## ABSTRACT

**Context.** Eclipsing time variations are observed in many close binary systems. In particular, for several post-common-envelope binaries (PCEBs) that consist of a white dwarf and a main sequence star, the Observed minus Calculated (O-C) diagram suggests that real or apparent orbital period variations are driven by Jupiter-mass planets or as a result of magnetic activity, the so-called Applegate mechanism. The latter explains orbital period variations as a result of changes in the stellar quadrupole moment due to magnetic activity.

**Aims.** In this work we explore the feasibility of driving eclipsing time variations via the Applegate mechanism for a sample of PCEB systems, including a range of different rotation rates.

**Methods.** We used the MESA code to evolve 12 stars with different masses and rotation rates. We applied simple dynamo models to their radial profiles to investigate the scale at which the predicted activity cycle matches the observed modulation period, and quantify the uncertainty. We further calculated the required energies to drive the Applegate mechanism.

**Results.** We show that the Applegate mechanism is energetically feasible in 5 PCEB systems. In RX J2130.6+4710, it may be feasible as well considering the uncertainties. We note that these are the systems with the highest rotation rate compared to the critical rotation rate of the main-sequence star.

**Conclusions.** The results suggest that the ratio of physical to critical rotation rate in the main sequence star is an important indicator for the feasibility of Applegate's mechanism, but exploring larger samples will be necessary to probe this hypothesis.

**Key words.** dynamo – stars: activity – binaries: close – stars: low-mass – stars: rotation

## 1. Introduction

Post-common-envelope binaries (PCEBs) are systems that consist of a low-mass main-sequence secondary and a white dwarf (WD). Their evolution, first proposed by Paczynski (1976), starts when the more massive component evolves up to a stage where its surface goes beyond the outer Lagrangian point, thus engulfing its companion. At this point the less massive star experiences friction as it orbits and thus loses orbital energy and angular momentum to the common envelope, spiraling inwards until enough energy is transferred to the envelope for it to be expelled. This leaves a close binary consisting of an M dwarf (dM) or a subdwarf and a white dwarf, with a binary period of normally less than three hours (see e.g., Parsons et al. 2013).

Besides the common envelope evolution itself, these systems reveal an intriguing characteristic when the observed minus calculated (O-C) eclipse times diagram is constructed. Periodic variations on timescales of a few years to a few tens of years suggest the existence of giant planets orbiting the binary (see e.g., Beuermann et al. 2010; Nasiroglu et al. 2017). There are two possibilities to explain the presence of these hypothetical planets. They might have formed together with the binary and then survived the common envelope phase (first-generation planet formation), or they could have formed from the common envelope material (second-generation planet formation). A hybrid scenario may be also possible, with accretion of the ejected gas onto already existing planets. Several studies have been carried out on this matter and some authors favor one scenario over the other (see e.g., Völschow et al. 2014; Schleicher & Dreizler 2014; Bear & Soker 2014; Schleicher et al. 2015). In any case, these scenarios must take into account that ~90% of the PCEBs, as found by Zorotovic & Schreiber (2013), have observed apparent period variations, implying that the hypothetical planets are very good at surviving the PCEB formation process and/or the common envelope material is very efficient in forming planets.

Another possible explanation that does not invoke the presence of planets is the so-called Applegate mechanism (Applegate 1992). In this scenario, the magnetic activity of the M dwarf redistributes the angular momentum within the star, thus changing its gravitational quadrupole moment (i.e., the shape of the star). This in turn produces a variation on the binary separation which translates into variations of the O-C diagram. The original Applegate model has been improved by several authors. For instance, Lanza & Rodonò (1999) improved the model by adopting a consistent description for stellar virial equilibrium (Chandrasekhar 1961), while Brinkworth et al. (2006) extended the model by introducing a finite shell formalism, considering the exchange of the angular momentum between the shell and the core. This model was further examined and systematically applied by Völschow et al. (2016) to a sample of 16 close binary systems, involving predominantly PCEBs, showing that the Applegate mechanism is a viable process in the shortest and most massive binary systems.

As they discuss, many of the PCEBs indeed show signs of magnetic activity. For instance in the case of V471 Tau, magnetic activity was inferred via photometric variability, flaring events and H $\alpha$  emission along with a strong X-ray signal (Kamiński et al. 2007; Pandey & Singh 2008). In case of DP Leo, magnetic activity was shown through X-ray observations (Schwope et al. 2002), while for QS Vir, it has been inferred via detections of Ca II emission and Doppler imaging (Ribeiro et al. 2010) and observed coronal emission (Matranga et al. 2012). In the case of HR 1099, a 40 year X-ray light curve suggesting a long-term cycle was recently compiled by Perdelwitz et al. (2017), and similar studies have been pursued via optical data (e.g., Donati et al. 2003; Lanza 2006; Berdyugina & Henry 2007; Muneer et al. 2010). It is also worth mentioning that in case of V471 Tau, the possibility of a third body has been ruled out via direct imaging observations (Hardy et al. 2015).

In this paper, our goal is to further assess whether magnetic activity is a feasible alternative to the presence of a third body, at least in some of the systems. In particular, we note that in the context of isolated stars, characteristic relations have been inferred between the activity cycle and the rotation period (Saar & Brandenburg 1999; Böhm-Vitense 2007), which can be interpreted in terms of simple dynamo models, as put forward by Soon et al. (1993) and Baliunas et al. (1996). In this study we have employed these models to estimate the expected duration of the activity cycle for a sample of PCEBs, and compared it to the observed modulation periods. In addition, we re-assess the feasibility of the Applegate mechanism using the model of Völschow et al. (2016), using improved stellar structure parameters for the individual systems.

The structure of this paper is as follows: In Section 2, we describe the stellar structure calculations to derive the stellar profiles, our dynamo model as well as the system of equations required to assess the feasibility of the Applegate mechanism. Our results are presented in Section 3, and a comparison with selected systems is given in Section 4. The final discussion and conclusions are presented in Section 5.

## 2. Simulations and calculations

In the following, we describe the MESA star calculations as well as the analytical framework employed in this paper.

### 2.1. MESA star calculations

We used the Modules for Experiments in Stellar Astrophysics (MESA; Paxton et al. 2011) code<sup>1</sup> to simulate the secondary star for every system under consideration. In particular we used the module MESA star, which is a one-dimensional stellar evolution code to evolve a single star. Within this code, we focused on three main input parameters of interest for our simulation, which are:

1. Stellar mass: Conserved during the simulation and equal to the mass of the convective star in each system.
2. Rotation: Set as the fraction  $\Omega_{\text{ZAMS}}/\Omega_{\text{crit}}$ , where  $\Omega_{\text{crit}} = \sqrt{GM/R^3}$  is the critical angular velocity, above this limit the star breaks up.  $\Omega_{\text{ZAMS}}$  is the angular velocity of the star at the zero age main sequence (ZAMS). We chose to evolve the stars at a fixed  $\Omega_{\text{ZAMS}}/\Omega_{\text{crit}}$  during all the simulation. Hereafter we drop the ZAMS subscript

3. Maximum age. We stopped the simulation when the star reaches the derived system age or radius.

We used this last profile, at its maximum age, for our calculations. For stars with masses lower than  $0.14 M_{\odot}$  the very low mass test-suite available in MESA was used as a guide to properly evolve these systems. For every run we chose the 'ML1' mixing length implementation with the free parameter  $\alpha_{\text{MLT}} = 1.5$  and the basic reaction network. The calculations were pursued assuming solar metallicity. We note that Völschow et al. (2016) shows that the resulting stellar profiles are rather insensitive to the precise value of the age or metallicity in the case of low-mass stars.

### 2.2. Analytical dynamo models

The MESA models are used as input for the stellar structure to explore the expectations based on simple dynamo models. We employed here a similar approach to that of Schleicher & Menickent (2017) and Perdelwitz et al. (2017), using the relation between the period of the cycle and the period of rotation (Soon et al. 1993; Baliunas et al. 1996)

$$P_{\text{cycle}} = D^{\gamma} P_{\text{rot}}, \quad (1)$$

with  $P_{\text{cycle}}$  the activity cycle of the star,  $D$  the dynamo number, and  $P_{\text{rot}}$  the rotation period of the star. As the PCEBs are close binaries, we were able to assume the secondary star is tidally locked (Zahn 1989; Zahn & Bouchet 1989), making  $P_{\text{rot}}$  equal to the binary period.  $\gamma$  is a parameter that depends on the level of activity of the star (Dubé & Charbonneau 2013).  $D$  is further related to the Rossby number  $Ro$  via  $D = Ro^{-2}$ , where  $Ro = P_{\text{rot}}/\tau_c$  is the ratio between the stellar rotation period  $P_{\text{rot}}$ , and the convective turnover time,  $\tau_c$ . Following Soker (2000), we calculated  $Ro$  as

$$Ro = 9 \left( \frac{v_c}{10 \text{ km/s}} \right) \left( \frac{H_p}{40 R_{\odot}} \right)^{-1} \left( \frac{\omega}{0.1 \omega_{\text{Kep}}} \right)^{-1} \left( \frac{P_{\text{Kep}}}{\text{yr}} \right). \quad (2)$$

Here,  $v_c$  and  $H_p$  are the convective velocity and pressure scale height, respectively. Both are stellar properties given in the MESA output files.  $\omega$  is the angular velocity,  $\omega_{\text{Kep}}$  and  $P_{\text{Kep}}$  are the Keplerian angular velocity and orbital period, respectively. These last three values are obtained from the binary parameters.

As described by Perdelwitz et al. (2017), we first simulated a Sun-like star to obtain  $\gamma$  in (1) taking into consideration that the tachocline at  $r = 0.7 R_{\odot}$  is where the dynamo is expected to give rise to a strong toroidal magnetic field with a cycle of 22 years. From this calibration, we obtained a reference value of  $\gamma = 0.86$ . However, the Sun has a rather slow rotation rate, with a period of about 24.5 days at the equator, and a relatively weak magnetic field of about  $\sim 1$  G. Even single M-dwarfs, on the other hand, have rotation periods of less than ten days (Somers et al. 2017), and in PCEBs rotation periods of less than three hours, with field strengths on the order of a few kG (Johns-Krull & Valenti 1996). As a result, the actual value of  $\gamma$  may be different, and we thus also explored  $\gamma = 0.7$  and  $\gamma = 1.0$  in Table 1. For a given value of  $\gamma$ , it is then possible to calculate the fraction of the stellar radius  $R_d/R$  where the predicted activity period is equal to the observed one.

### 2.3. The Applegate mechanism

Given an idea of the radius where the dynamo operates inside the star, it is now also important to find out whether it is energetically feasible to produce the observed eclipsing time variations

<sup>1</sup> Webpage MESA: <http://mesa.sourceforge.net/>

via magnetic activity. We employed the Applegate mechanism in the formulation presented by Völschow et al. (2016), which we recently implemented in the now publicly available Applegate calculator<sup>2</sup>. The latter in particular allows us to calculate the required energy  $\Delta E$  as a fraction of the available energy in the magnetically active star,  $E_{\text{sec}}$ , to drive the corresponding change of the quadrupole moment. The equation is given as

$$\frac{\Delta E}{E_{\text{sec}}} = k_1 \frac{M_{\text{sec}} R_{\text{sec}}^2}{P_{\text{bin}}^2 P_{\text{mod}} L_{\text{sec}}} \left( 1 \pm \sqrt{1 - k_2 G \frac{a_{\text{bin}}^2 M_{\text{sec}} P_{\text{bin}}^2 \Delta P}{R_{\text{sec}}^5 P_{\text{bin}}}} \right)^2, \quad (3)$$

where  $P_{\text{bin}}$ ,  $a_{\text{bin}}$ , and  $\Delta P/P_{\text{bin}}$  are the orbital period, semi-major axis, and observed relative change of the orbital period during one cycle of the binary, respectively;  $P_{\text{mod}}$  is the observed modulation period of the binary;  $M_{\text{sec}}$ ,  $R_{\text{sec}}$ ,  $L_{\text{sec}}$ ,  $T_{\text{sec}}$  are the mass, radius, luminosity, and temperature of the magnetically active star, respectively. The  $k_1$  and  $k_2$  parameters are defined as

$$k_1 = \frac{4\pi^2}{5} \frac{\lambda(\gamma+1)(\xi^3 - \xi^{-2})}{1 + \lambda(\xi^3 - 1)} \frac{(f - \gamma)^2}{(\gamma^2/\lambda + f)^2}, \quad (4)$$

$$k_2 = \frac{15}{36\pi^2} \frac{\xi^5}{\lambda} \frac{(\gamma/\lambda + f)}{(f - \gamma)^2}. \quad (5)$$

These parameters depend on the stellar structure. The first parameter regulates the overall magnitude of the required energy to drive quasi-periodic period variations, and the second affects the separation between low- and high-energy solution for the Applegate mechanism. Both  $k_1$  and  $k_2$  depend on two mean densities inside the star:  $\rho_{\text{in}}$  from the bottom to  $R_d$ , and  $\rho_{\text{out}}$  from  $R_d$  to  $R_{\text{star}}$ . The model assumes interchange of angular momentum between these two zones. The additional parameters  $\lambda$  and  $\xi$  are defined as  $\lambda = \rho_{\text{out}}/\rho_{\text{in}}$  and  $\xi = R_{\text{star}}/R_d$ .

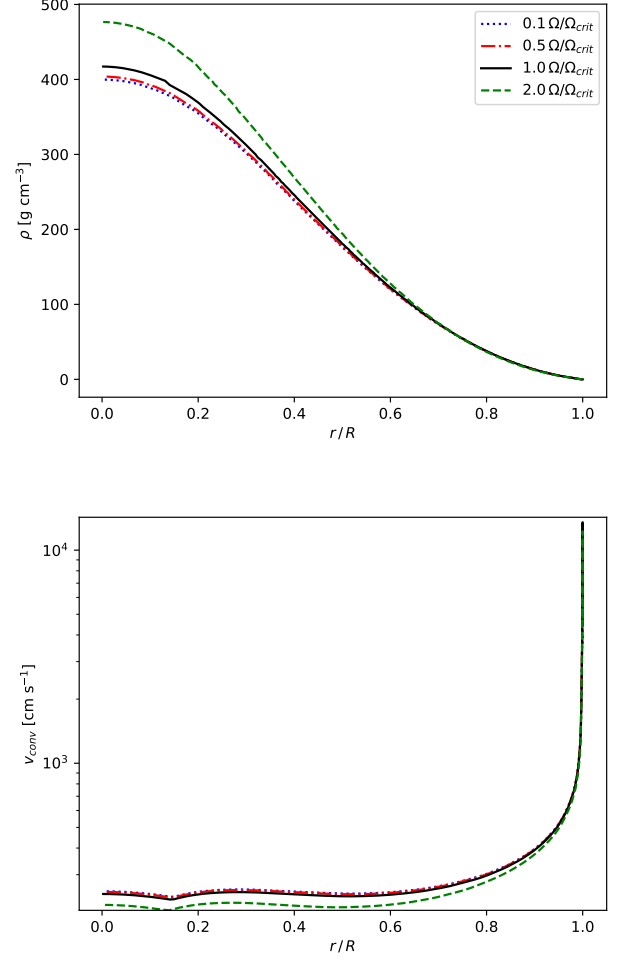

An important parameter here is  $R_{\text{core}}$ , the radius that separates the core and the shell between which angular momentum is exchanged. As a first approach, we assumed that it corresponds approximately to the scale where the dynamo model produces an activity cycle that corresponds to the observed period. We however also discuss other choices and explore their implications. We note that we explicitly evaluated here the parameters  $k_1$  and  $k_2$  based on the stellar profiles obtained from MESA. As also discussed by Lanza (2006), the angular velocity variations in the radiative core are confined to a thin layer, so its contribution to the changes on the quadrupole moment are negligible. We therefore have chosen to assume that the interchange of angular momentum is confined to the convective zone, thus neglecting any contribution of the radiative cores found in the secondaries of QS Vir and V471 Tau. The latter was taken into account when calculating the mean density in the core and thus in the resulting stellar structure parameters.

### 3. Results

In the following, we present the results from our stellar structure calculations, focusing initially on the resulting timescales for the magnetic activity cycles, and subsequently assessing the implications for the feasibility of the Applegate mechanism.

#### 3.1. Stellar structure and dynamo timescales

As an example of our stellar structure calculations, Fig. 1 shows the convection velocity and density profile for DP Leo as simulated with MESA. As we are considering rather rapidly rotating

**Fig. 1.** Density profile (top) and convection velocity profile (bottom) for DP Leo simulated by MESA for different rotation velocities. The ratio  $1.0 \Omega/\Omega_{\text{crit}}$  corresponds to the observed one and is  $\sim 0.288$  for DP Leo.

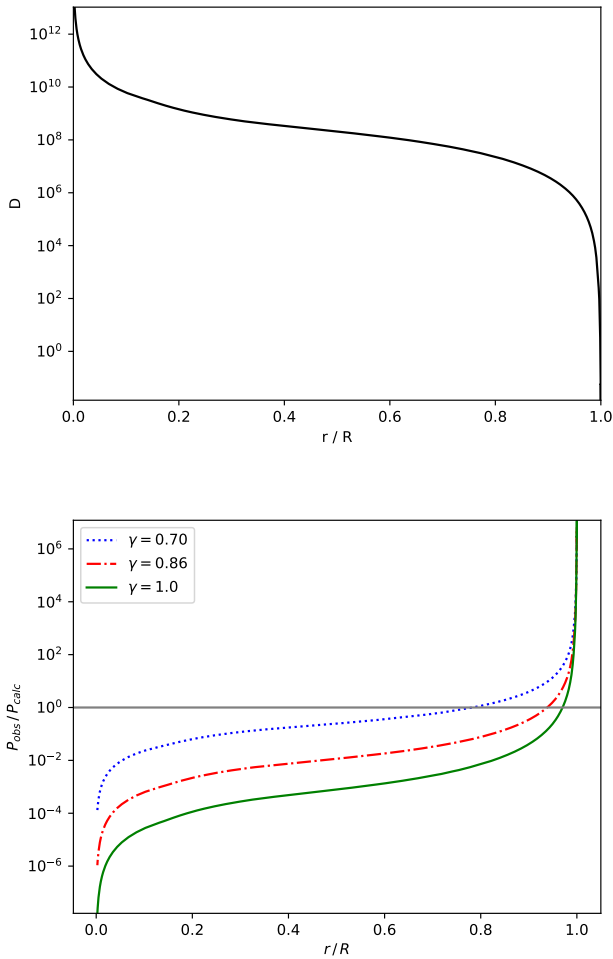

stellar systems as a result of tidal locking, we have explored the impact of varying the rotational velocity of the star, which is illustrated in Fig. 1, but find overall still moderate effects, with density changes of at most 20% even in strong rotation scenarios.

Figure 2 shows the dynamo number  $D$  calculated as a function of radius for DP Leo based on eq. (2). With  $\gamma = 0.86$  and  $P_{\text{rot}} = P_{\text{binary}}$  we then calculated  $P_{\text{cycle}}$  using Eq. (1) and the resulting dynamo number  $D$ . Figure 2 also shows the normalized period as a function of the radius. The horizontal gray line corresponds to a ratio of one, and the intersection thus marks the point where the calculated activity period equals the observed modulation period. This intersection point provides a first estimate for the effective radius that produces the observed modulation period.

We have pursued the corresponding analysis for the 12 PCEB systems provided in the sample by Völschow et al. (2016), and summarize the obtained results together with the main parameters of the secondary in table 1. In particular, we provide the calculated ratios  $R_d/R$  for  $\gamma = 0.7, 0.86$  and  $1.0$ . We generally find a reduced ratio of  $R_d/R$  for a lower value of  $\gamma$ . Specifically, for  $\gamma = 0.7$ , the ratios range between 0.6 and 0.88, for  $\gamma = 0.86$  they range between 0.78 and 0.97, and for  $\gamma = 1.0$  the ratios range between 0.87 and 0.98. While the correct value of  $\gamma$  is not clear, we

<sup>2</sup> Applegate calculator:

<http://theory-starformation-group.cl/applegate/>

**Fig. 2.** Dynamo number profile (top) and ratio of the observed vs. calculated activity cycle (bottom) for DP Leo calculated using Eq. 1.

nevertheless note the general trend that the dynamo appears to be driven within the outer parts of the star, corresponding to ratio of at least 60% of the stellar radius. Only in case of V471 Tau, we have to note that the observed activity cycle cannot be reproduced for  $\gamma = 0.7$  or less, providing a stronger constraint on dynamo models for that system.

### 3.2. Feasibility of the Applegate mechanism

We now assess whether the Applegate mechanism in these systems is capable of driving the observed eclipsing time variations. For this purpose, the ratio of required to available energy is calculated using Eq. 3. The results of the calculation are summarized in Table 2 for different scenarios. We note that our calculations from Table 2 are different from those reported in Völschow et al. (2016) two-zone model (their Table 4). While they determined the core radius based on radial density profiles obtained with Evolve ZAMS<sup>3</sup> that were rescaled to the stellar radius, we have employed here the radial profiles obtained via MESA star. More importantly, we varied the position that is considered as the separation point between the core and the shell, and we also explore the effect of choosing this position according to the

radius where the modulation period is reproduced by our dynamo model. The Völschow et al. (2016) results are reobtained at  $r/R \sim 0.88$ . To give an idea of the uncertainties in the energetics, we provide error bars on  $\Delta E/E$  in case of RX J2130.6+4710 in Table 2, which are evaluated adopting the upper and lower limits for secondary mass and radius, respectively. The latter shows that the values of  $\Delta E/E$  should be taken as indicative, but come with uncertainties of about a factor of two. A more accurate determination of stellar parameters would certainly help to reduce these errors, though we caution the reader that intrinsic uncertainties are also present within the two-zone approximation of the model, and further theoretical development will be necessary as well. Particularly in the case of RX J2130.6+4710, we note that  $\Delta E/E$  may still be less than one if the error are taken into account.

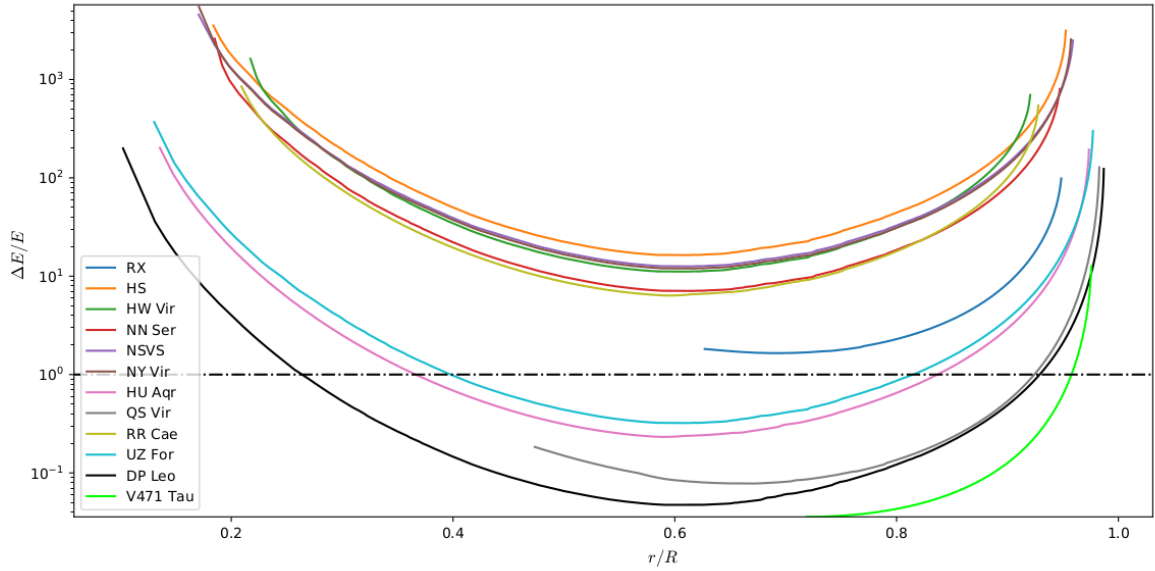

If we first focus on our reference case with  $\gamma = 0.86$  and adopt the radius  $R_d$  as the radius that separates the shell from the core, we find that in three systems, QS Vir, DP Leo and V471 Tau, the Applegate mechanism is energetically feasible, in two of them (QS Vir and DP Leo) though only marginally so. The system RX J2130.6+4710 in principle yields values  $\Delta E/E > 1$ . Considering the error bars, it may however be consistent still with the scenarios where Applegate is marginally feasible. We also note that, in case of RX J2130.6+4710, there is only a lower limit available for the modulation period, translating into an upper limit on  $\Delta E/E$ . As we noted above, it is not clear that the normalization to  $\gamma = 0.86$  is appropriate for these type of systems, or if even a constant value of  $\gamma$  is justified, given the different types of secondary stars in the sample. We thus explore how the energetic feasibility of our results depends on the adopted ratio of  $R_{\text{core}}/R$ , exploring ratios of 0.85, 0.75 and 0.65, which lie within the plausible range determined in the previous subsection. We find in particular that the required energy at least initially decreases when adopting a larger shell, only for some systems it starts increasing again at  $R_{\text{core}}/R = 0.65$ . Exploring the results in this parameter space, we then find that in five systems, HU Aqr, QS Vir, UZ For, DP Leo and V471 Tau, the Applegate mechanism is potentially feasible, with ratios  $\Delta E/E$  ranging from 0.036 to 0.98.

To illustrate this further, we plot  $\Delta E/E$  as a function of  $r/R$  in Fig. 3. The curves end when there is no longer a physically meaningful solution, that is, when the required change in the angular momentum is no longer consistent with angular momentum conservation within the star. For all systems, we see that the required energy fraction follows an approximately parabolic shape with a minimum near  $R_{\text{core}}/R \sim 0.6$ . While all curves are of similar shape and share the same asymptotic behavior, the magnitude or normalization varies significantly, and the systems can be roughly divided into two groups. In particular, there is a first group of six systems with the minimum  $\Delta E/E \sim 60 - 300$ , where thus the Applegate mechanism is clearly not feasible, and another group consisting of the systems identified above, with minimum  $\Delta E/E \sim 0.03 - 0.9$ , where the mechanism becomes feasible. While the gap between these groups appears striking within the figure and corresponds to roughly two orders of magnitudes in  $\Delta E/E$ , we cannot entirely exclude in full that the later is due to the relatively small number of systems in our sample. While the system RX J2130.6+4710 appears to lie somewhat in between the gap, though towards the lower end, it is important to note that the values of  $\Delta E/E$  here represent only an upper limit, and better constraints on the modulation period will be necessary to evaluate whether the systems lies within the gap, or if it is part of the lower group. Now, within the error bars, the system

**Fig. 3.**  $\Delta E/E$  calculated for varying radii for all systems. Two groups can be identified, those that fell below  $\Delta E/E = 1$  and those above it. At the borders the solutions for the Applegate energy become imaginary (see Völschow et al. 2016, for a discussion on this).

is now already consistent with potentially driving the Applegate mechanism.

In order to determine if there is a physical origin of the bimodality that is indicated in the plot, we examined whether the minimum value of  $\Delta E/E$  depends critically on relevant physical parameters of the system. To do so, we introduced the parameters

$$\alpha = k_1 \frac{M_{\text{sec}} R_{\text{sec}}^2}{P_{\text{bin}}^2 P_{\text{mod}} L_{\text{sec}}} \quad (6)$$

and

$$\beta = k_2 G \frac{a_{\text{bin}}^2 M_{\text{sec}} P_{\text{bin}}^2}{R_{\text{sec}}^5} \frac{\Delta P}{P_{\text{bin}}}, \quad (7)$$

from our Eq. 3. In Fig. 4, we plot  $\Delta E/E$  as a function of both parameters. While  $\Delta E/E$  shows no correlation with  $\alpha$ , it is clearly recognizable that the lowest values of  $\Delta E/E$  can be found for the lowest values of  $\beta$  with a clear trend, with the remaining scatter

being introduced by the dependence on  $\alpha$ . The latter provides a first indication that the parameter  $\beta$  is most relevant in determining the feasibility of the Applegate mechanism.

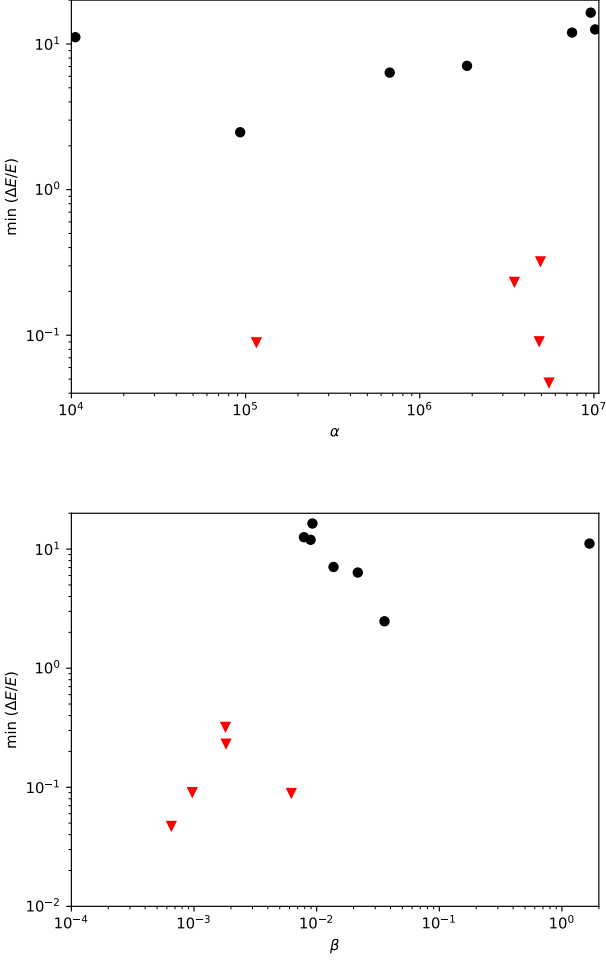

While the parameter  $\alpha$  shows no correlation with  $\Delta E/E$ , we show in Fig. 5 that the minimum value of  $\Delta E/E$  clearly depends on the parameter  $\beta$ , with the remaining scatter being due to the dependence on  $\alpha$ . In the following, we also consider the ratio of binary period vs critical period of the secondary star, where the critical period is defined through the breakup velocity when the star reaches Keplerian rotation, i.e.,

$$P_{\text{crit}}^2 = 4\pi^2 \frac{R_{\text{star}}^3}{GM_{\text{star}}}, \quad (8)$$

thus

$$\left( \frac{P_{\text{binary}}}{P_{\text{critic}}} \right)^2 = \frac{M_{\text{sec}}}{M_{\text{total}}} \left( \frac{a_{\text{bin}}}{R_{\text{sec}}} \right)^3. \quad (9)$$

Under the assumption of tidal locking, which is highly plausible within these systems, this ratio thus describes the ratio of ac-

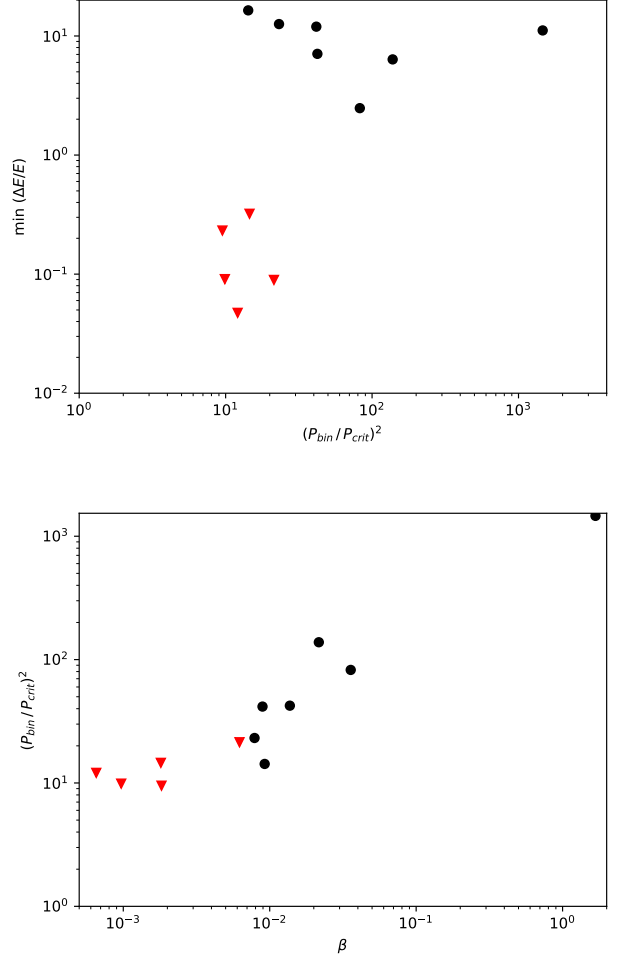

**Fig. 4.** *Top:* Minimum value of  $\Delta E/E$  as a function of the parameter  $\alpha$  defined in Eq. 6. *Bottom:* Minimum value of  $\Delta E/E$  as a function of  $\beta$  defined in Eq. 7. Red triangles represent the systems falling below the horizontal dashed line at Fig. 3.

tual over critical rotation period of the secondary star. We show in Fig. 5 how minimum  $\Delta E/E$  depends on this quantity. In this case, the correlation is less clear as the correlation with  $\beta$ , but it is nevertheless visible that low ratios of  $\Delta E/E$  occur only for low ratios of  $P_{\text{binary}}/P_{\text{critic}}$ , thus implying that high rotation rates (relative to breakup) are beneficial to drive the Applegate mechanism. In the same figure, we also explore whether the parameter  $\beta$  is correlated with  $P_{\text{binary}}/P_{\text{critic}}$ , and also here we find that low values of  $P_{\text{binary}}/P_{\text{critic}}$  imply low values of  $\beta$ , and vice versa. The latter strengthens our conclusion that rapid rotation may play a central role in the feasibility of the Applegate mechanism in PCEB systems.

In fact, one can show that

$$\beta = k_2 \frac{4\pi^2 a_{\text{bin}}^2}{R_{\text{sec}}^2} \frac{P_{\text{bin}}^2}{P_{\text{critic}}^2} \frac{\Delta P}{P_{\text{bin}}}, \quad (10)$$

suggesting a quadratic dependence on the ratio of rotation period over critical period. We further note here that rapid rotation may frequently imply a short binary period and thus also a lower value of  $a_{\text{bin}}$ , which strengthens this correlation further. The remaining parameter  $R_{\text{sec}}$  depends primarily on the mass of the secondary star, which is very similar in many of the PCEB

**Fig. 5.** *Top:* Minimum value of  $\Delta E/E$  against the squared fraction between the binary period  $P_{\text{bin}}$  and the critical period  $P_{\text{crit}}$  defined as the period the binary would have if the secondary is rotating at its critical rotation velocity under the assumption of tidal lockment. *Bottom:*  $(P_{\text{bin}}/P_{\text{crit}})^2$  plotted against  $\beta$  defined in Eq. 7; the rightmost circle corresponds to HW Vir. Red triangles are the systems falling below the horizontal dashed line at Fig. 3.

systems (see Table 1), and only occasionally introduces scatter when the secondary star is more massive. Equation 10 can be rewritten using Eq. 9, leading to

$$\beta = k_2 4\pi^2 \left( \frac{P_{\text{bin}}}{P_{\text{critic}}} \right)^{10/3} \left( \frac{M_{\text{total}}}{M_{\text{sec}}} \right)^{2/3} \frac{\Delta P}{P_{\text{bin}}}. \quad (11)$$

This last equation provides evidence of a stronger dependence on the ratio of the rotation period over critical period. It is then plausible overall that the main visible dependence is due to rotation.

## 4. Discussion of selected systems

### 4.1. HW Vir

Consisting of a primary of  $0.485 M_{\odot}$  and a secondary of  $0.142 M_{\odot}$ , this system was first proposed to have a two-planet system by Lee et al. (2009) that was later proven to be secularly unstable and replaced with another two-planet secularly-stable system by Beuermann et al. (2012b). We find rather high values

**Table 2.** Results for the energy required to drive the Applegate mechanism for all systems considered in this work.  $R_d/R$  denotes the core-shell transition radius.  $\Delta E/E_{\text{sec}}$  is the necessary energy to drive the change in the quadrupole moment to give raise to the observed period, as a fraction of the available energy, calculated considering different shells including the point at which the observed period matches the calculated, i.e.,  $R_d/R$ . Results with  $\Delta E/E_{\text{sec}} < 1$  are highlighted in bold. RX J2130.6+4710 is presented with errors, as mentioned in section 3.2

System	$\Delta E/E_{\text{sec}}$			
	$R_d/R = R_d/R(\gamma = 0.86)$	$R_d/R = 0.85$	$R_d/R = 0.75$	$R_d/R = 0.65$
RX J2130.6+4710	$4.2^{+2.3}_{-7.6}$	$3.6^{+1.8}_{-5.4}$	$1.8^{+0.96}_{-2.5}$	$1.7^{+0.93}_{-2.3}$
HS 0705+6700	1354	56	22	93
HW Vir	93	43	15	16
NN Ser	-	24	9.5	6.7

of  $\Delta E/E$  for this system (see Figure 3), and thus HW Vir might be a good candidate to test the planetary hypothesis using direct imaging.

#### 4.2. NN Ser

This system consists of a white dwarf with a M4 companion (Parsons et al. 2010). The planetary solutions that explain the eclipsing time variations were proven to be dynamically stable (Beuermann et al. 2013). This, together with the recent detection of dust around NN Ser by Hardy et al. (2016) that was not expelled from the common envelope phase, add credibility to the planetary hypothesis. On the other hand, the most recent data require the subtraction of a quadratic term from the ephemeris to obtain the planet solution (Bours et al. 2016). Based on the calculations in this paper, we find that it is energetically difficult to explain the observed eclipsing time variations based on the Applegate effect alone, as there are no solutions with  $\Delta E/E < 1$ . However, there are solutions with  $\Delta E/E \lesssim 10$ , suggesting that relevant fluctuations of the eclipsing time variations could be induced by the Applegate mechanism, even if it is not the entire signal.

#### 4.3. HU Aqr

HU Aquarii is a system of particular interest. First discovered by Schwöpe et al. (1993), it has a strongly magnetized primary white dwarf and a M4 secondary and it is constantly being monitored by several groups. Bours et al. (2014) concluded that a planetary model with up to three members cannot explain the observed ETVs as they are dynamically unstable over short periods of time. Goździewski et al. (2015) revisited the planetary hypothesis and concluded that it might be possible that a three-planet system is present. However, either one of these planets must have a retrograde orbit or they should have high mutual inclinations.

In our calculations, HU Aqr was found to indeed have solutions that might trigger the Applegate mechanism, with  $\Delta E/E \sim 0.3$ . Such solutions require the dynamo to operate further in the interior of the star. The ratio of  $\Delta E/E$  is reduced compared to the value reported by Völschow et al. (2016) due to the evaluation of the coefficients  $k_1$  and  $k_2$  from the stellar structure profiles.

#### 4.4. QS Vir

Horner et al. (2013) performed a detailed dynamical study of the proposed planets for QS Vir. The authors performed more than 180 thousand simulations of the proposed planetary systems but found that none of them with long enough stability to explain the eclipsing time variations. More recently, Parsons et al. (2016) used high-resolution spectroscopy to study the magnetic activity of this PCEB and found that the M dwarf is covered with a large number of star spots, thus indicating that it is a very active star.

We have found that the M dwarf on this system is among those with the highest relative rotation, where the Applegate mechanism appears to be feasible (see Table 1). The secondary dM star has a radiative core, which we assumed here not to contribute to the Applegate mechanism.

#### 4.5. V471 Tau

It was predicted by Beavers et al. (1986) that a third body with a period of  $\sim 25$  years could exist in this system. Recently, Hardy et al. (2015) used direct imaging to test the hypothesis, resulting in a nondetection of the proposed brown dwarf. Later, Vaccaro et al. (2015) analyzed the system and proposed several ways for the third body to have avoided detection. However, Vanderbosch et al. (2017) studied the eclipsing time variations with two independent clocks, namely the orbital period of the binary and white dwarf spin period. They do not find the same magnitude of variation of the O-C of the spin period as for the diagram based on the binary period. The latter thus favors the Applegate mechanism as opposed to the presence of a third body.

As the secondary of V471 Tau is a Sun-like star with a mass of  $\sim 0.93 M_{\odot}$ , it is expected to have an  $\alpha\Omega$  dynamo operating on the radiative-convective interphase. As this star is rotating much faster than the Sun, one may expect that a strong magnetic field due to rapid rotation may trigger the Applegate mechanism, consistent with our findings.

#### 4.6. NSVS 14256825

For the system NSVS 14256825, the cyclic behavior of the O-C residuals was previously attributed to the presence of one or two Jupiter-like planets (Beuermann et al. 2012a; Almeida et al. 2013; Wittenmyer et al. 2013), new data by Nasiroglu et al.

(2017) revealed a systematic, quasi-sinusoidal variation deviating from the older ephemeris by about 100 s. As the most plausible explanation for this deviation, they propose a one-companion model to be the most reliable explanation and propose that the Applegate mechanism is not energetically feasible to drive the changes. We note here that while there are no solutions with  $\Delta E/E < 1$  that could explain the eclipsing time variations entirely, there are solutions with  $\Delta E/E \sim 10$ , implying that magnetic activity could at least induce relevant scatter in the observed variations.

#### 4.7. RX J2130.6+4710

This PCEB consists of a red dwarf with a mass of  $0.555 M_{\odot}$  and radius  $0.534 R_{\odot}$ , and a white dwarf of mass  $0.554 M_{\odot}$  and radius  $0.0137 R_{\odot}$  with a separation of 2–3  $R_{\odot}$  (Maxted et al. 2004). The large O-C variations from a relatively long observational baseline were detected by Bours et al. (2016). They identified this system to have a lower limit for the period of the mechanism at work to be 30 yr and we adopted this limit for our calculation together with an eclipsing time variation of  $\sim 250$  s. This translates into  $\Delta P/P = 1.6 \times 10^{-6}$ . Considering the error bars, the system may be able to drive the Applegate mechanism. In addition, if the modulation period is greater, say 50 yr, then  $\Delta P/P \sim 9 \times 10^{-7}$  and the system will clearly fall below the line  $\Delta E/E = 1$ . As noted by Bours et al. (2016), the observational baseline is yet too small to draw a more robust conclusion for this system and further eclipsing observations will be crucial.

## 5. Conclusions

In this paper we have explored whether the Applegate mechanism can drive the observed eclipsing time variations in a sample of 12 PCEB systems. For this purpose, we have obtained radial profiles of the secondaries using the MESA code (Paxton et al. 2011), and applied simple dynamo models following Soon et al. (1993) and Baliunas et al. (1996) to determine the radius at which the expected activity cycle matches the observed modulation period. This radius was found to depend on the power-exponent  $\gamma$ , but even for different choices of  $\gamma$ , we found that the dynamo can generally be expected to be driven in the outer layers, at radii  $R_d/R \gtrsim 0.6$ .

We subsequently explored whether the Applegate mechanism to drive the eclipsing time variations is also energetically feasible, employing the framework presented by Völschow et al. (2016), which is now publicly available through the Applegate calculator<sup>4</sup>. Based on this analysis, we show that the Applegate mechanism may be energetically feasible in up to five systems, HU Aqr, QS Vir, UZ For, DP Leo and V471 Tau. Plotting the required energy  $\Delta E/E$  as a function of the assumed radius of the core, we also find that the latter yields a characteristic shape for all systems explored here, with a minimum at a core radius  $R_{\text{core}}/R \sim 0.6$ . The normalization of the curves depends however on the system, which appears to be separated into two groups, those with  $\Delta E/E \sim 0.03$ – $0.9$  where the Applegate mechanism is clearly feasible, and another group with  $\Delta E/E \sim 60$ – $300 \gg 1$ . Our current sample shows a gap in between these groups of about two orders of magnitude in  $\Delta E/E$ . It does, however, remain to be explored whether the gap is of physical origin. In the case of RX J2130.6+4710, whether or not it is part of the lower group, with  $\Delta E/E < 1$ , or if it indeed lies within the gap needs

to be further explored. Such a determination is currently not possible, as there is only a lower limit on its modulation period, and observations over a longer baseline will be necessary to test this possibility.

We explored further what determines if the Applegate mechanism is feasible in a particular system, focusing on the parameters  $\alpha$  and  $\beta$  in our Applegate framework. While the first parameter appears uncorrelated to the minimum  $\Delta E/E$ ,  $\beta$  shows a clear correlation for our sample. We also show that this correlation appears related to the strength of rotation in the system, particularly the ratio of the rotation period of the secondary star (which is equal to the binary period in the case of tidal locking) over the critical breakup period of the secondary. In particular, we emphasize that all systems with low minimum values of  $\Delta E/E$  have low ratios of  $P_{\text{bin}}/P_{\text{critic}}$ . The latter suggests that rotation plays a relevant role in determining the feasibility of the Applegate mechanism. The effect that rapid rotation plays on the magnetic field of M dwarfs is explored by Morgan et al. (2012) using WD+dM binaries and comparing the activity level and strength to field dM. The authors find that dM have a higher activity fraction in the range of spectral types M0 to M7, when they are in a close binary and it was attributed to the increment of stellar rotation in the paired dMs. In the same study, it was also found that the activity is increased in WD+dM across all spectral types when compared to the unpaired dM. This strengthens our main conclusion, namely higher rotation relative to critical rotation supports the Applegate mechanism PCEBs.

We also note that there may be other mechanisms that can change the quadrupole moment of a star. A minor effect could be related to the side of the M dwarf facing the white dwarf, which will be more deformed than the other side, and this effect is expected to depend on the binary separation. The magnetic fields from the white dwarfs in the systems considered here have been neglected so far, but it is also straightforward to show that their expected contributions would be smaller than typical surface fields from M dwarfs required to drive the Applegate mechanism (see Applegate 1992). A generic remark that is important to make is that several of the systems examined here cannot be explained under the Applegate hypothesis (at least with the two-zone model adopted here), and it remains to be explored if another mechanism is operating in them, or if the latter hints at a more fundamental problem in our current understanding.

To make further progress on this topic, we encourage direct imaging attempts as pursued by Hardy et al. (2015), particularly for cases where the presence of planets appears plausible. In addition, other methods like radial velocity measurements can be employed to determine independent constraints on the potential motion of the secondary star (Oshagh et al. 2017). The precise photometry obtained via the Gaia satellite<sup>5</sup> may further be valuable to determine if motions of the center of mass of the systems can be confirmed in the plane of the sky. Such independent constraints or measurements will be extremely valuable to confirm or rule out the existence of planets.

At the same time, it will be important to probe the presence of magnetic activity and in particular the duration of the magnetic cycle, as recently pursued for instance by Perdelwitz et al. (2017). The latter is critical to understanding if the observed modulation period is consistent with the activity cycle of the secondary star, and provides an independently relevant test to probe the physics of the eclipsing time variations. We also note here that stellar magnetism and the presence of planets are not necessarily mutually exclusive alternatives, but may simulta-

<sup>4</sup> Applegate calculator:  
<http://theory-starformation-group.cl/applegate/>

<sup>5</sup> Webpage Gaia: <http://sci.esa.int/gaia/>

neously occur. In particular, we have identified several systems here where we expected that magnetic activity may not explain the observed eclipsing time variations, but include relevant scatter in the observed eclipsing times, due to values of  $\Delta E/E \sim 10$ , corresponding to fluctuations on the 10% level. The presence of such fluctuations may potentially also explain that in some cases, the subtraction of approximately quadratic terms is needed, as noted recently by Bours et al. (2016) in the case of NN Ser. They also presented eclipsing times for a set of 67 close binaries. Besides the PCEBs from Völschow et al. (2016) we have included RX J2130.6+4710. This is because this is the only new system with a long enough observational baseline to constrain the modulation period, namely at least 30 yr, and with large O-C variations. Extending the baselines will be important to extend the analysis presented in this paper.

We expect additional theoretical work to be necessary in the future, as the Applegate model employed here (Völschow et al. 2016), while being a significant improvement compared to the first version laid out by Applegate (1992), is still based on a two-zone approximation. While some suggestions for generalizations exist (e.g., Lanza 2005, 2006), the models require further exploration before applying them systematically to a larger sample of systems, and need to be linked more strongly to the dynamo itself. We expect this to be a promising area for further developments.
