I. INTRODUCTION

The exponentially growing size of the Hamiltonian (H) with increasing system size means that exact, Born-Oppenheimer electronic energies are not easily achievable for polyatomic molecular systems. Recent years have seen impressive progress in methods that produce FCI-quality energies at greatly reduced cost, such as density matrix renormalization group (DMRG), FCI quantum Monte Carlo (FCIQMC), and incremental FCI (iFCI).

Another avenue for obtaining FCI-quality energies has also recently become available due to the revival of the selected configuration interaction plus perturbation theory (SCI+PT) algorithms. SCI+PT consists of two steps. In the first step, the most important determinants of the wavefunction of interest are identified iteratively and the Hamiltonian in this subspace (V) is diagonalized to obtain the approximate variational energies and wavefunctions. In the second step, the perturbative step of SCI+PT attempts to correct these energies and wavefunctions. The first such SCI+PT method was called Configuration Interaction by Perturbatively Selecting Iteratively (CIPSI), which established the basic steps of the SCI+PT algorithms. Since then, many variations of CIPSI have been developed over the years, all of which try to improve upon the CIPSI algorithm. However, a common drawback of all these variants is that, to construct the selected space V iteratively, the algorithm has to loop over all the determinants connected to any determinant in previous iteration of V. This becomes prohibitively expensive as the size of space V increases to several million determinants. Some of us have recently proposed the Heat-bath CI (HCI) algorithm that eliminates this expensive step by changing the selection criterion such that it enables an algorithm that loops over only those determinants that will be included in the selected space V, a small fraction of all the possible connected determinants. This results in orders of magnitude speed up over other variants of SCI+PT for this step of the algorithm. HCI was further improved by semistochastic evaluation of the pertubative energy in semistochastic HCI (SHCI), which eliminated the need to store a long list of perturbative determinants in memory. SHCI’s potential has been demonstrated in previous works, where it was shown to efficiently treat CI spaces orders of magnitude larger than is possible with conventional CI algorithms.

In this paper, highly accurate benchmarks for electronically excited states of the polyatomics in Figure 1 are computed using SHCI. Methylene is presented as the first test case, due to its small size yet challenging electronic structure. Additionally, ozone is examined to answer a long-standing question regarding the existence of a theorized meta-stable ozone species. Finally, SHCI is applied to the first few polyenes — ethylene, butadiene, and hexatriene — which have long been studied for their role as prototypical organic conducting polymers. The state ordering of the low-lying valence excited states, 2^1A_g and 1^1B_u, in butadiene and hexatriene have been especially challenging due to the significant numbers of highly correlated electrons and the near-degenerate nature of the valence states. Herein, extrapolated SHCI state energies will provide high accuracy 2^1A_g/1^1B_u state orderings in butadiene and hexatriene.

This article is organized as follows. In Section II, the excited-state SHCI algorithm is reviewed, and the path to convergence to the FCI limit is discussed. In Section III, results on the smaller methylene and ethylene systems are used to validate SHCI against current benchmark values and establish convergence with respect to FCI. These observations are then used to estimate FCI-quality energies for the larger ozone, butadiene, and hex-
atriene molecules. Section IV provides conclusions and an outlook on the SHCI method.

II. METHODS

A. Semistochastic Heat-Bath Configuration Interaction

As HCI and semistochastic perturbation theory have been described in detail\cite{cite1, cite2}, only a brief overview will be given here. The HCI algorithm can be divided into variational and perturbative stages, each of which selects determinants through threshold values, $\epsilon_V$ and $\epsilon_{PT}$, respectively. The current variational space of determinants is denoted by $V$ and the space of all determinants connected by single or double excitations to $V$, but not in $V$, is denoted by $C$.

The variational stage iteratively adds determinants to $V$ by

1. Adding all determinants $a$ connected to determinants in the current $V$ that pass the importance criterion $\max_x |H_{ai}| \max_x |c_i^n| > \epsilon_V$, where $c_i^n$ is the coefficient of determinant $i$ in state $n$.

2. Constructing the Hamiltonian and solving for the roots of interest, in the basis of all determinants in the newly expanded $V$.

3. Repeat 1-2 until convergence.

Convergence of the variational wavefunction for a given $\epsilon_V$ is signified by the addition of a small number of new determinants or small changes in the variational energy ($E_{var}$). The second-order Epstein-Nesbet perturbative energy correction ($\Delta E_2$) is added to $E_{var}$ to obtain the total HCI energy ($E_{tot}$). This correction is

$$\Delta E_2 = \sum_{a \in C} \left( \sum_{i \in V} H_{ai}c_i \right)^2$$

where $a$ runs over determinants in $C$, and $i$ over determinants in $V$. Similar to the variational stage, the perturbation only considers the determinants connected to the final $V$ space that have an importance measure greater than a parameter $\epsilon_{PT}$, which is typically orders of magnitude smaller than $\epsilon_V$. In both the variational and the perturbative stages, the fact that the number of distinct values of the double-excitation matrix elements scales only as $N^4$ is used to avoid ever looking at the unimportant determinants. Nevertheless, storing the full space of determinants used in the perturbative correction becomes a memory bottleneck for larger systems.

SHCI sidesteps this memory bottleneck using a semistochastic second-order perturbation correction. In this procedure, the perturbative correction is split into deterministic and stochastic contributions. A larger $\epsilon_{PT}$, automatically determined to correspond to a determinant space of manageable size depending on available computer memory, is first used to obtain a deterministic energy correction. The remaining correlation is then calculated stochastically by taking the difference of the second-order corrections evaluated with $\epsilon_{PT}$ and $\epsilon_{PT}^d$. Samples are taken until the statistical error falls below a specified threshold.

B. Converging SHCI Energies to the FCI Limit

The target accuracy for total or relative energies are typically be chosen to be 1 mHa or 1.6 mHa (1 kcal/mol, representing chemical accuracy), though for the smaller systems it is easy to achieve much higher accuracy. In SHCI, the error in the variational energy can be straightforwardly estimated by the magnitude of the perturbative correction.

In methylene and ethylene, SHCI can provide such highly converged variational energies. In larger systems, however, converging the variational energy would require prohibitively large variational spaces. Instead, we fit the variational energy or the total energy, $E_{tot} = E_{var} + \Delta E_2$, to $E_{var} - E_{tot}$ using a quadratic function and use the fitted function to extrapolate to the no perturbative correction ($E_{var} - E_{tot} = 0$) limit. The fit coefficients for variational and total energies are the same, except that the coefficients of the linear terms differ by one, so the two energies extrapolate to precisely the same value. There is not a well-defined method for estimating the extrapolation error, but a reasonable choice is one fifth of the difference between the calculated energy with the smallest value of $\epsilon_V$ and the extrapolated energy. In many cases the fitted function is very nearly linear (see e.g. Figs. 2, 4 and 5). Furthermore, even when the fitted functions are not close to linear, the functions for different states are often close to parallel, making the estimates of the energy differences particularly accurate.

C. Computational Details

SHCI is implemented in Fortran90, parallelized using MPI, and makes use of spatial symmetry, and time-reversal symmetry when the number of up- and down-
spin electrons is equal. The variational iterations are terminated when the number of new determinants added is less than 0.001% of the current variational space or when the change in variational energy is less than 1 \times 10^{-5} \text{Ha}. For all calculations, \( \epsilon_V \) is set to 1 \times 10^{-7} \text{Ha}, which provides converged perturbative corrections. \( \epsilon_V \) is made as small as possible on our hardware, obtaining either small \( \Delta E_2 \) or enough data points to reliably extrapolate to \( \Delta E_2 = 0 \). The threshold for statistical error of the stochastic perturbative correction is generally set to 5 \times 10^{-5} \text{Ha}, although the larger hexatriene/ANO-L-pVDZ computations use 1 \times 10^{-4} \text{Ha}.

For the smaller systems (methylene and ethylene) achieving convergence is relatively easy, allowing the use of Hartree-Fock and HCI natural orbitals (obtained with achieving convergence is relatively easy, allowing the use of Hartree-Fock and HCI natural orbitals (obtained with Hartree-Fock and Hartree-Fock calculations). For the larger systems (ozone, butadiene, hexatriene), the convergence was improved by using orbitals that minimize the HCl variational energy \(^{53} \) for \( \epsilon_V = 2 \times 10^{-4} \). Possible, yet better convergence could be obtained by using orbitals that make the total energy stationary.

Basis sets used are aug-cc-pVQZ \(^{58} \) for methylene, ANO-L-pVTZ \(^{59} \) for ethylene, ANO-L-pVDZ \(^{60} \) for butadiene and hexatriene, and cc-pVTZ \(^{61} \) for ozone. Geometries for methylene are FCI/TZVP quality, taken from Sherrill et al. \(^{62} \) and Chan et al. \(^{63} \) For the polyenes, all geometries are of MP2/cc-pVQZ quality, with ethylene and hexatriene geometries the same as in Zimmermann \(^{64} \) but butadiene the same as in Alavi et al. \(^{65} \) All calculations utilize the frozen-core approximation. For comparisons to coupled cluster theories, the same geometries and basis sets are used with the Q-Chem 4.0 \(^{66} \) CR-EOM-CC(2,3)D \(^{67} \) implementation.

III. RESULTS AND DISCUSSION

A. Methylene

Methylene is a prototypical test case for advanced electronic structure methods, being small enough to be amenable to canonical FCI benchmarks, yet still requiring accurate treatment of dynamic and static correlations for correct excitation energies. \(^{58,62,63} \) The four lowest lying states of methylene vary in spin and spatial symmetry: \( 1^3B_1 \), \( 1^1A_1 \), \( 1^1B_1 \), and \( 2^1A_1 \). With only six valence electrons to correlate, SHCI can handle obtain FCI-quality energies even with the large aug-cc-pVQZ basis (Table I), obtaining perturbative corrections less than 0.01 mHa with \( \epsilon_V = 10^{-5} \text{Ha} \).

Table I shows the most accurate SHCI adiabatic energy gaps calculated with \( \epsilon_V = 10^{-5} \text{Ha} \), which differ from experiment by about 0.01 eV. Comparing canonical FCI in the TZ2P basis with SHCI in the larger aug-cc-pVQZ basis shows differences of up to 0.158 eV \(^{58} \), demonstrating that large basis sets are necessary to fully describe correlation in methylene. This was first demonstrated using diffusion Monte Carlo (DMC) results, \(^{68} \) which are much less sensitive to basis sets and agree with SHCI to within about 0.02 eV. CR-EOMCC(2,3)D relative energies are generally within 1.6 mHa (0.044 eV) of the benchmark SHCI values, indicating that high-level multi-reference coupled cluster calculations are able to correlate six electrons sufficiently to obtain FCI-quality energy gaps.

B. Ethylene

Ethylene is another prototypical benchmark system for electronic excitations, including an especially challenging \( 1^1B_2 \) state. Although the \( 1^1B_2 \) state is qualitatively well described by a \( \pi^{-1}\pi^* \) excitation, a quantitative description requires a thorough accounting of dynamic correlation between \( \sigma \) and \( \pi \) electrons. \(^{58,65,69} \) Here, SHCI is applied to the low-lying valence states of ethylene: \( 1^1A_g \), \( 1^1B_1^u \) and \( 1^3B_1^u \), in the ANO-L-pVTZ basis.

Fully correlating ethylene’s twelve valence electrons is a considerably more difficult task than correlating methylene’s six. This is reflected in the fact that SHCI perturbative corrections start to fall below 1.6 mHa only at \( \epsilon_V = 7 \times 10^{-6} \text{Ha} \) (Figure 2). These results suggest that polyatomics with up to twelve valence electrons and triple-zeta basis sets are amenable to treatment at the FCI level using just the variational component of SHCI. Table II compares SHCI total and relative energies with previous FCIQMC \(^{70} \) and iFCI \(^{71} \) results. SHCI total energies are only about 1 mHa lower than FCIQMC and the \( 1^1B_1^u - 1^1A_g \) excitation energy is in even better agreement. The \( 1^1B_1^u - 1^1A_g \) energy obtained from iFCI is also in reasonably good agreement, thought it is obtained using a different triple-zeta basis. On the other hand, Table II also indicates that coupled cluster methods must include more than triples excitations in order to obtain FCI-quality relative energies, as CR-EOMCC(2,3)D results show errors considerably greater than 1.6 mHa (0.044 eV) with respect to the SHCI benchmark values. The SHCI relative energies support the notion that the vertical excitations cannot be quantitatively compared to the experimental band maxima in ethylene. \(^{68,71} \)

Ethylene is the largest system tested for which the perturbative correction is less than 1.6 mHa. This requires using \( \epsilon_V = 7 \times 10^{-6} \text{Ha} \) and 10^8 determinants in the variational space, which is near the limit of what can be reasonably stored on contemporary hardware.

As mentioned in Methods: Converging SHCI Energies to the FCI Limit, in larger systems we fit \( E_{\text{tot}} \) or \( E_{\text{var}} \) to \( E_{\text{var}} - E_{\text{tot}} \) using a quadratic function and use the fitted function to extrapolate to the no perturbative correction limit, thereby obtaining accurate energies even when the variational energies are not converged. \(^{58} \) The fits of \( E_{\text{tot}} \) and \( E_{\text{var}} \) are shown in Fig. 2. The \( E_{\text{tot}} \) is nearly flat. To estimate the error of the extrapolation, we performed an additional fit omitting the black points in Fig. 2.

C. Ozone

Ozone’s potential energy surfaces have held great interest due to its role in atmospheric chemistry. An interesting feature predicted by computational studies is the existence of a metastable ring geometry on the ground state surface. A lack of experimental evidence for such a species has fueled multiple studies of the pathway leading to the ring species over the years. The most recent such study by Ruedenberg et al. utilizes multi-reference CI with up to quadruple excitations, expending considerable effort on selecting and justifying an active space. To provide an accurate picture at critical points along the theorized pathway with even treatment of all valence electrons, SHCI is applied to ozone’s \(2^1\)A\(_1\)-1^1\)A\(_1\) gap with the cc-pVTZ basis at the three geometries of interest shown in Figure 3: the equilibrium geometry (termed the open...
FIG. 2. Fit of variational and total energies of ethylene using all data points. The black line is placed at 1.6 mHa. States are separated from one another by 0.01 Ha for clarity. The tightest SHCI calculation used \( \epsilon_V = 7 \times 10^{-16} \) Ha. The extrapolated energies obtained using all data points are compared to those obtained by omitting the black points in Table III.

D. Shorter Polyenes: Butadiene and Hexatriene

Butadiene and hexatriene are part of the polyene series, long studied for their role as prototypical organic conducting polymers. In particular, the spacing of the low-lying valence excited states has proven especially challenging for electronic structure methods. Butadiene and hexatriene are of special interest because their \( 1^1B_{1u} \) and \( 2^1A_g \) states are nearly degenerate, resulting in conflicting reports of state ordering at lower levels of theory. In the ANO-L-pVTZ basis, butadiene and hexatriene’s FCI spaces of \( 10^{26} \) and \( 10^{38} \) determinants, respectively, are too large for the routine application of FCI-level methods, although limited FCIQMC studies as well as SHCI ground state calculations have been performed on butadiene. Herein, SHCI is applied to the \( 1^1A_g, 1^1B_{1u}, 1^3B_{1u}, \) and \( 2^1A_g \) states to provide accurate benchmarks and state orderings.
1. Butadiene

Similar to ozone, extrapolation is used to obtain FCI energy estimates for butadiene in the ANO-L-pVDZ basis, as the tightest SHCI calculations at \( \epsilon_V = 3 \cdot 10^{-5} \) Ha had perturbative corrections ranging from 12-29 mHa (Figure 3). Besides using orbitals that minimize the SHCI variational energy, for molecules with more than a few atoms a further improvement in the energy convergence can be obtained by localizing the orbitals. Butadiene has \( C_{2h} \) symmetry, but the localized orbitals transform as the irreducible representations of the \( C_2 \) subgroup of \( C_{2h} \). Both the \( A_g \) and the \( B_u \) irreducible representations of \( C_{2h} \) transform as the \( A' \) representation of \( C_2 \). Hence calculating the three singlet states, \( 1^1A_g \), \( 2^1A_g \) and \( 1^1B_{2u} \) would require calculating three states simultaneously if localized orbitals are used, and further we would not know if the \( 2^1A_g \) or the \( 1^1B_{2u} \) is lower in energy. Consequently, we calculated only the \( 1^1A_g \) and \( 1^3B_{2u} \) orbitals using localized orbitals and computed the \( 2^1A_g \) and \( 1^1B_{2u} \) states with extended orbitals.

Table VI shows that using the same geometry as in prior FCIQMC, DMRG, and iFCI calculations leads to a SHCI \( 1^1A_g \) energy that is 0.4 and 0.9 mHa below the extrapolated DMRG and iFCI energies respectively. Although FCIQMC has yielded very accurate energies for many systems, in the case of butadiene all three methods (SHCI, iFCI, and DMRG) are in agreement that the FCIQMC energy for the \( 1^1A_g \) is 8-9 mHa too high. This may be either because of FCIQMC initiator bias or because of an underestimate of the FCIQMC statistical error because of the very long auto-correlation times encountered for large systems. A similar conclusion can be reached for the FCIQMC \( 1^1B_{2u} \) calculation, as the SHCI energy falls below it by a large amount, 12 mHa.

Turning to relative energies, we see that SHCI is in close agreement with all prior FCI-level theoretical calculations. Both the \( 1^3B_{2u}-1^1A_g \) and \( 1^3B_{2u}-1^1A_g \) gaps are 0.08 eV away from the iFCI and FCIQMC values respectively. Although the \( 2^1A_g-1^1A_g \) gap does not currently have FCI-level benchmarks, the agreement of SHCI’s other relative energies with existing benchmarks supports the accuracy of the extrapolated SHCI value for this gap, which is 6.58 eV. This places the \( 2^1A_g \) state above \( 1^3B_{2u} \) in butadiene by 0.13 eV. This small gap is consistent with recent theoretical and experimental investigations demonstrating ultrafast population transfer from \( 1^3B_{2u} \) to \( 2^1A_g \) which implies close proximity of the two states. As with ethylene, relative energies only qualitatively agree with experiment, supporting prior indications that experimental band maxima of butadiene do not correspond to the vertical excitation energy.

2. Hexatriene

Hexatriene is at the current frontier of FCI-level computations, with a demanding FCI space of \( 10^{38} \) determinants in the ANO-L-pVDZ basis. Only one other algorithm, iFCI, has approached FCI energies for such a large polyatomic - and then only for its singlet-triplet gap. Here we compute the energies of the lowest three singlet states and the lowest triplet state, using values of \( \epsilon_V \) as small as 2 \( \cdot 10^{-5} \) Ha (Figure 3), which results in as many as 9 \( \cdot 10^7 \) variational determinants.

The extrapolated hexatriene energies are reported in Table VII. With the same geometry, SHCI produces a \( 1^1A_g \) total energy 4 mHa below iFCI. This difference is within the extrapolation uncertainty of SHCI for this
FIG. 5. Extrapolation of hexatriene SHCI energies. States are separated from each other by 0.01 Ha for clarity. The tightest SHCI calculation used $\epsilon_V = 2 \cdot 10^{-5}$ Ha.

system. Prior investigations of hexatriene photo dynamics place $1^1B_u$ close in energy to $2^1A_g$. At the vertical excitation geometry, SHCI places $2^1A_g$ below $1^1B_u$ with a small gap of only 0.01 eV. The triplet-singlet $1^3B_u$-$1^1A_g$ gaps computed by SHCI and iFCI (using the slightly smaller 6-31G* basis) differ by only 0.04 eV. As in the case of butadiene, the SHCI $1^3B_u$-$1^1A_g$ gap differs significantly from experiment$^{119}$ indicating that experimental band maxima do not correspond to vertical excitation energies in hexatriene.

IV. CONCLUSION

SHCI represents an important step forward for SCI methods, providing FCI-quality energies in the largest molecular systems to date. SHCI easily correlates systems of 12 electrons in a triple-zeta basis and can reach FCI-level energies in larger systems through extrapolation. In this paper, CI spaces of $10^7$ – $10^8$ determinants were used to effectively handle FCI spaces of $10^{26}$ and $10^{38}$ determinants.

This work has provided new benchmarks and insights for the valence states of some commonly investigated molecular systems. Specifically, high-quality SHCI energetics for ozone give strong evidence that the theorized RM structure has a significant barrier to relaxation, and thus should be observable by experiment. Investigation of butadiene and hexatriene lead to the highest level $2^1A_g$-$1^1B_u$ state-orderings in these systems to date, placing $2^1A_g$ above $1^1B_u$ in butadiene, and minutely below $1^1B_u$ in hexatriene. In short, SHCI has shown itself to be an efficient means of obtaining FCI-level energetics, and we look forward to it providing physical insight into other chemically interesting systems with up to dozens of electrons.

ACKNOWLEDGMENTS

ADC and PMZ would like to thank David Braun for computational support and the University of Michigan for financial support. SS acknowledges the startup package from the University of Colorado. AAH, MO and CJU were supported in part by NSF grant ACI-1534965. Some of the computations were performed on the Bridges computer at the Pittsburgh Supercomputing Center, supported by NSF award number ACI-1445606.

An extrapolated value of -155.5578 was obtained by fitting the values in Table VI of Ref. [12] to either a linear or a quadratic function of $1/M$, where $M$ is the DMRG bond dimension.
