We propose a theoretical framework to calculate capillary stresses in complex mesoporous materials, such as moist sand, nanoporous hydrates, and drying colloidal films. Molecular simulations are mapped onto a phase-field model of the liquid-vapor mixture, whose inhomogeneous stress tensor is integrated over Voronoi polyhedra in order to calculate equal and opposite forces between each pair of neighboring grains. The method is illustrated by simulations of moisture-induced forces in small clusters and random packings of spherical grains using lattice-gas Density Functional Theory. For a nano-granular model of cement hydrates, this approach reproduces the hysteretic water sorption/desorption isotherms and predicts drying shrinkage strain isotherm in good agreement with experiments. We show that capillary stress is an effective mechanism for internal stress relaxation in colloidal random packings, which contributes to the extraordinary durability of cement paste.

Capillary condensation is a ubiquitous process of vapor-liquid phase transition in porous media, such as sand piles, plaster, paints, silica gels, cementitious materials, which has an important yet poorly understood effect on mechanical behavior. The confined fluid can generate enormous local stresses, as observed in granular material aging, wet floor friction, nano-tribology, multi-phase immiscible flows, cement drying shrinkage, and in everyday life experiences such as hardening of a drying sponge or building a sand castle on the beach. Capillary condensation and evaporation potentially bring undesirable fracture processes, as in drying cracking of colloidal films and paints, but capillary stress can also be exploited in nanomaterials fabrication by capillary force lithography, capillary rise infiltration, evaporation-driven assembly and self-organization, and composite imbibition, and even used to evaluate the atmosphere of planets.

Despite the broad importance of capillary forces, they remain challenging to predict in complex porous materials over the full range of liquid saturation, either in equilibrium or during a dynamical process of drainage/imbibition. For granular or colloidal materials, existing models addressing partial saturations are oversimplified and only apply either to low humidity (so called pendular/funicular regimes) or to idealized geometries (slit/cylindrical independent pores or single sphere against a wall). The standard continuum model, based on capillary bridges described by the Kelvin and Young-Laplace equations, breaks down for more complex liquid distributions at higher saturations. Molecular simulations are also difficult to apply, since naively integrating liquid-solid forces over complex solid surfaces leads to significant noise and spurious net forces.

In this Letter, we present a theoretical framework to compute accurate capillary forces and associated structural relaxation in complex porous media. The method is illustrated through calculations of moisture-induced capillary stress in colloidal systems, based on lattice-gas simulations of adsorbed water. As an important application, we calculate drying shrinkage of cement paste, where the heterogeneous and multi-scale, fully connected porous network induces significant mechanical irreversibilities during drying-wetting cycles, disqualifying simple models.

Theory — For any molecular simulation model of a two phase, liquid-vapor system, the first step of our method is to parameterize the mean-field approximation of a Cahn-Hilliard-like phase-field free energy functional

$$F[\rho] = \int_V dV \left( f(\rho) + \frac{\kappa}{2} (\nabla \rho)^2 + ... \right) + \int_{\partial V} d\vec{S} \cdot (g(\rho) \vec{n} + h(\rho) \nabla \rho + ...)$$

(1)

The homogeneous free energy density $f(\rho)$, e.g. a regular solution model with particle-vacancy interaction energy $\Omega \rho (1 - \rho)$, can be fitted to simulation results in periodic cells, and the gradient penalty is related to the liquid/vapor surface tension

$$\gamma = \int_{\partial V} \kappa (\nabla \rho)^2 d\vec{S} \cdot \vec{n}$$

The planar liquid-vapor interface width for regular solution model is given by $\lambda = (\kappa / \Omega)^{1/2}$, with interfacial...
energy $\gamma = (\kappa \Omega)^{1/2}$\cite{31,32}. Solid/fluid surface tension can also be parameterized from simulations, e.g. by interpolating the surface energy term, represented in the above equation by the surface integral, between stable end states of liquid or vapor. 

In some cases, the parameters in the free energy functional can also be derived analytically from the molecular model. For example, for mean-field lattice gas DFT\cite{28} in the continuum limit, we have

$$G = \int \left( k_B T \left[ \rho \ln(\rho) + (1 - \rho) \ln(1 - \rho) \right] - \mu \rho \right) dv
+ \int \left[ \frac{w_{ff} \nu a^2}{4} (\bar{\nabla} \rho)^2 - \frac{w_{ff} \nu}{2} \rho^2 \right] dv
+ \int_{\partial V} dS \cdot \left( w_{sf} \rho \hat{n} - \frac{w_{ff} \nu}{4} a^2 \rho \bar{\nabla} \rho \right)$$

where $w_{ff}$ and $w_{sf}$ are the liquid-liquid and solid-liquid nearest neighbor interactions, $\mu$ the chemical potential for liquid-vapor equilibrium, $\nu$ the neighbor number and $a$ the size of lattice constant in the lattice gas model. $\partial V$ represents the liquid-solid boundary.

Once we have a suitable free energy, we define the capillary stress tensor, first derived by Korteweg\cite{33,34},

$$\bar{\sigma} = \left( p_0(\rho) - \frac{\nu a^2 w_{ff}}{4} (\bar{\nabla} \rho)^2 \right) \mathbb{I}
+ \frac{\nu a^2}{2} w_{ff} \bar{\nabla} \rho \otimes \bar{\nabla} \rho + \tilde{\sigma}_0$$

and use it to express the stress in terms of only the density profile from molecular simulations in the porous structure. (See Supporting Information.) In principle, surface forces can be calculated by integrating the normal stress over the solid pore walls, but we find that this procedure leads to large errors for complex geometries.

We thus introduce the second step of our method, which is to utilize the Stokes’ theorem\cite{35} and deform the contour away from the solid surface and integrate the normal stress over a space-filling tessellation of the microstructure. In this way, equal and opposite forces are applied at each face of the tessellation, perfectly satisfying Newton’s third law in the fluid, despite fluctuations in the molecular simulation and complex surface geometry.

For colloidal or granular systems of spherical particles, the most natural choice is the Voronoi tessellation, for which fast algorithms are available, such as the package Voro++\cite{36} used below.

Let us apply the method first to the simplest case of two nearly touching grains, which form a stable capillary bridge, using the lattice-gas DFT model for water, as shown in Fig.1a. Analytical results are available to describe the capillary force\cite{21,27,37}, and most models for wet granular materials rely on this picture of a capillary bridge\cite{38–43}. The simulated capillary force versus humidity is shown in Fig.1b, in agreement with the solution to the Kelvin-Laplace equation\cite{44–46}, assuming bulk water surface tension. The forces are simulated on the adsorption branch and thus compared with the smaller Kelvin radius “solution 1”, augmented by a wetting layer of thickness 0.25 nm.

To illustrate the challenges posed by any other geometry, consider the next simplest case of 3 spheres nearly in contact as shown in Fig.1c. At low humidity, the capillary bridge theory still holds and accurately predicts simulation results, but at high humidity, these bridges coalesce to fill the region between the particles and drastically alters the forces, in a way that only the simulation can easily capture, in part since the liquid-vapor interface takes a non-convex shape in three dimensions with regions where the two principal curvatures have opposite signs.

Next we consider a 3D random packing of colloidal particles...
In general, we find that capillary forces facilitate macroscopic stress relaxation in granular or colloidal cohesive media, which present rough and glassy potential energy landscapes having an abundance of meta-stable states. For the case of cement paste, this mechanism is able to quantitatively explain the experimentally observed volume shrinkage (see Fig. 4). Reactive heterogeneous materials such as cement have residual stresses due to the out-of-equilibrium solidification process\cite{51-53}. The cement paste structure analyzed here has accumulated tensile eigen-stress of -47 MPa through the precipitation of nano-grains \cite{54, 55}.

Figure 4 shows how capillary forces affect the relaxation of two different samples, young cement paste sample with initial tensile eigen-stresses (-47MPa) and hardened sample (the relaxed version of the young sample). In Fig. 4 the hardened sample exhibits shrinkage only due to capillary effect whereas the young sample shrinks under the combined action of tensile eigenstresses and capillary forces. In the hardened sample, the "pure capillary effect" decreases with increasing humidity, and predicted strain is in excellent agreement with experiments \cite{9, 54} for $h > 30\%$. In contrast, the young sample shrinks more than the hardened one and with the opposite trend: shrinkage increases upon increasing humidity. (It is interesting to note that our relative strain results are in quantitative agreement with the total strain measurement of Fig.4 in Ref. \cite{30}).

In Fig. 4 we further predict the stress relaxation under a constant volume constraint. Minimal residual stresses are observed in hardened sample for all humidities. Residual stresses in young sample relaxed to -30.52 MPa at $h = 31\%$, significantly different than that obtained in fully dry condition (-44.4 MPa). This counterintuitive behavior has also been observed by short-term drying cement experiments after long-term curing at different humidities \cite{30}.

These results demonstrate that capillarity at intermediate humidity is an effective mechanism of stress relaxation and therefore beneficial to cement durability. Although the order of magnitude of capillary forces on each nano-grain is small (~1 nN) compared to the grain-grain interactions (~10 nNs), these forces still have an observable effect on the mesoscale. For materials that are “softer” than cement paste, capillary forces are expected to have even larger aging effects. Overall capillary forces help to relax eigenstresses without major volume shrinkage. It is remarkable to notice the synergetic effect of capillaries and eigen-stresses, reducing the shrinkage compared to both dry and fully saturated conditions.

In conclusion, we have described a general framework to calculate capillary stress in complex porous media, without any assumptions on the pore morphology or topology, across the full range of liquid saturation. The method is able to accurately predict capillary stress and structural relaxation in cement paste, which has both theoretical and practical importance due to its

or granular spheres of different sizes. Voro++ \cite{36} easily computes the tessellation and stresses can be efficiently and accurately computed. Fig.2 shows the Voronoi tessellation cells around the colloidal nano-grains. Zooming in on a single grain, the inset of Fig.2 shows the fluid density on the faces of its polygonal Voronoi cell at $h = 30\%$. Due to the complex granular structure, straightforward integration of the mean stress field over the surface leads to errors that accumulating into a non-zero net force on the solid, violating Newton’s third law, but integration over the tessellation allows equal and opposite forces to be assigned to each pair of neighboring particles. This example demonstrates the capability to predict the stress and deformation of composite materials, subject to either out-of-equilibrium multi-phase flow or equilibrium capillary condensation during drying and wetting processes.

\textbf{Results—} As a practical application of our method, we predict capillary stresses and structural relaxation in hardened cement paste during hydration cycles, which are associated with various degradation mechanisms in concrete structures and pavements. We simulate capillary condensation in our previously developed colloidal model of cement paste\cite{47}, illustrated in Fig.2 using interaction parameters imported from atomistic simulations \cite{48, 49}. (See Supporting Information.) First, we show the lattice DFT method\cite{28} for this structure is able to predict the room temperature hysteretic water adsorption/desorption isotherm in agreement with experiments \cite{60} (Fig.3a) with no adjustable parameter. Next, we analyze the fluid distribution in the pore network (Fig.3b) and calculate the mechanical effect of capillary stress, for the first time to our knowledge in such a complex porous structure.

In general, we find that capillary forces facilitate

multi-scale porous structure and wide usage in everyday life. Other possible applications include the drying and collapse of wet sand castles, capillary-driven liquid/solid composite manufacturing, and the evaporation-driven assembly and self-organization of colloidal particles.

The authors thank S. Yip and N. Nadkarni for useful discussions and C. Rycroft for help with visualization.

Figure 4: Stress relaxation in two different models of cement paste, a young sample with initial tensile eigen-stress $\sim$-47 MPa (lower curves) and a hardened sample, relaxed from the young to 10 kPa (upper curves). For simulations at constant pressure (NPT) in (a), the hardened sample results are in excellent agreement with experiments on first-cycle drying shrinkage, and the young sample shrinkage strain agrees well with experiment data for total strain. At constant volume (NVT) in (b), no significant stress produced in the hardened sample, but the young sample’s initial solid stress without capillary forces relaxed to -44.27 MPa, blue circles showing more solid stress relaxed by capillary forces.

portland cement paste as deduced from sorption-length change and mechanical properties,” *Materials and structures*, vol. 1, no. 6, pp. 509–520, 1968.
