(Dated: March 21, 2018)

We experimentally investigate the unitarity-limited behavior of the three-body loss near a \( p \)-wave Feshbach resonance in a single-component Fermi gas of \(^6\)Li atoms. At the unitarity limit, the three-body loss coefficient \( L_3 \) exhibits universality in the sense that it is independent of the interaction strength and follows the predicted temperature scaling law of \( L_3 \propto T^{-2} \). When decreasing the interaction strength from the unitarity regime, the three-body loss coefficient as function of the interaction strength and temperature can be described by the theory based on the association of an excited resonant quasi-bound state and its relaxation into a deep stable dimer by collision with third atom in the framework of the standard Breit-Wigner theoretical approach. The results reported here are important to understand the properties of a resonant \( p \)-wave Fermi gas in the prospect of quantum few- and many-body physics.

In a system of particles with strong interactions, universal features often emerge. A prime example of such a system is \( s \)-wave unitary Fermi or Bose gases, where a tunable interaction parameter known as the scattering length diverges. Such a unitary gas exhibits universal properties that are independent of scattering length and depend only on the atomic density and temperature \([1–3]\). Furthermore, ultracold atomic gases at the unitarity limit attract interest from the context of few-body physics because unitary Bose gases have been confirmed to show the universal feature that the three-body loss coefficient depends only on the temperature \([4, 5]\).

In contrast to an isotropic \( s \)-wave interactions, anisotropic nature of \( p \)-wave interactions make it possible to realize exotic topological many-body superfluid phases \([6, 7]\). The universal features of the atoms with \( p \)-wave interactions have been extensively studied theoretically \([8–13]\). Interactions among ultracold atoms across the \( p \)-wave Feshbach resonance are characterized by the scattering volume \( V \), the collision energy \( E \), and the effective range \( k_e \) \([14, 15]\). The scattering volume as a function of the external magnetic field is parameterized as \( V = V_{bg}[1 - \Delta B/(B - B_0)] \), where \( V_{bg}, \Delta B, B, \) and \( B_0 \) are the background scattering volume, resonance width, external magnetic field, and resonance position, respectively. The effective range can be safely assumed to be constant due to its very weak dependence on the magnetic field \([16, 17]\).

Yoshida et al. recently measured the temperature and magnetic field dependence of three-body losses near the \( p \)-wave Feshbach resonance in the lowest internal state of \(^6\)Li atoms, where the two-body dipolar loss is prohibited \([18]\). This measurement confirmed the predicted scaling law of the three-body collision coefficient \( L_3 \propto V^{8/3} \) near \( p \)-wave Feshbach resonance at a relatively small scattering volume and in a low-temperature regime. However, when the scattering volume was increased or in other words the magnetic field was tuned closer to the resonance position, the three-body loss coefficient rapidly enhanced and began to deviate from the scaling law. The unitarity-limited behavior of three-body loss in a strongly interacting \( p \)-wave Fermi gas has so far eluded experimental confirmation.

In this article, we report on the observation of the unitarity-limited behavior of the three-body loss coefficient in the vicinity of a \( p \)-wave Feshbach resonance in a spin-polarized Fermi gas of \(^6\)Li atoms. We experimentally show that at sufficiently large negative scattering volume or small magnetic field detuning from the resonance, the three-body loss coefficient reaches the limit imposed by the unitarity. We confirmed that at the unitarity limit, the three-body loss coefficient \( L_3 \) is not dependent on the interaction parameters and shows the temperature dependence of \( L_3 \propto T^{-2} \) as predicted theoretically \([16, 17]\). We construct a simple theoretical model by taking into account the formation of a resonant quasi-bound state and its vibrational quenching by inelastic collision with other atom based on the Breit-Wigner theoretical approach. Our theoretical approach successfully explains the magnetic-field and the temperature dependence of a three-body loss coefficient in a strongly interacting regime.

Our experiment begins by trapping \(^6\)Li atoms in the lowest hyperfine ground state \([1] \equiv |F = 1/2, m_F = 1/2\rangle \), using a single beam optical dipole trap, as described in detail elsewhere \([19, 20]\). After trapping of the atoms in the single beam optical dipole trap, evaporative cooling was performed at 300 G and the magnetic field was ramped to the vicinity of the \([1] \rightarrow [1] \) \( p \)-wave Feshbach resonance located at \( B_0 = 159.17(5) \) G. We reduced the magnetic field fluctuation down to 8 mG \([20]\). The magnetic field was initially tuned far above the \( p \)-wave Feshbach resonance \( B_0 \). Then, we abruptly ramped down the magnetic field to jump across the resonance toward Bose-Einstein...
Condensation (BEC) side to avoid adiabatic creation of Feshbach molecules [30]. Then, we quickly ramped the magnetic field to the various magnetic field detunings \(B - B_0\) and hold the atoms in the trap to measure the loss of the atomic number. As an example, Fig. 1(b) shows number of atoms for a hold time of 20 ms at various magnetic field detunings. Here, the temperature of the atoms is \(T \sim 1.5 \mu K\) and each data point is the average of 3 repeated measurements. The sharp edge of the loss feature in the lower magnetic field side corresponds to the resonance position \(B_0\) [28]. We treat the doublet structure of the \(p\)-wave Feshbach resonance due to the spin-dipole interaction [29] as being completely overlapped with each other, because the splitting of the two resonances in \(^6\text{Li}\) is quite small compared with the resonance width. The solid curve in Fig. 1 shows the result of our theoretical description obtained using Eq. (7) into the solution of rate equation (1), as discussed in a later part of the text.

To measure the three-body loss coefficient \(L_3\), we monitored the hold-time dependence of the number of atoms \(N\) at a fixed temperature \(T\) and detuning from the Feshbach resonance \(B - B_0\). The number of atoms decay according to the rate equation

\[
\frac{\dot{N}}{N} = -L_3 \langle n^2 \rangle,
\]

where \(\langle n^2 \rangle = (1/N) \int n(x)^2 dx\) is the mean square density determined from the atomic density profile obtained via absorption imaging. To simplify the analysis, we always keep the atomic temperature greater or equal to the Fermi temperature such that the density profile of atoms is assumed to be a Gaussian. We limited the atomic loss up to 30-35 % of the initial number of atoms, and the temperature change during the hold time is less than 10 %. Therefore, we extracted the three-body loss coefficient \(L_3\) from the solution of Eq. (11) assuming a constant temperature approximation. In our experiment, the one-body loss rate can be safely neglected because the one-body decay time of the atoms due to background-gas collision is 80 s and has negligible influence on the determination of \(L_3\).

Figure 2 shows \(L_3\) as a function of magnetic field detuning on the negative-scattering-volume side of the resonance at temperatures of 2.1 \(\mu K\) (filled orange circles) and 4.5 \(\mu K\) (black diamonds). At a sufficiently far-off resonance regime, \(L_3\) follows the scaling law of \(L_3 \propto V^{8/3}\), as indicated by the green solid line for the case of 4.5 \(\mu K\) [10, 29]. As the magnetic field detuning decreases, \(L_3\) increases by orders of magnitude and eventually reaches to the maximum limit imposed by the unitarity condition. In the unitarity limit, \(L_3\) shows no further dependence on the magnetic field detunings towards the resonance which is clearly reflected by flat regions in the inset plot of Fig. 2. These results of Fig. 2 show a clear contrast to the case of an \(s\)-wave interacting unitary Bose gas, where the critical point of the magnetic field at which \(L_3\) reaches the unitarity-limited value is independent of...
The strength of the resonant coupling at collision energy...dotted lines in Fig. 3 indicate the point where temperature regime, and the data start to deviate from detuning show the scaling behavior at the relatively high-

Another feature evident from Fig. 2 is that the $L_3$ plateau at the unitarity regime is shifted to the lower value at the higher temperature. Therefore, we measured the temperature dependence of $L_3$ near zero detuning regions. Fig. 3 shows the temperature dependence of $L_3$ at the unitarity-limited regime for three magnetic field detunings: $B - B_0 = 15$ (orange circles), 30 (green diamonds), and 44 mG (blue squares). In this measurement, the atomic temperature was changed by controlling the degree of the evaporative cooling and the recompression condition of the dipole trap. Each data point is the average of 5 repeated measurements under the same experimental conditions. The error bars indicate 1 $\sigma$ standard deviation. In Fig. 3 all the data points for $B - B_0 = 15$ mG satisfy the condition of the unitarity limit, $k_T/k_{\text{res}} \geq 1$. At the unitarity limit, $L_3$ is expected to obey the following scaling law for the temperature $\sigma$.

$$ L_3^{\text{max}} = \lambda \times \frac{36\sqrt{3}\pi^2\hbar^5}{m^3(k_B T)^{\eta}}. $$ (2)

Here, $\lambda \leq 1$ is a non-universal dimensionless constant whose unity value indicates the maximum upper bound of the three-body loss. The value of $\lambda$ is generally less than unity and is species dependent. We fitted the data of $B - B_0 = 15$ mG with Eq. (2) keeping $\lambda$ and $\eta$ as free parameters. The red dashed line shows the best fit result with $\lambda = 0.10 \pm 0.03$ and $\eta = 2.10 \pm 0.09$, which agrees with the prediction of $L_3 \propto T^{-2}$. In the same way, the data taken at $B - B_0 = 30$ and 44 mG detuning show the scaling behavior at the relatively high-temperature regime, and the data start to deviate from the scaling behavior at low temperature. The vertical dotted lines in Fig. 3 indicate the point where $k_T/k_{\text{res}} = 1$. It is clearly evident that the deviation of the data from the unitarity scaling behavior occurs at $k_T/k_{\text{res}} = 1$, indicates the system is departing from the unitarity regime. The solid curves in Fig. 3 are the theory curve based on the model explained below.

Next, we discuss the simplified theoretical interpretation for the line shapes of the atomic loss near the unitarity regime. Our scheme is based on Breit-Wigner resonance scattering theory utilized to describe the laser-induced photoassociation trap loss and the $s$-wave three-body losses. We assume that the two atoms with relative kinetic energy $E$ collide in the presence of a molecular bound state that is resonant with the collision energy. The two colliding atoms are then resonantly coupled to the quasi-bound state (i.e., $Li + Li \leftrightarrow Li_2(e)$). The strength of the resonant coupling at collision energy $E$ exhibits a Wigner threshold form

$$ \Gamma_e = \frac{2\sqrt{m}E^{3/2}}{k_e\hbar}. $$ (3)

This threshold law also explains the lifetime of the quasi-bound molecular state, the dissociation energy of Feshbach molecules, and the dynamics of contact relations on the negative side of $p$-wave Feshbach resonances. The atoms in the quasi-bound state undergo a relaxation into a deeply-bound dimer $Li_2(\delta)$ as a result of the collision with the third atom, which is represented by the relaxation event

$$ Li_2(e) + Li \rightarrow Li_2(\delta) + Li + \delta e, $$ (4)

with excess energy $\delta e$ added to the kinetic energy of the atom and dimer.

To obtain the cross section for the resonance enhanced three-body recombination, we consider the effective range expansion of the $p$-wave scattering phase shift $\delta_k$ as

$$ \delta_k^p = -1/V - k_e k^2, $$

where $k$ is a relative wave number between the two colliding atoms and the effective range $k_e$ defined in this way is positive. In order to include the linewidth of the energy level associated with the dimer relaxation channels, we added the imaginary part $V_i > 0$ to the inverse of the scattering...
volume in the effective range expansion \[31, 39, 40\]

\[ k^3 \cot \delta_k = - \frac{1}{V} - i - k \varepsilon. \tag{5} \]

Using \( S \)-matrix \( S(k) = 1 + 2i k|k \cot \delta(k) - i k|^{-1} \) \[41\], the scattering cross section for the three-body recombination can be written as \( \sigma_{\text{res}} = (\phi_{\text{ae}}/\phi_{\text{ana}}) \times \frac{4}{\pi} |1 - |S(k)|^2 | \) \[42\]. Here, \( \phi_{\text{ae}} \) represents the phase space of an atom and resonant bound state while \( \phi_{\text{ana}} \) is the phase space of three atoms. From \( N \)-particle phase space integral, one can obtain \( \phi_{\text{ae}}/\phi_{\text{ana}} = 96 \sqrt{3 \pi / k^3} \) \[43\]. The three-body rate constant is described as \( K_3 = (2 \hbar k/m) \times \sigma_{\text{res}} \) with relative velocity \( v_{\text{rel}} = 2 \hbar k/m \). As a result, we obtain the three-body rate constant in the form of the Breit-Wigner expression given as

\[ K_3 = \frac{144 \sqrt{3 \pi \hbar^5}}{m^3 E^2} \times \frac{4 \Gamma_e \Gamma_d}{(E - E_{\text{res}})^2 + (\Gamma_e + \Gamma_d)^2/4}. \tag{6} \]

In this expression, \( E_{\text{res}} = \hbar^2 k_{\text{res}}^2 / m \) is the binding energy of the resonant quasi-bound state. The expression of the energy width \( \Gamma_d = 2 \hbar^2 / (mk_{\text{res}} V_i) \) can be derived from the simple mathematics and \( \Delta_{\text{res}} \) describes the rate of Eq. \[4] \. Therefore, \( V_i \) quantifies the strength of relaxation of the dimer into the deeply-bound dimer. The measured value of the three-body loss coefficient \( L_3 \) is the thermal average of \( L_3 = 3K_3/6 \) \[10\] for an atomic ensemble. Therefore, we consider the thermal averaging over the Maxwell-Boltzmann distribution \[13, 14\].

\[ L_3 = \frac{2}{\sqrt{\pi} (k_B T)^{3/2}} \int_0^\infty l_3 x \sqrt{E} e^{-E/k_B T} dE. \tag{7} \]

We fit both the 2.1 and 4.5 \( \mu \)K data sets shown in Fig. \[2\] with Eq. \[7\] using \( V_{\text{BG}} \Delta B = -2.8 \pm 0.3 \times 10^6 a_0^3 \) \[80\], \( k_\varepsilon \approx 0.091 \pm 0.01 a_0^{-1} \) and \( V_i \) as the only free parameter. Here, we can safely consider \( k_\varepsilon = -\hbar^2 / (mV_{\text{BG}} \Delta B \mu) \) because of the large scattering volume limit and narrowness of the resonance \[44, 46\], where \( \Delta \mu = k_B \times 113 \pm 7 \ \mu \text{K/G} \) is the relative magnetic moment between the molecular state and the atomic state \[47\]. The dashed line curves in Fig. \[2\] show the best fit result with \( V_i = (6.5 \pm 1.5) \times 10^{-22} \text{ m}^4 \). These theoretical curves explain the data at the intermediate region between the unitarity-limited regime and the weakly-interacting regime.

Now we fix the value of \( V_i \) and extract the theory curve of \( L_3 \) versus temperature for the data lying in the non-unitary regime in Fig. \[3\]. The data shown in Fig. \[3\] in the region over which \( k_T/k_{\text{res}} < 1 \) agrees fairly well with the theoretical results as shown by the solid green and blue curves for \( B - B_0 = 30 \) and \( B - B_0 = 44 \text{ mG} \), respectively. Similarly, Eq. \[7\] is used in the solution of the rate equation \[6\] with the fixed trapping conditions \[33\], and a theoretical curve is drawn for the number of atoms as the function of magnetic field detunings. The resultant curve is shown by the blue solid curve in Fig. \[4\] which is fairly consistent with the experimental data.

The obtained value of the imaginary scattering volume \( V_i \) corresponds to the relaxation width of \( \Gamma_d \sim k_B \times 0.15 \ \mu \text{K} \) which is higher than the width of the resonant bound state \( \Gamma_e \sim k_b \times 0.01 \ \mu \text{K} \) and \( \Gamma_e \sim k_B \times 0.04 \mu \text{K} \) calculated from Eq. \[4\] at \( T = 2.1 \mu \text{K} \) and \( T = 4.5 \mu \text{K} \), respectively. This implies that the timescale of the relaxation described by Eq. \[4\] is shorter than the timescale of the association of the shallow Feshbach dimers scaled by \( \Gamma_e^{-1} \). Therefore, the loss rate is dominantly set by the slow coupling of two atoms into the resonant quasi-bound state via barrier tunneling. Furthermore, \( k_B T \gg (\Gamma_e + \Gamma_d) \) indicates the thermal broadening of the line shape of atomic losses as observed in the data of Fig. \[2\].

In summary, we experimentally investigated the unitarity-limited behavior of the three-body atomic loss near the \( p \)-wave Feshbach resonance in a single-component Fermi gas of \( ^6 \text{Li} \) atoms. We confirmed the universal scaling law of \( L_3 \propto T^{-2} \) at the unitarity limit, and we also confirmed that the condition for the unitarity limit can be described by \( k_T/k_{\text{res}} \approx 1 \). The magnetic-field and temperature dependence of \( L_3 \) at the large negative scattering volume nearby the unitarity-limited regime shows good agreement with our theoretical description using the Breit-Wigner theoretical approach, which is based on the association of the resonant-bound state and its relaxation into a deep stable state by collision with other atom. Our approach directly relates the imaginary part of the inverse scattering volume to the relaxation lifetime of the Feshbach molecular bound state into deeply-bound dimer states. Our result provides a promising direction to explore the approach to the quantum-degenerate regime and test the anisotropic many-body physics at unitarity.
