The laser cooling and trapping of europium is demonstrated herein. The atoms are optically pumped to a metastable state and then loaded from an atomic-beam source via conventional Zee-man slowing and magneto-optical trapping techniques using a \( J = 13/2 \leftrightarrow J = 15/2 \) quasi-adiabatic transition. The trapped populations contained up to \( 1 \times 10^7 \) atoms, and the density-dependent loss rate is estimated as \( 1 \times 10^{-10} \text{ cm}^3/\text{s} \) from the non-exponential loss of atoms at high densities. We also observed leakage out of the quasi-adiabatic transition to the \( J = 9/2 \) and \( 11/2 \) metastable states, which is adequate to pump the laser-cooled atoms back to the ground state.

Magneto-optical traps (MOTs) for atoms have become standard tools in atomic physics, enabling the investigations of fundamental and applied physics in diverse scientific fields such as degenerate quantum gases [1], quantum information processing [2, 3], and optical frequency standards [4]. Laser cooling using optical transitions in a nearly closed subset of atomic states is required to operate an MOT. Except for ytterbium, the complex energy structures of the lanthanides, which are owing to the presence of open f-shells, have hindered successful laser cooling. Forming an MOT with a lanthanide was first demonstrated in 2006 using erbium [5]. Demonstrations of MOTs with dysprosium [6], thulium [7], and holmium [8] followed a few years later. Exploring the lanthanides is motivated by several topics in current research areas. Examples include dipolar phenomena that rely on magnetic dipole-dipole interactions [9–12] that capitalize on the large magnetic dipole moments of the lanthanides as well as quantum information processing using collective encoding of multi-qubit quantum registers [13] that depend on the large spin degrees of freedom of these elements.

Herein, we report the formation of an MOT using europium (Eu), a lanthanide possessing two stable bosonic isotopes: \(^{151}\text{Eu}\) (comprising 48\% of the natural abundance of this element) and \(^{153}\text{Eu}\) (52\%). Both isotopes have nuclear spins \( I = 5/2 \) and large dipole moments \( \mu = 7 \text{ Bohr magnetons} (7\mu_B) \). The Eu atom has a spherically symmetric \( ^8S_7/2 \) electronic ground state in contrast to the other dipolar lanthanides. The large electronic orbital angular momentum of the ground state provides strong anisotropy, which leads to a rich behavior of the interactions between the atoms [14, 15]. The highly symmetric electronic ground state of Eu reduces the density of magnetic-field-induced Feshbach resonances [16]. In addition to the dimer \( \text{Eu}_2 \) [17], Eu forms heteronuclear molecules with alkaline or alkaline-earth atoms, which possess both large electric and large magnetic dipole moments. These molecules are promising candidate systems for quantum simulations of many-body physics [18, 19].

The hyperfine structure of Eu enables us to control the scattering length using RF fields [20, 21] even under the ultra-low DC magnetic fields. In addition, the hyperfine state with the largest magnetic-dipole moment in the electronic ground state corresponds to the lowest-energy state in the hyperfine manifold. These features are of interest for exploring ground-state phases, such as spin textures and vortices [22–25], where the magnetic dipole-dipole interaction couples the spin and orbital angular momenta.

An energy level diagram of neutral Eu [26, 27] showing the pumping and laser-cooling transitions. Only the well-assigned energy levels are plotted up to the energy of \( 32948.41 \text{ cm}^{-1} \), which corresponds to the uppermost level \(|e2\rangle\) in our experiment. The relevant levels are labeled for a convenient comparison with the schematic shown in Fig. 2. Odd-parity states are indicated by gray lines (red online).

FIG. 1. (Color online) The energy levels of Eu [26, 27] showing the pumping and laser-cooling transitions. Only the well-assigned energy levels are plotted up to the energy of \( 32948.41 \text{ cm}^{-1} \), which corresponds to the uppermost level \(|e2\rangle\) in our experiment. The relevant levels are labeled for a convenient comparison with the schematic shown in Fig. 2. Odd-parity states are indicated by gray lines (red online).
The wavelength is 460 nm and exhibits a broad linewidth of 27 MHz. However, eleven low-lying odd-parity states exist for \(|e1\). The lower limit to the probability of leakage of the \(|g\) ↔ \(|e1\) system was spectroscopically determined to be 1.05(2) × 10⁻³ [28]. This suggests a pessimistic outlook for laser-cooling using this transition; we cannot expect to laser-cool the atoms without using a substantial amount of repumping light. Rather than preparing many repumping light sources, a simple alternative is to use the cyclic transition \(|m3\) ↔ \(|e3\) (with a transition wavelength of 583 nm and a natural linewidth of \(\Gamma/2\pi = 8.2\) MHz). For laser cooling using this transition, the atoms are first pumped from the ground state \(|g\) to the intermediate states \(|m1\) and \(|m2\) by driving the \(|g\) ↔ \(|e1\) transition with a pumping beam at 460-nm wavelength. Adding two additional pumping beams at the wavelengths 507 and 513 nm enables us to pump the atoms to \(|m3\), as schematized in Fig. 2.

Although the metastable Eu* (state \(|m3\) = 5d(⁹D⁰)⁹⁶s a ¹⁰D₁₃/₂) has the large magnetic moment \(\mu = 11\mu_B\), a concern in bringing an ensemble of Eu* atoms into quantum degeneracy is that the cooled atoms are in the uppermost energy level \((F = 9)\) in the hyperfine manifold. Figure 2 also shows the hyperfine states relevant to the MOT. To avoid losses caused by hyperfine-changing collisions, pumping to the lowest hyperfine state \((F = 4)\) is required for evaporative cooling. Consequently, for future studies involving Eu, the trapped atoms will be used as a precooled atomic source and irradiation with other light beams will be utilized for pumping back to \(|g\).

Our Eu atomic beam was produced using an effusive oven operating at 870 K. The atoms emitted from the oven are first pumped to \(|m3\) and then decelerated in a 210-mm-long Zeeman slower. Our Zeeman slower operates with light that is red-detuned by \(\Delta_s/2\pi = 240\) MHz from the unshifted resonance of the cyclic transition \(F = 9 \leftrightarrow F' = 10\). This system allows the deceleration of \(^{151}\text{Eu}\) atoms in the metastable state \(|m3, F = 9\) that have velocities lower than 150 m/s, which corresponds to the lower 7.5 % of the velocity distribution. The three-color pumping light beams (at the wavelengths of 460, 507, and 513 nm) copropagate along the slowing light beam. The optically pumped and decelerated atoms are fed into the chamber used for the MOT, which has a pressure of ~1 × 10⁻⁸ Pa with the atomic beam running. Our MOT is formed in a quadrupole magnetic field provided by anti-Helmholtz coils and three pairs of counter-propagating, circularly polarized cooling-light beams. The cooling light is also red-detuned by \(\Delta_c\) from the \(F = 9 \leftrightarrow F' = 10\) cyclic transition. On-resonant repumping light tuned to \(F = 8 \leftrightarrow F' = 9\) overlaps with all the cooling beams. The beams have Gaussian waists (1/\(e^2\) intensity radii) of 11 mm and are truncated by a circular aperture of 21.6-mm-diameter.

The total number of trapped atoms is determined using an absorption imaging technique with a circularly polarized probe pulse tuned to the \(F = 9 \leftrightarrow F' = 10\) transition. After atom loading, we turned off all the light beams and the quadrupole magnetic field and applied a
weak magnetic field of \(\sim 1\) G along a given direction. Irradiation with a two-color, \(\sigma^+\)-polarized light pulse tuned to \(F = 9 \leftrightarrow F' = 9\) and \(F = 8 \leftrightarrow F' = 9\) enables us to pump the atoms into the dark state \(|F = 9, M = 9\rangle\), where \(M\) is a magnetic quantum number. By rotating the magnetic-field either to be parallel or antiparallel to the propagation direction of the probe pulse, we confirm that the degree of spin polarization is sufficient to determine the number of atoms assuming that the atomic ensemble is fully polarized. In addition, we find that the spin polarization of the atoms varies in a complicated manner for the parameters used for the MOT. Consequently, the effective saturation intensity for the multilevel system \(F = 9 \leftrightarrow F' = 10\) is not constant, which makes the quantitative determination of excitation fraction difficult. Figure 3 summarizes the number of trapped atoms as a function of the total power \(P\) of the six cooling beams, the detuning \(\Delta_c/\Gamma\) of the cooling light, and the magnetic-field gradient \(dB/dz\) along the symmetry axis \(z\). With the optimized parameters \(\Delta_c/\Gamma = -2.4, P = 36\) mW, and \(dB/dz = 17.5\) G/cm, we successfully loaded an MOT with \(1 \times 10^7\) atoms. The power of 36 mW corresponds to a total intensity of \(1.3 I_s\), where \(I_s \approx 2.7 \times 5.4\) mW/cm\(^2\) is the conventional saturation intensity; the factor of 2.7 accounts for averaging over equally populated Zeeman sublevels and for the random polarization of the light field in the MOT.

In temperature determination using ballistic expansion, we observed a dual-component gas comprising a cold core surrounded by a hot shell, which resembles the structures reported in an MOT for dysprosium [6, 30]. For the optimal parameters mentioned above, the temperatures of the core and the shell are estimated to be \(230(21)\) \(\mu\)K and \(1.1(1)\) mK, respectively. Doppler-cooling theory predicts the MOT temperature for this intensity and detuning to be \(\sim 500\) \(\mu\)K, and the Doppler-cooling limit for Eu with the 583-nm transition is \(200\) \(\mu\)K. Much lower temperatures have been obtained with smaller magnetic-field gradients and smaller detunings. We observed a core temperature of \(41(4)\) \(\mu\)K and a shell temperature of \(40(80)\) \(\mu\)K with \(dB/dz = 5\) G/cm and \(\Delta_c/\Gamma = -1.1\). The number of atoms in the core and the shell are \(\sim 50\%\) of the total population; however, note that this percentage may contain significant error because herein the atom numbers are determined without using the spin polarizing procedure.

Turning off the pumping laser beams allows us to measure the trap lifetime. For example, Fig. 4 shows the decay curve observed with the optimal MOT parameters. The dots indicate the measured fluorescence intensity. The phenomenological equation for the number \(N(t)\) of trapped atoms as follows:

\[
\frac{dN}{dt} = -\gamma N - \beta \int n^2(r, t) d^3r.
\] (1)

Assuming that the density distribution \(n(r, t)\) can be expressed as a Gaussian with a root-mean-square (RMS) size \(\sigma_{x,y,z}\) along the three axes, we can rewrite the last term in Eq. 1 as \(-\beta N^2/V_{\text{eff}}\), where \(V_{\text{eff}}\) is a volume given by \(V_{\text{eff}} = (2\sqrt{\pi})^3 \sigma_x \sigma_y \sigma_z\). Herein, we chose the axial direction of the MOT coil as \(z\) and the other two orthogonal radial directions as \(x\) and \(y\). We determined the RMS sizes via absorption imaging with the probe pulse propagating along the \(x\) direction, just after releasing the cloud and turning off the light fields for the MOT. Although the magnetic-field gradient remains, the gradient does not affect the size determination owing to the small volume of our MOT and the near equality of the g-factors of the lower and excited states. Using the absorption imaging dataset obtained with various MOT-holding durations (< 0.75 s), we found the dimensions to be \(\sigma_x = 324(8)\) \(\mu\)m and \(\sigma_z = 178(6)\) \(\mu\)m; the numbers in parentheses here denote the respective standard deviations. We confirmed that these sizes are approximately independent of the MOT-holding durations or the number of atoms remaining in the trap. We assume \(\sigma_x = \sigma_y\) for the following determination of \(\beta\). The decay of the number of trapped atoms \(N\) is obtained by integrating Eq. 1. This gives

\[
\frac{N}{N_0} = \frac{1}{(1 + \gamma_2/\gamma)e^{\gamma t} - \gamma_2/\gamma}.
\] (2)

where \(N_0\) is the initial number of atoms and \(\gamma_2\) is defined as \(\beta N_0/V_{\text{eff}}\). We extracted the coefficients from fitting Eq. 2 to the experimental data; this gives \(\gamma = 1.9\) s\(^{-1}\) and \(\gamma_2/\gamma = 0.55\), which corresponds to \(\beta \approx 1 \times 10^{-10}\) cm\(^3\)/s. This result provides an upper limit to the two-body collision rate constant. Although the magnitude of \(\beta\) obtained for the metastable Eu\(^+\) atoms in the MOT is comparable to that for metastable noble gases in traps without near-resonant light fields [31], a penning collision (Eu\(^+\) + Eu\(^+\) \(\rightarrow\) Eu + Eu\(^+\) + e\(^-\)) might not occur even for a collision between Eu atoms in a lower level ([m, 3]) = (13778.68 cm\(^{-1}\)) and an excited state ([e3], 30923.71 cm\(^{-1}\)), because the ground-state energy of ionized Eu\(^+\) (\(\beta\)S\(_{24}\), 45734.74 cm\(^{-1}\)) is large compared with the energy of the metastable states. Such a large

![FIG. 4. (Color online) The observed MOT fluorescence-decay curve for the optimal trapping parameters. The data were obtained by averaging five MOT loading/decay cycles. The solid curve is a fit to the non-exponential decay model given by Eq. 2. For comparison, the dashed line shows a simple exponential fit to the data after 0.75 s.](image-url)
amount of $\beta$ can also be found in a system of magnetically trapped $L \neq 0$ atoms such as erbium (3.0 $\times$ $10^{-10}$ cm$^3$/s [32]) or thulium (1.1 $\times$ $10^{-10}$ cm$^3$/s [32]) owing to the long-range electrostatic quadrupole-quadrupole interaction, in contrast to the $L = 0$ ground state of europium (2.5(1.5) $\times$ $10^{-13}$ cm$^3$/s; see reference [33]). Further investigations will focus on collisional processes among Eu atoms at rest in a magnetic or an optical trap.

To determine the one-body loss rate $\gamma$, we measured the fluorescence decays by changing the power of the cooling light, i.e., the excitation fraction, to study the cause of its large magnitude. We found that $\gamma$ depends strongly on the existence of pumping laser beams, particularly at the wavelength of 513 nm and on the power of the cooling-laser beams, as shown in Fig. 5. The 513-nm repumper can return the atoms from the metastable state $|m2\rangle$ to the cyclic transition $|m3\rangle \leftrightarrow |e3\rangle$ with an efficiency of $\lesssim 75\%$, where the branching ratio limits the repumping capability. We assume that the finite repumping efficiency is the main cause of the residual dependence on the cooling-laser power for the case wherein two repumpers are used. In addition, the repumping seems to work well even for a small cooling-laser power. This suggests that other decay paths exist from the lower metastable state $|m3\rangle$. Since an even-parity state with $J = 13/2$ exists at 1800 cm$^{-1}$ above $|m3\rangle$ as shown in Fig. 1, the excitation from $|m3\rangle$ driven via thermal blackbody radiation and the spontaneous decay to $|m2\rangle$ (and to the other states) may be participating in the loss mechanism.

The main conclusion from fitting the fluorescence decays is that, in addition to the two-body collisions, the fractional leakage owing to non-E1 transitions from the excited state $|e3\rangle$ limits the number of trapped atoms in our MOT. This may be the reason for the saturation of atom number even with moderate cooling-light power, as shown in Fig. 3. Although the leak to $|m2\rangle$ seems dominant, it is difficult to determine the specific leakage pathways owing to the large number of associated energy levels. However, the leakage is useful for pumping the atoms back to the ground state $|g\rangle$. As shown in Fig. 1, pumping through the transition $|m2\rangle \rightarrow |e1\rangle$ enables us to return almost all of the atoms in $|m2\rangle$ to $|g\rangle$. This enables the continuous loading of the pump-back atoms to a magnetic trap or a second narrow-line MOT using transitions such as $6s^2a^8S_{7/2} \leftrightarrow 6s6p(3P^o)z^{10}F_{9/2}$, where the transition wavelength and the natural linewidth are 687 nm and 97(2) kHz [34], respectively.

In conclusion, we demonstrated an MOT containing up to $1 \times 10^7$ metastable $^{151}$Eu atoms. We found a large one-body loss rate owing to leakage from the quasi-cyclic transition used to create the MOT. The leakage is helpful for this pumping-back process, and we can also enhance the pumping-back efficiency using some additional repumping light beams.
