(Dated: March 12, 2018)

We consider linear and nonlinear optical coherent perfect absorbers (CPAs) in multidimensional geometries and construct explicitly the respective perfectly absorbed solutions. The multidimensional CPAs have a structure of the so-called simple layers which represent the generalization of the point $\delta$ function potential to higher dimensions. The considered examples include broadband CPAs confined to a straight line (in a two-dimensional setting) and to a plane (in the three-dimensional space); CPAs for topological vortices on an absorbing circle; as well as axially-symmetric CPAs on a sphere. Additionally, it is shown that a paraxial beam propagating along a surface nonlinear CPA embedded in the three-dimensional space can be stable against perturbations.

I. INTRODUCTION

The concept of coherent perfect absorber (CPA) was theoretically introduced in \cite{1}, experimentally observed in \cite{2}, and received significant attention over the last years \cite{3}. A CPA refers to a complex potential which completely absorbs radiation incident on it without any reflection or emission of outgoing waves. It also can be interpreted as a time-reversed laser \cite{1}, i.e., as a complex potential which emits radiation in the absence of incident one. While the simplest CPAs operate in one-dimensional geometry, multidimensional CPAs are also known. In the planar 2D geometry, the perfect absorption can be implemented using composite films of finite width \cite{4} or lossy ultrathin dielectric layers \cite{5}. Broadband perfect absorption of microwaves by ultrathin films was demonstrated experimentally \cite{7}. Plasmonic perfect absorption of TM-polarized modes by a patterned surface was discussed and implemented experimentally \cite{6}, too. Further results on multi-dimensional CPAs include the absorption of electromagnetic waves incident on a spherical barrier \cite{8} and excited inside a 2D cavity with absorbing circular boundary \cite{9}, perfect absorption of TM-polarized modes by a metallings nanocylinders and nanospheres \cite{10}, exploiting coupling to the surface plasmons. Beyond the optics, cylindrical CPAs for acoustic waves have been reported on in \cite{11}.

Both CPAs and lasers in 1D geometry are characterized by a specific value of the wavelength absorbed and emitted, respectively. Finding such a wavelength requires fine tuning of the parameters. Once the respective wavelength is found and other parameters are fixed, shifting the wavelength (frequency) from the resonant value destroys the CPA or the laser. In 1D, where the theory can be formulated either in terms of the scattering matrix \cite{1} or in terms of the transfer matrix \cite{2}, the effect of the “destroying” a CPA or a laser can be easily understood in terms of the zeros of the respective diagonal elements of the transfer matrix, which are displaced from the real axis under the change of the wavelength or of the system parameters. In 2D and 3D cases, there appears an additional degree of freedom, expressed by the angle of incidence of a beam. Thus even for a monochromatic wave one can pose the question of creating CPAs or lasers operating in a finite-band angular spectrum. Physically, this means that such devices totally absorb or emit radiation at different angles of incidence (emission).

Another aspect of the theory, relevant to the present study, is a possibility of finding exact analytical solutions for either CPA (or laser) models. When such solutions are available, they allow for quite complete understanding of the phenomenon. However, even in the 1D setting the problem of spectral singularities (or time-reversal spectral singularities) is not solvable analytically, except for a very few cases, like potentials modeled by the Dirac delta-function \cite{18}.

In the present paper, we introduce line (in 2D) and surface (in 3D) absorbing or active potentials which (i) allow for exact analytical solutions, (ii) some of them operate as broadband CPAs (or lasers), (iii) bear Kerr nonlinearity. The corresponding solutions feature totally absorbed incoming radiation without emission (or perfectly emitted radiation without incoming one) in a finite range of the incident angles, although the requirement for the wave to be monochromatic remains.

Absorption of all incoming radiation by linear potentials embedded in nonlinear media was reported previously for effectively 1D \cite{13} and 2D \cite{14} Bose-Einstein condensates. In this work, our interest is in absorbing potentials having either finite or infinite spatial extensions which are either linear or nonlinear and are embedded in a linear medium. In the latter sense, the presented results can be viewed as multidimensional extensions of 1D nonlinear CPAs reported in earlier studies \cite{15}. We show that the multidimensional CPA can be made nonlinear, still preserving the above properties of allowing for exact solutions and operating in a finite range of the wavelengths.

From the mathematical point of view, the potentials considered here are known as simple layers \cite{16} which describe the Dirac $\delta$ function “distributed” on a line or on a surface. Simple layers model either absorbing (active) wires incorporated in thin planar waveguides or absorbing (active) surfaces in the three-dimensional space.
The approach employed in this paper is somewhat different from the used in conventional scattering problems, where for given a potential one studies the scattered radiation. We adopt the “inverse engineering” approach (similar to one used in [17] for constructing complex potentials and the respective solutions) where for a given incident wave we construct the distribution of gain-loss landscape, and eventually nonlinear Kerr coefficient of a simple layer ensuring the total absorption or lasing of a given wave.

The rest of the paper is organized as follows. In the next section II we introduce the main model which is the multidimensional Helmholtz equation with a simple layer potential. In Sec. III we study the CPAs confined to the lines or curves in a two-dimensional plane. Simple layer CPA for vortices are discussed in Sec. IV. In Sec. V we consider the stability of a paraxial beam propagating along the absorbing simple layer. In Sec. VI we generalized some of the results onto the case of the CPA confined to a sphere. Section VII concludes the paper.

II. LINE AND SURFACE POTENTIALS

We are interested in absorbing or lasing potentials of two geometries: (i) a line (curve) in $\mathbb{R}^2$, and (ii) a surface in $\mathbb{R}^3$. Such potentials can be described using distributions $\delta_S(\mathbf{r})$, which are referred to as simple layers [16] and represent multidimensional generalizations of the Dirac $\delta$-function. A simple layer $\delta_S(\mathbf{r})$ is defined by the following characteristic property:

$$\int_{\mathbb{R}^D} \delta_S(\mathbf{r}) f(\mathbf{r}) d^D \mathbf{r} = \int_S f(\mathbf{r}) dS.$$  \hspace{1cm} (1)

Here $\mathbf{r} \in \mathbb{R}^D$ (in our case $D = 2$ or 3), $f(\mathbf{r})$ is a complex-valued test function, and $S$ is the set of points forming the curve or the surface where the potential is confined. Respectively, the integral $\int_S dS$ in the r.h.s. of (1) is a curvilinear integral or a surface integral (for the sake of brevity below $S$ is referred to as surface in either case). We will use the property $\delta_S(\mathbf{r}/\ell) = \ell^D \delta_S(\mathbf{r})$, where the characteristic scale $\ell > 0$ is introduced to make $\delta_S(\mathbf{r}/\ell)$ physically dimensionless.

Let us assume that the surface $S$ is characterized by the permittivity $1 + \varepsilon(\mathbf{r})$ whose variation is complex-valued: $\varepsilon(\mathbf{r}) = \varepsilon_0(\mathbf{r}) + i\gamma(\mathbf{r})$, where $\mathbf{r} = (x, y, z)$. The parts of the surface with $\gamma(\mathbf{r}) > 0$ [$\gamma(\mathbf{r}) < 0$] are absorbing [active]. In a general case it will be also allowed for the layer to bear Kerr nonlinearity described by the real-valued function $\sigma(\mathbf{r})$: $\sigma(\mathbf{r}) > 0$ [$\sigma(\mathbf{r}) < 0$] corresponds to a defocusing [focusing] surface.

We consider a monochromatic wave, with the frequency $\omega$, incident on the surface $S$ (from different sides) and thus governed by the Helmholtz equation for the dimensionless electric field $\Psi$:

$$- \nabla^2_r \Psi - k_0^2 \delta_S(\mathbf{r}/\ell) (\varepsilon(\mathbf{r}) - \sigma(\mathbf{r})|\Psi|^2)\Psi = k_0^2 \Psi,$$  \hspace{1cm} (2)

where $\nabla^2_r$ is the 3D Laplacian, $k_0 = \omega/c$, and $c$ is the speed of light in the vacuum.

III. LINE POTENTIALS IN A PLANE

First we address the situation where a simple layer is $z$-independent, i.e., it can depend only on $x$ and $y$. Then, looking for a solution of Eq. (2) in the form $\Psi = \psi(x, y) e^{i k z}$, we reduce (2) to the 2D Helmholtz equation

$$- \nabla^2 \psi - \delta_S(\mathbf{r}) [\varepsilon(\mathbf{r}) - \sigma(\mathbf{r})]|\psi|^2 \psi = \kappa^2 \psi$$  \hspace{1cm} (3)

where $\rho = (\xi, \eta) = k_0 (x, y)$ are the dimensionless coordinates, $\nabla \rho = (\partial_\xi, \partial_\eta)$ and $\kappa = \sqrt{1 - k_0^2 / k_0^2}$ (in these notations the parameter $\ell$ introduced above is chosen as $\ell = 1/k_0 = \lambda/(2\pi)$, where $\lambda$ is the wavelength of the incident beam).

A. Straight-line CPA

We start with the simple example when $S$ is a straight line which coincides with the $\xi$ axis. Such a potential in [3] takes the form

$$\delta_S(\mathbf{r}) \varepsilon(\mathbf{r}) = \delta(\eta) \varepsilon(\xi),$$  \hspace{1cm} (4)

where $\delta(\eta)$ is the conventional Dirac delta function, and $\varepsilon(\xi)$ describes the variation of the dielectric permittivity along the line. Additionally, we assume that the layer is linear, i.e., $\sigma(\mathbf{r}) = 0$.

In order to construct a CPA, i.e., to find distributions of losses (and eventually of gain for construction of a laser) assuring absorption of incident waves for some angles of incidence in the plane $(\xi, \eta)$, we look for an incident-beam solution of (3) in the form

$$\psi_\kappa(\rho) = \int_0^\infty \left[ \hat{\psi}_+(\xi, q) + \hat{\psi}_-(\xi, q) \right] e^{-i q \eta} dq,$$  \hspace{1cm} (5)

$$\hat{\psi}_\pm(\xi, q) = a_\pm(q) e^{\pm i \sqrt{\kappa^2 - q^2} \xi},$$  \hspace{1cm} (6)

where $a_\pm(q)$ are, so far, arbitrary complex functions describing amplitudes of the angular-spectrum of the incident beam. Obviously, Eq. (5) solves the 2D Helmholtz equation (3) in the free space, and is continuous at $\eta = 0$, i.e. in the points where the line-potential (4) is located. Imposing the matching condition for the field derivative at $\eta = 0$, one can solve the problem as follows. Given an angular-spectrum distribution of a beam incident from both sides of the surface, i.e., given as $(q)$, one can design the dielectric permittivity landscape $\varepsilon(\xi)$ which operates as a CPA, i.e., absorbs the incident beams entirely. The solution of this problem is given by

$$\varepsilon(\xi) = \frac{2i}{\kappa} \int_0^\infty q \left[ \hat{\psi}_+(\xi, q) + \hat{\psi}_-(\xi, q) \right] dq$$  \hspace{1cm} (7)
and is valid for any beam for which the field is different from zero at $\eta = 0$.

A simple example is given by the CPA for an incident plane wave, as well as for a superposition of plane waves having the same wavelength and equal angles of incidence, $\theta$, the latter defined by $\cos \theta = q/\kappa$. Consider $a_\pm (q) = \alpha_\pm \delta(q - q_\pm)$, where $q_\pm \in (0, \kappa)$. Then $\gamma(\xi) \equiv 2i q_\pm$, i.e., $\epsilon_0 \equiv 0$, and the CPA is characterized by a uniform distribution of the absorption: $\gamma(\xi) \equiv 2q_\pm$. The corresponding perfectly absorbed solution reads

$$\psi_s(\rho) = e^{-i q_\pm |y|} (\alpha_+ e^{i \sqrt{\kappa^2 - q_\pm^2} \xi} + \alpha_- e^{-i \sqrt{\kappa^2 - q_\pm^2} \xi}).$$

Here $\alpha_\pm$ describe the amplitudes of the absorbed waves which propagate in opposite $\xi$-directions towards the potential (illustrated in Fig. 1).

B. Plane absorber for nondiffracting beams

The obtained CPA is a straightforward generalization of the 1D result [18], which however appears a broadband CPA if considered in the context of the 3D scattering described by Helmholtz equation (2). In such a 3D problem, the formal line CPA [4] is nothing but the absorbing plane $y = 0$. Indeed, with the constant dielectric permittivity, the potential in model (2) becomes separable. The absorption depends only on the $y$- ($\eta$-) component of the wavevector. Thus any wave with the same $q_\pm$ and different $\kappa$, i.e. different $k_\pm$, will be coherently absorbed [i.e., solution (3) remains valid for such waves], provided $k_\pm^2 + k_0^2 < k_\pm^2$, where $k_0 = k_0 q_\pm$ is a parameter characterizing the plane absorber.

Thus, returning to the original physical variables, a solution of (2) can be written down as a superposition of four beams ($s_1 = \pm$ and $s_2 = \pm$):

$$\psi(s_1, s_2)(\mathbf{r}) = e^{-ik_\pm |y|} \int_0^{\infty} \alpha_{s_1}(k_\pm) e^{i \sqrt{k_\pm^2 - k_0^2} k_\pm \xi} d k_\pm,$$

where $\alpha_{s_1_s_2}(k_\pm)$ describe the angular spectra of the beams. Such solution will be coherently absorbed by the surface $y = 0$ characterized by the absorption $\varepsilon(\mathbf{r}) = 2i(k_\pm/k_0) \delta_s(y)$. Representing $k_\pm = \sqrt{k_\pm^2 - k_0^2} \sin \varphi$ and considering $\varphi$ as an integration variable, we convert (9) to the form

$$\psi(s_1, s_2)(\mathbf{r}) = e^{-ik_\pm |y|} \int_0^{\pi/2} A_{s_1}(\varphi) e^{i \sqrt{k_\pm^2 - k_0^2} (s_1 x \cos \varphi + s_2 z \sin \varphi)} d \varphi,$$

where $A_{s_1}(\varphi) = \sqrt{k_\pm^2 - k_0^2} \cos \varphi \alpha_{s_1}(k_\pm)$. Using a proper superposition of these four beams, one can readily construct a general nondiffracting beam [19]

$$\psi(\mathbf{r}) = e^{-ik_\pm |y|} \int_0^{2\pi} A(\varphi) e^{i \sqrt{k_\pm^2 - k_0^2} (x \cos \varphi + z \sin \varphi)} d \varphi$$

which is coherently absorbed by the plane CPA. In (11), $A(\varphi)$ is a properly defined combinations of amplitudes $A_{\pm}(\varphi)$.

C. Line absorber with periodic dielectric permittivity

A more complex example is the incidence of two plane waves with different $y$- ($\eta$-) projections of the wavevectors:

$$a_{\pm}(q) = \alpha_{\pm} \delta(q - q_{\pm}), \quad 0 < q_{\pm} < \kappa, \quad q_+ \neq q_-, (12)$$

on the absorbing potential in a form of a line a 2D. If the real amplitudes of the modes are different, i.e. $\alpha_+ \neq \alpha_-$, one computes the distribution

$$\varepsilon(\xi) = 2i q_+ \alpha_+ e^{i \sqrt{\kappa^2 - q_\pm^2} \xi} + q_- \alpha_- e^{-i \sqrt{\kappa^2 - q_\pm^2} \xi}$$

$$\alpha_+ e^{i \sqrt{\kappa^2 - q_\pm^2} \xi} + \alpha_- e^{-i \sqrt{\kappa^2 - q_\pm^2} \xi}$$

which is a periodic function of $\xi$, with the period

$$L = \frac{2\pi}{\sqrt{\kappa^2 - q_+^2} + \sqrt{\kappa^2 - q_-^2}}$$

In the limit $|\alpha_+| \to |\alpha_-|$, the distribution $\varepsilon(\xi)$ becomes singular at the points $\xi = L/2 + \pi n$ (where $n$ is integer). This is a dimensional effect. It occurs due to the destructive interference of the incident waves propagating in opposite $\xi$-directions (i.e. parallel the simple layer). Indeed, now the field intensity in the points $(\xi_n, \eta)$ becomes zero at nonzero field gradient. Since the discontinuity of the gradient is proportional to the field intensity, it cannot be “induced” by any finite potential in the points $\xi_n$ where the field is zero.

An essential difference from the previous case of the constant dielectric permittivity is that the broken translational invariance along the absorbing line, makes $\varepsilon(\xi)$ $\kappa$-dependent, i.e. its CPA can be realized now only for the given left- and right-incident waves. Now the dielectric permittivity has both real and imaginary parts modulated. An unusual property, is that the described coherent perfect absorption depends on the relation between the complex amplitudes, $\alpha_-/\alpha_+$, rather than on the wavevectors only.
D. Nonlinear straight-line CPA

Now we consider the nonlinear problem \[4\] with a real Kerr nonlinearity, i.e., we let the CPA-line bear defocusing nonlinearity with the strength distribution given by the function \(\sigma_\varepsilon(\rho)\). 1D nonlinear CPA were previously studied in \[15\]. We again focus on a simple case when the absorber is confined to the straight line \(\eta = 0\). Since in the plane \((\xi, \eta)\) outside the line the field solves the homogeneous Helmholtz equation, we consider incidence of a single plane wave from each side of the absorbing line (rather than beams considered above), i.e., we look for solution of \[14\] in the form
\[
\psi(\rho) = a e^{i\varepsilon_0 \sqrt{\kappa^2 - \sigma_\varepsilon^2} \xi - iq_\varepsilon |\eta|}, \quad s = \pm 1
\]
where \(a > 0\) is the wave amplitude, and the freedom of choice \(s\) reflects the invariance of the model under the inversion of the \(\xi\) axis. Solution \[15\] is formally tantamount to that obtained for the linear CPA on a line [Eq. \[3\]] with \(\alpha_+ = 0\) or \(\alpha_- = 0\) (Fig. \[1\]). However, in the nonlinear case the matching condition for the \(\eta\)-component of the field gradient acquires the form
\[
2iq_\varepsilon - \varepsilon(\xi) + \sigma(\xi)a^2 = 0.
\]
Recalling that the dielectric permittivity of the simple layer is a complex function, and allowing for its real part to vary in time, \(\varepsilon = \varepsilon_0(\xi) + i\gamma\), we observe that a solution of \[16\] can be found in the case when the dielectric permittivity and nonlinearity strength are connected as \(\varepsilon_0(\xi) = a^2\sigma(\xi)\). The perfectly absorbed wave has the form
\[
\psi(\rho) = a \exp \left( \frac{i s}{2} \sqrt{4\kappa^2 - \gamma^2} \xi - \frac{i}{2} \gamma |\eta| \right)
\]
which is valid for \(\varepsilon_0(\xi)\sigma(\xi) > 0\) and sufficiently small losses: \(\gamma^2 < 4\kappa^2\).

IV. NONLINEAR CPA FOR VORTICES

All CPAs considered above have infinite extensions. Now we consider an example with different properties. We are interested in a spatially limited CPA which has nonzero curvature, and is embedded in the 2D space. More specifically we describe a CPA in a form of a circle (in 3D this CPA has the cylindrical form) of the radius \(\rho_\ast > 0\) centered at the origin. Concentrating on the simplest case, we assume that the distributions of dielectric permittivity, losses, and nonlinear coefficient are constant on the circle, i.e. \(\varepsilon(\rho) \equiv \varepsilon\) and \(\sigma(\rho) \equiv \sigma\). In the dimensionless polar coordinates \((\rho, \phi)\), where \(\rho = \sqrt{\xi^2 + \eta^2}\) and \(\phi\) is the polar angle, Helmholtz equation \[2\] takes the form
\[
- \frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial \psi}{\partial \rho} \right) - \frac{1}{\rho^2} \frac{\partial^2 \psi}{\partial \phi^2} - \delta(\rho - \rho_\ast)[\varepsilon - \sigma |\psi|^2]\psi = \kappa^2 \psi.
\]
We look for solutions carrying integer vorticity (topological charge) \(m\): \(\psi = e^{im\phi}\). Then in the free space we have the well known equation
\[
R_{\rho\rho} + \rho^{-1} R_\rho + (\kappa^2 - m^2 \rho^{-2}) R = 0,
\]
whose general solution is a linear combination of the Bessel functions \(J_m(\kappa\rho)\) and \(Y_m(\kappa\rho)\). First, we require the continuity of the field on the circle \(S\): \(R(\rho_\ast - 0) = R(\rho_\ast + 0)\). The second condition is the discontinuity of the derivative normal to the simple layer (the circle in our case):
\[
R_\rho(\rho_\ast + 0) - R_\rho(\rho_\ast - 0) + [\varepsilon - \sigma |R(\rho_\ast)|^2] R(\rho_\ast) = 0.
\]
Note that, generally speaking \(R(\rho)\) is a complex valued function, but its amplitude and argument are functions of the radius only.

Using the cross-product
\[
\mathcal{P}(\rho) = \frac{\pi \rho_\ast}{2} [J_m(\kappa\rho_\ast) Y_m(\kappa\rho_\ast) - J_m(\kappa\rho_\ast) Y_m(\kappa\rho_\ast)],
\]
the sought solution can be written down as
\[
R(\rho) = C \left\{ \begin{array}{ll}
J_m(\kappa\rho) & \text{at } \rho < \rho_\ast \\
J_m(\kappa\rho_\ast) - \varepsilon J_m(\kappa\rho_\ast) \mathcal{P}(\rho) & \text{at } \rho > \rho_\ast,
\end{array} \right.
\]
where \(C\) is an arbitrary constant.

It is instructive to illustrate the obtained solution using the quantity \(\Pi\) which is proportional to the radial projection of the Poynting vector (the proportionality coefficient depends on the physical units used):
\[
\Pi(\rho) = i (RR^*_\rho - R^* R_\rho).
\]
One immediately observes that \(\Pi(\rho) = 0\) for \(\rho < \rho_\ast\), and hence there is no radiation incident over the absorber in the inner domain. For \(\rho > \rho_\ast\) one computes
\[
\Pi(\rho) = -2i |C|^2 \gamma \rho_\ast J_m^2(\kappa\rho_\ast).
\]
In the absorbing regime, \(\gamma > 0\), the radial component of the Poynting vector \(\Pi(\rho)\) is negative, which is consistent with the energy transfer from the infinity towards the absorbing surface.

The found solution however is, in general, not a CPA solution, since it contains both incident and reflected waves. Indeed, using the well-known asymptotic behavior for Bessel functions:
\[
J_m(\kappa\rho) \rightarrow \sqrt{\frac{2}{\pi \kappa \rho}} \cos \left( \kappa \rho - \frac{\pi m}{2} - \frac{\pi}{4} \right) r \rightarrow \infty,
\]
\[
Y_m(\kappa\rho) \rightarrow \sqrt{\frac{2}{\pi \kappa \rho}} \sin \left( \kappa \rho - \frac{\pi m}{2} - \frac{\pi}{4} \right) r \rightarrow \infty,
\]
we observe that at large polar radii solution \[21\] becomes a linear combination of functions \(e^{-i\kappa\rho}/\sqrt{\rho}\) and \(e^{i\kappa\rho}/\sqrt{\rho}\), i.e., of incoming and outcoming radiation, respectively.
The CPA regime is characterized by the absence of any reflected radiation. This means that the general solution (21) corresponds to the CPA only if the contribution with $e^{i\kappa \rho}/\sqrt{\rho}$ vanishes. Performing straightforward computation, we obtain that this condition is satisfied if the dielectric permittivity is chosen as

$$\varepsilon_* = \frac{2|Y_m(\kappa \rho_*) - iJ_m(\kappa \rho_*)|}{\pi \rho_* J_m(\kappa \rho_*)[J_m^2(\kappa \rho_*) + Y_m^2(\kappa \rho_*)]}.$$  

(25)

The imaginary part of the dielectric permittivity is positive reflecting the fact that in the CPA regime the circle is absorbing. The real part of the dielectric permittivity is generically nonzero, but can be tuned by the nonlinearity coefficient $\sigma$ and by the amplitude of the absorbed solution $C$. On the other hand, relation (25) can be viewed as the definition of the intensity of the perfectly absorbed nonlinear vortex for a given $\varepsilon_*$, and suitable choice of the nonlinearity $\sigma$ ensuring the existence of solution of (25) with respect to $|C|^2$. Additionally we notice that if $\kappa \rho_*$ is a zero of the Bessel function $J_m(\kappa \rho_*)$, then the expression for $\varepsilon_*$ diverges, what means that the CPA operating at the given wavelengths cannot be implemented using a surface of the corresponding radius.

Substituting (25) to (21), we finally obtain that in the exterior domain of the circle the CPA solution for perfectly absorbed vortices is given by the expression

$$R_*(\rho) = C J_m(\kappa \rho_*) H_m^2(\kappa \rho)/H_m^2(\kappa \rho_*).$$  

(26)

where $H_m^2 = J_m - iY_m$ is the Hankel function of the second kind. In the interior domain of the circle, $\rho < \rho_*$, the solution $R_*(\rho)$ has the form of the Bessel function presented in [21].

In contrast to the CPA solution on the straight line [17], the nonlinear CPA solution [26] features the algebraically decaying field amplitude. Inside the absorbing circle, both the the incident and reflected radiation exist, although they are balanced inside the circle (in fact this property is more general and holds for any, either perfectly or not perfectly, absorbed vortex). Outside the circle only the incident radiation exists, which means that the CPA operates as a one-sided CPA, in contrast to the nonlinear CPA on the line constructed above in [17], where the radiation is absorbed perfectly from both sides of the line. This property is physically natural, since perfect absorption of the radiation of the cavity inside the circle would require the existence of a source also located inside the cavity.

As a particular example, let us address in more detail the case when the nonlinearity-assisted CPA is implemented using a purely absorbing layer, i.e., with purely imaginary variation of the dielectric permittivity, which means that the real part of $\varepsilon_*$ is zero. From (25), the corresponding requirement reads

$$\sigma|C|^2 = \frac{2|Y_m(\kappa \rho_*)|}{\pi \rho_* J_m^2(\kappa \rho_*)[J_m^2(\kappa \rho_*) + Y_m^2(\kappa \rho_*)]}.$$  

(27)

If the nonlinearity is defocusing ($\sigma > 0$) then the nonlinear CPA on the purely imaginary simple layer is possible only if $Y_m(\kappa \rho_*)/J_m(\kappa \rho_*) > 0$. Stability analysis (see Sec. [V]) shows that the paraxial propagation of the CPA solution in such a nonlinear absorber is stable against localized perturbations if $Y_m(\kappa \rho_*)/J_m(\kappa \rho_*) < 1$. Several examples of stable perfectly absorbed states with topological charges $m = 0, 1, 2$ are presented in Fig. [2]. In this figure, the nonlinearity coefficient is fixed ($\sigma = 0.1$) and the amplitude of a vortex perfectly absorbed by a purely imaginary layer is computed from (27).

![FIG. 2. Pseudocolor plots for intensity and phase distributions of perfectly absorbed nonlinear vortices on a purely absorbing circular layer with $\rho_* = 10$ (shown with dashed black line). The three rows correspond to topological charges $m = 0, 1,$ and 2, respectively. The corresponding parameters are $\kappa = 0.1$, $\varepsilon_* \approx 0.11 i$ ($m = 0$), $\kappa = 0.3$, $\varepsilon_* = 0.29 i$ ($m = 1$), and $\kappa = 0.4$, $\varepsilon_* = 0.35 i$ ($m = 2$). In all panels, $\sigma = 0.1$.](image)

The constructed CPA solution can be easily converted to the solution on a lasing circle. To this end, it is sufficient to take the complex conjugate of $R_*(\rho)$ and of $\varepsilon_*$ (that is to invert sign of imaginary part of the dielectric
permittivity replacing the absorbing surface with a lasing one).

V. PARAXIAL APPROXIMATION AND STABILITY

So far we considered the field distributions in the whole space. Now we turn to the propagation of a paraxial beam along z-axis in the half-space $z > 0$ in the presence of an absorbing surface defined by a line in the plane $(x, y)$ and homogeneous along $z$. Making the standard ansatz $\Psi(r, \rho) = \psi(x, y, z)e^{ik_0z}$ with $\psi$ being a slow function of $z$ $|\partial \psi/\partial z| \ll k_0$, we obtain the equation of paraxial approximation. In the dimensionless units $(\xi, \eta, \zeta) = (k_0(x, y, z)$ it reads

$$2i\psi_\zeta = -\nabla_\rho^2\psi - \delta_S(\rho)|\varepsilon(\rho) - \sigma(\rho)|\psi|^2\psi. \quad (28)$$

On the whole $z$-axis, for the plane wave solution corresponding to $z$-independent amplitude $\psi$ we recover the model (3).

Now a perfectly absorbed solution, i.e. a beam having no radiation outgoing from the absorbing simple layer, has the form $\psi(\zeta, \rho) = \psi_\ast(\rho)e^{-i\beta \zeta}$, and the question of its stability (at $\zeta > 0$) arises. To check the stability of such beam we consider propagation of a perturbed solution in the form $\psi = [\psi_\ast + \chi(\zeta, \rho)]e^{-i\beta \zeta}$, where $\chi$ is small perturbation whose behavior can be described in terms of the linearized version of equation (28).

$$i\chi_\zeta = -\nabla_\rho^2\chi - \delta_S(\rho)|\varepsilon(\rho) - \sigma(\rho)|(2|\psi_\ast|^2\chi + \psi_\ast^2 \chi^\ast)|. \quad (29)$$

Since the waveguiding medium is linear and the CPA-surface bears defocusing nonlinearity, one can expect that the eventual instability can result only from spatially localized perturbations. We therefore limit our analysis to perturbations carrying finite power $X(\zeta) = \int_{R_\ast} |\chi|^2 d\rho$. Direct integration over the whole space $R^2$ gives

$$\frac{dX(\zeta)}{d\zeta} = -2\int_S \gamma(\rho)|\chi|^2 dS + 2\text{Im} \int_S \sigma(\rho)|\psi_\ast|^2(\chi^\ast)^2 dS \quad (30)$$

where $S$ if the CPA-surface in the dimensionless variables $(\xi, \eta)$. If

$$\sigma(\rho)|\psi(\rho)|^2 \leq \gamma(\rho) \quad \text{for all } \rho \in S, \quad (31)$$

then the r.h.s. of (30) is negative, i.e., the power of perturbations monotonously decays.

In particular, the stability condition (31) for the CPA solution on the line (17) takes the form $0 < \varepsilon(\rho) \leq \gamma$. For CPA on the nonlinear ring in Eq. (21) stability condition takes the form $\sigma|C|^2J_n^2(\kappa \rho_\ast) \leq \gamma$.

VI. NONLINEAR SPHERICAL CPA IN 3D

In this section we show that the previous analysis can be generalized to the effectively 3D geometry, where a CPA is confined to a simple layer. Specifically, we consider a CPA on a nonlinear waveguiding sphere $S$ of a radius $r_\ast > 0$ and focus on the simplest axially symmetric solutions which depend only on the radius $r = |r|$, i.e., on solutions of the form $\Psi(r) = R(r)$. If the sphere is characterized by the uniform distributions of the dielectric permittivity, losses and nonlinearity, i.e., $\varepsilon(\rho) \equiv \varepsilon_0 + i\gamma$, $\sigma(\rho) \equiv \sigma$, and $\ell = k_0^{-2/3}$, then the Helmholtz equation (3) reduces to

$$-\frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{dR}{dr} \right) - \delta(r - r_\ast)(\varepsilon - \sigma R^2)R = k_0^2 R. \quad (32)$$

In the free space the general solution is a linear combination of functions $\cos(k_0r)/r$ and $\sin(k_0r)/r$. Imposing the matching conditions at $r = r_\ast$, one finds

$$R(r) = C \frac{\sin(k_0r)}{r} \quad \text{at } 0 < r < r_\ast \quad (33a)$$

and

$$R(r) = C \frac{\sin(k_0r)}{r} - C \frac{\sin(k_0(r - r_\ast)) \sin(k_0r_\ast)}{r^2} \quad \text{at } r > r_\ast. \quad (33b)$$

Like in the case of circular absorbing layer, the obtained solution is characterized by the freedom of choice of the amplitude $C$, as well as of the coefficients $\varepsilon_0$ and $\gamma$. The radial component of the Poynting vector can be computed using the expression $\Pi(r) = \rho(\vec{R} R^2 - R^2 \vec{R})$. Thus $\Pi(r)$ vanishes in the cavity inside the absorbing sphere, while for $r > r_\ast$ one computes

$$\Pi(r) = -\frac{2C^2\gamma \sin^2(k_0r_\ast)}{r^2}, \quad (34)$$

which is always negative for $\gamma > 0$, thus corresponding to the energy flow from the infinity towards the absorber.

Since the constructed solution (33b) is a linear combination of incident ($e^{-ik_0r}/r$) and reflected ($e^{ik_0r}/r$) waves, it is, in general, not the perfectly absorbed one. In order to obtain the parameters when the sphere operates as a CPA, we require the outgoing radiation to vanish in the exterior region of the absorber. This requirements leads to the following expression for the variation of the dielectric permittivity:

$$\varepsilon_\ast = k_0[\cot(k_0r_\ast) + i] + \frac{\sigma|C|^2}{r^2} \sin^2(k_0r_\ast). \quad (35)$$

In the CPA regime, the imaginary part of $\varepsilon_\ast$ is positive; the real part vanishes for $\sigma = 0$ and $k_0r_\ast = \pi/2 + \pi n$. Substituting (35) to the general solution (33b), we obtain that for $r > r_\ast$, the perfectly absorbed solution reads

$$R_\ast(r) = \frac{C}{r} \sin(k_0r_\ast)e^{-ik_0(r-r_\ast)}. \quad (36)$$

Inside the CPA sphere, $r < r_\ast$, the solution $R_\ast(r)$ is given by expression (33a).
VII. CONCLUSION

In this work, we have constructed explicit solutions for several examples of coherent perfect absorbers (CPAs) confined in straight lines or surfaces embedded in two-dimensional and three-dimensional spaces. From the mathematical point of view, the considered surfaces represent simple layers, which are multidimensional generalizations of the Dirac delta-function. We explored different geometries, including line, surface, cylindric and spherical surfaces. Both linear and nonlinear CPAs are presented. Some of the surface CPAs appear to be broad-band with respect to the angular spectrum of incidence. The closed lines or surfaces perfectly absorbing vortices do not require incident energy flows from both sides of the surface, and in this sense can be viewed as unidirectional CPAs. Nevertheless, the field is nonzero in the interior domain of the CPA-surface and perfectly absorbed vortices are characterized by the energy flows tangential to the surface either in the interior and exterior domains of the respective CPA. Stability of the resulting CPA solutions on nonlinear surfaces has been demonstrated, provided that the intensity of the solution is below a certain threshold value.

Finally, the presented coherent perfect absorbers can be straightforwardly transformed in multidimensional simple-layer lasers by changing absorption by gain.
