextuality-by-Default (CbD) theory [3-6].

In the diagram below the random variables sharing a context (and no other) are jointly distributed:

\[ R_1 \xrightarrow{c_1} R_2 \]
\[ R_1 \xrightarrow{c_3} R_3 \]
\[ R_2 \xrightarrow{c_2} R_3 \]

This system is said to be consistently connected if the distribution of random variables measuring the same property is the same irrespective of their contexts. (There is a variety of synonyms for consistent connectedness used in physics, such as “non-disturbance,” “non-invasiveness,” “non-signaling,” etc.) The criterion of noncontextuality for a consistently connected cyclic system of rank 3 is [1,7,8]

\[
K_3 = \max \left( \begin{array}{c}
-\langle R_1^1 R_1^1 \rangle - \langle R_2^1 R_2^1 \rangle - \langle R_3^1 R_3^1 \rangle \\
-\langle R_1^1 R_1^1 \rangle + \langle R_2^3 R_2^3 \rangle + \langle R_3^3 R_3^3 \rangle \\
+ \langle R_1^2 R_1^2 \rangle - \langle R_2^2 R_2^2 \rangle + \langle R_3^3 R_3^3 \rangle \\
+ \langle R_1^2 R_1^2 \rangle + \langle R_2^2 R_2^2 \rangle - \langle R_3^3 R_3^3 \rangle 
\end{array} \right) \leq 1. \quad (3)
\]

In the language of CbD, the meaning of saying that this system is noncontextual [4] is that there exists a random vector \( S = \{S_1^1, S_2^1, S_2^2, S_3^2, S_3^3, S_3^3\} \) such that

1. \( S \) is a coupling of the observed \( (R_1^1, R_1^2), (R_2^2, R_2^3), \) and \( (R_3^3, R_3^3) \), i.e., their pairwise distributions are the same as those of \( (S_1^1, S_1^2), (S_2^2, S_3^3), \) and \( (S_3^3, S_3^1) \), respectively;

2. this coupling is maximally connected, i.e., each of the equalities \( S_1^1 = S_3^3, S_1^2 = S_2^2, S_2^3 = S_3^3 \) holds with the maximal probability consistent with the individual distributions of the equated random variables (this maximal probability always equals 1 if the system is consistently connected).

It might appear that for a consistently connected system the contextual notation is superfluous: if \( R_i^j \) and \( R_i^{j'} \) are identically distributed, why cannot one consider the 3-component system \( \{(R_1, R_2), (R_2, R_3), (R_3, R_1)\} \) instead of the 6-component \( \{(R_1^1, R_1^2), (R_2^2, R_2^3), (R_3^3, R_3^3)\} \)? A detailed answer is given in Ref. [4], but its gist is as follows. In classical probability theory the relation of being jointly distributed is transitive. The joint distribution of any two of

\[ 1 \text{ Contextually Labeled Random Variables} \]
the three pairs \((R_1, R_2), (R_2, R_3), (R_3, R_1)\) exists if and only if all three random variables \((R_1, R_2, R_3)\) are jointly distributed. This creates a paradox if the criterion (3) is found to be violated. To dissolve this paradox, one has to either abandon classical probability theory (a formidable task given that the very formulation of contextuality involves the classical understanding of joint distributions) or abandon noncontextual labeling, which is clearly a less dramatic solution. The contextual labeling makes the pairs of random variables with known distributions disjoint, ensuring thereby the existence of some coupling \(S\), interpreted as a distribution imposed on all six random variables in play. The question of contextuality is reformulated as one of the existence, among all these couplings, of specific ones, those that are maximally connected.

2 Contextually Labeled Observables

A quantum-theoretic representation of a system like (2) is traditionally understood as a representation by noncontextually-labeled observables, often identified with Hermitian matrices in a Hilbert space: e.g., a matrix \(M_1\) represents both \(R_1^1\) and \(R_3^1\) in (2), so that \(\langle R_1^1 \rangle = \langle R_3^1 \rangle = \text{Tr} [\Psi M_1]\), where \(\Psi\) is a density matrix. The matrices representing jointly distributed random variables commute, and conversely, any commuting matrices generate jointly distributed random variables. This view leads to difficulties. Commuting \(M_1\), \(M_2\), and \(M_3\) imply the existence of a maximally connected coupling \(S\) in the definition of noncontextuality of the system (2). Therefore any consistently connected cyclic-3 quantum system is bound to be noncontextual. This makes it difficult to explain violations of (3) in the original Bell paradigm [9] using observables in a single Hilbert space (see Section 3). Also, a Leggett-Garg system [10] prepared in a maximally mixed state \(\Psi \propto I\) (identity) may violate (3) [11], and non-commutativity seems to play no role in explaining these violations or in deriving the Tsirelson-type bounds for them.

We propose a simple way out, based on understanding an observable as a pair \((\nu, M)\) where \(\nu\) is the name (identity) of the observable, and \(M\) is a Hermitian matrix a Hilbert space. The observable \(\left(i, j\right), M_i^j\) is said to represent a random variable \(R_i^j\) if the matrix \(M_i^j\) generates \(R_i^j\) in accordance with standard quantum-mechanical rules. Thus, if \(R_i^j\) is binary, then its distribution is determined by \(\langle R_i^j \rangle\), and if \(\left(i, j\right), M_i^j\) represents \(R_i^j\), then \(\langle R_i^j \rangle = \text{Tr} [\Psi M_i^j]\). We will conveniently use \(M_i^j\) to denote both the matrix and the entire observable \(\left(i, j\right), M_i^j\), with the understanding that the observable \(M_i^j\) has its name \((i, j)\) and its “operator content.” We write \(M_i^j \sim M_i^{j'}\) to indicate the equality of the operator contents of two observables (or an observable and a matrix).

We posit the following rules.

\footnote{Mutatis mutandis this was pointed out to the author by Andrei Khrennikov in several personal communications (July 2017 – February 2018).}
2.1. There is a bijective correspondence between contextually labeled random variables and the observables representing them. (This correspondence is indicated by the identical labels of $R_j^i$ and $M_j^i$.)

2.2. If random variables $R_j^i$ and $R_j^{i'}$ are represented by observables $M_j^i$ and $M_j^{i'}$, then $R_{j''}^i = c_i R_j^i + c_{i'} R_j^{i'}$ (with $c_i, c_{i'}$ arbitrary reals) and $R_{j''}^{i'} = \left( R_j^i \right)^{n_1} \left( R_j^{i'} \right)^{n_2}$ (with $n_1, n_2$ arbitrary integers) are represented by, respectively, $M_j^i = c_i M_j^i + c_{i'} M_j^{i'}$ and $M_j^{i'} = \left( M_j^i \right)^{n_1} \left( M_j^{i'} \right)^{n_2}$.

2.3. If $j \neq j'$ and random variables $R_j^i$ and $R_j^{i'}$ are represented by observables $M_j^i$ and $M_j^{i'}$, then no random variable is represented by $f \left( M_j^i, M_j^{i'} \right)$, whatever the transformation $f$ mapping pairs of Hermitian matrices into Hermitian matrices. (Perhaps in this case $f \left( M_j^i, M_j^{i'} \right)$ could be appropriately called an “unobservable” or “quasi-observable.”)

2.4. For a consistently connected system of random variables, $M_j^i \sim M_j^{i'}$.

Applying these rules to our cyclic system (2), we have six observables $M_j^i$ representing $R_j^i$ ($i \in \{j, j \oplus 1\}, j \in \{1, 2, 3\}$), where $\oplus 1$ is ordinary $+1$ except for $3 \oplus 1 = 1$). We have, for any admissible combination of $i, i', j, j'$,

$$M_j^i \sim M_j^{i'}$$

and

$$M_j^i M_j^{i'} \sim M_j^{i'} M_j^i$$

(5)

The commutator $[M_j^i, M_j^{i'}]$ is zero because $R_j^i R_j^{i'} = R_j^{i'} R_j^i$ is one and the same random variable, and there can be only one observable representing it.

Note a radical difference between the distribution of a product of two random variables and the product of the corresponding observables: the former is not uniquely determined by the individual distributions of the multiplicands, whereas the product of two Hermitian matrices is uniquely defined. Moreover, one can form products of observables across contexts, when there is no corresponding joint distribution.

From (4) and (5) it follows that for any $i, i', j, j' \in \{1, 2, 3\}$,

$$M_j^i M_j^{i'} \sim \left( M_j^i \right)^2 \sim \mathbb{1}$$

(because all matrices have eigenvalues $\pm 1$), and

$$M_j^i M_j^{i'} \sim M_j^{i'} M_j^i$$

(7)

Footnote 3: It is possible to relax commutativity by postulating that $R_j^i R_j^{i'}$ is represented by $(M_j^i + M_j^{i'})/2$. The rule (2.2) then has to be reformulated in its multiplicative part to involve all permutations of the matrices involved.
3 Application: Tsirelson Bound for Cyclic-3 System

A criterion of (a necessary and sufficient condition for) noncontextuality of a system of random variables is usually written in the form of $K \leq \text{const}$, where $K$ is some expression based on the observed distributions of the random variables sharing contexts, and the constant is referred to as the classical, or noncontextuality bound. Thus, (3) has the form $K_3 \leq 1$. In quantum mechanics it is of interest then to find the maximal possible value of $K$ that can be achieved if the random variables are outcomes of measurements in a quantum system. This maximal value is referred to as the quantum, or Tsirelson bound. Araújo et al. [1] provide criteria of noncontextuality for cyclic systems [3] of all ranks $n \geq 3$, in the form $K_n \leq n - 2$, and they also derive Tsirelson bounds for $K_n$. However, the latter are derived for $n \geq 4$, with the case $n = 3$ missing. The Tsirelson bound $K_n \leq (3n \cos (\pi/n) - n) / (1 + \cos (\pi/n))$ derived in Ref. [1] for all odd values of $n \geq 5$ gives a wrong value if $n = 3$. This singling out of $n = 3$ could be attributed to the pairwise commutation mentioned in Footnote 4. We will show, however, that this consideration is not critical, and that in fact the case $n = 3$ can be handled in essentially the same way as other cyclic systems.

The correct Tsirelson bound for a cyclic system of rank $n = 3$ is $3/4$, whose derivation by means of semidefinite programing can be found in work by Budroni and colleagues [12–14]. We provide below an elementary derivation, based on our contextual approach.

First of all, note that in the case of consistent connectedness we can present $M^j_i$ as $(M^j_i)^\dagger$ and view $M_i$ as a matrix in context $j$. The equality (4) therefore can be presented as

$$M^j_i \sim M_i.$$ (9)

Consider the Hermitian matrix $S$ defined by

$$S = M_1 + M_2 + M_3.$$ (10)

Using (6), (7), and (8),

$$S^2 = 3I + 2(M_1M_2 + M_2M_3 + M_3M_1).$$ (11)

---

4 This is a specific feature of a cyclic-3 system, reflecting the fact that all three pairs chosen from $q_1, q_2, q_3$ form contexts. Already for a cyclic-4 system we have four properties \{q_1, q_2, q_3, q_4\} with the pairs (q_1, q_3) and (q_2, q_4) that are not parts of any contexts. As a result, the observables $M^j_1$ and $M^j_3'$ need not (and generally do not) have commuting matrices, and similarly for $M^j_2$ and $M^j_4'$. 

(i.e., the matrices commute even if we deal with “unobservables”\(^4\). We have further

$$M^1_1M^1_2' \sim M^1_1M^1_2,$$

$$M^2_2M^2_3' \sim M^2_2M^2_3,$$

$$M^3_3M^3_1' \sim M^3_3M^3_1.$$ (8)
We have
\[ \text{Tr} \left[ \psi M_i^j M_i^j \right] = \left\langle R_i^j R_i^j \right\rangle, \] (12)
for any admissible \( i, i', j \), whence
\[ \text{Tr} \left[ \psi S^2 \right] = 3 + 2 \left( \left\langle R_1^1 R_2^1 \right\rangle + \left\langle R_2^2 R_3^2 \right\rangle + \left\langle R_3^3 R_1^3 \right\rangle \right). \] (13)
Since
\[ \text{Tr} \left[ \psi S^2 \right] \geq \left( \text{Tr} [\psi S] \right)^2 \geq 0, \] (14)
we have
\[ -\left\langle R_1^1 R_2^1 \right\rangle - \left\langle R_2^2 R_3^2 \right\rangle - \left\langle R_3^3 R_1^3 \right\rangle \leq \frac{3}{2}. \] (15)
This establishes a bound for one of the linear combinations in (15). To obtain the same bound for other linear combinations, e.g., \( \left\langle R_1^1 R_2^1 \right\rangle + \left\langle R_2^2 R_3^2 \right\rangle - \left\langle R_3^3 R_1^3 \right\rangle \), one can repeat the derivation using
\[ S' = M_1 - M_2 - M_3. \] (16)
Alternatively, one can replace \( R_1^1 \) and \( R_2^2 \) in (15) with \( -R_1^1 \) and \( -R_2^2 \), respectively. Since (16) holds for any \( \left\langle R_1^1, R_1^2, R_2^2, R_3^3, R_3^3 \right\rangle \), subject only to consistent connectedness, it should also hold for \( \left\langle R_1^1, -R_2^2, -R_2^2, R_3^3, R_3^3 \right\rangle \), whence
\[ \left\langle R_1^1 R_2^1 \right\rangle + \left\langle R_2^2 R_3^2 \right\rangle - \left\langle R_3^3 R_1^3 \right\rangle \leq \frac{3}{2}. \] (17)
That this bound can be attained by a realizable quantum system is shown by considering the Alice-Bob paradigm with two entangled spin-1/2 particles, in which Alice chooses one of axes \( \{q_1, q_3\} \) and Bob one of axes \( \{q_1, q_2\} \) (i.e., we have a special case of the EPR/Bohm paradigm, with one of the Bob’s axes being collinear to one of Alice’s). We have here the measurement of \( q_1 \) combined with that of \( q_2 \) being represented by random variables \( \{R_1^1, R_2^2\} \), with
\[ \left\langle R_1^1 R_2^2 \right\rangle = q_1 \cdot q_2 = \cos \angle_{q_1}^{q_2}, \] (18)
where \( \angle_{q_1}^{q_2} \) is the angle between the two axes. The measurements of \( q_1 \) together with \( q_3 \) are represented by \( \{R_1^1, R_3^3\} \), with
\[ \left\langle R_1^1 R_3^3 \right\rangle = q_1 \cdot q_3 = \cos \angle_{q_1}^{q_3}. \]
(The contextual notation \( R_1^1 \) and \( R_3^3 \) is especially transparent in this case, as the measurement of axis \( q_1 \) in one case is done by Alice and in the other by Bob.) The definition of \( \{R_2^2, R_3^3\} \) and the expression for \( \left\langle R_2^2 R_3^3 \right\rangle \) are analogous. The left-hand side of (18) is then the maximum of expressions including
\[ -\cos \angle_{q_1}^{q_2} - \cos \angle_{q_2}^{q_3} - \cos \angle_{q_1}^{q_3}. \] (19)
It is sufficient to observe that (19) attains the value \( \frac{3}{2} \) if one puts
\[ \angle_{q_1}^{q_2} = \angle_{q_2}^{q_3} = \angle_{q_1}^{q_3} = \frac{2\pi}{3}. \] (20)
4 Conclusion

With reference to Footnote 4 it can be shown (e.g., using a contextual version of the derivation in Ref. [15]) that in the case of a consistently connected cyclic-4 system (with binary random variables) the difference between the classical bound and the Tsirelson bound is due to the noncommutativity of the (matrices in the) observables $M^j_1$ and $M^j_4$, and observables $M^j_2$ and $M^j_4'$. In the cyclic-3 case we have no such noncommutativity, but the Tsirelson bound still exceeds the classical one. This comparison shows that the main factor behind the difference between the two bounds is not noncommutativity but rather the fact that products of matrices picked from different contexts do not correspond to any measurements.

4 Conclusion

A common way to formulate realism is to say that even when a physical quantity is not measured it has a definite value. This is inherently unclear. It is not even about whether the moon exists when no one is looking [16], but rather about whether a toss of a coin has a definite value before it is tossed — such a question can only be discussed counterfactually [17], and the answer belongs to philosophy rather than quantum mechanics. The belief that contextuality of a quantum system, say, in the Kochen-Specker paradigm, contradicts realism is based on noncontextual labeling of random variables. With sets of random variables in different contexts being disjoint, which is ensured by the “automatic” labeling of all random variables contextually, the contradiction disappears. The paradoxical (within the framework of classical probability) situations when certain joint distributions that must exist do not exist are replaced in CbD with the situations when the set of possible couplings (always non-empty) does not contain ones with certain properties of interest (e.g., maximally connected ones) [2, 3, 5, 6]. The Contextuality-by-Default (CbD) approach may be viewed as a way of implementing realism with no possibility of running into paradoxes.

This approach, however, remains an abstraction with no direct ties to quantum physics insofar as observables generating the contextually labeled random variables remain noncontextual themselves. This paper is a tentative step in the direction of expanding CbD from systems of classically understood random variables to quantum observables generating them. Many issues and potential directions of extension were not mentioned in this paper. Thus, we did not discuss the situation when the state of the system is not necessarily one and the same for different measurements within a single context, as it is, e.g., in the Leggett-Garg-type paradigms with sequential measurements [10, 11]. We did not discuss the possibility of using POVMs in place of Hermitian matrices. Nor did we discuss the possibility of incorporating inconsistent connectedness, the issue that served as the main motivation for the CbD on the level of random variables. When the observables measuring the same property in different contexts generate different distributions while coupled with a fixed density matrix, the contextual labeling of these observables becomes trivially obvious. This observation allows one to motivate contextual labeling of observables by the
“continuity” argument used in Ref. [18]. What if the difference between these distributions gets progressively smaller, converging to zero? It seems strange that contextual labeling should be “suddenly lost” and two distinct observables “suddenly merge” into one when the limit is reached.

Acknowledgments

The author is grateful to Andrei Khrennikov for elucidating discussions and criticism (see Footnote [2]). The author has also benefited from discussions with Pawel Kurzynski and Irina Basieva.
