Abstract—Student engagement localization can play a key role in designing successful e-learning systems. Facial expressions of an individual in response to stimuli videos provide important cues in estimating variations in engagement level. In this paper we study the association of a subject’s facial expressions with his/her engagement level, as annotated by labelers. We then localize engaging/non-engaging parts in the stimuli videos using a deep multiple instance learning based framework, which can give useful insight into designing Massive Open Online Courses (MOOCs) video material. Recognizing the lack of any publicly available dataset in the domain of user engagement, a new ‘in the wild’ database is created to study subject engagement. The dataset contains 725,000 frames (about 9 hours of recording), 102 videos captured from 75 subjects. The problem of engagement prediction is modeled as a weak label learning problem. The dataset is manually annotated by labelers for four levels of engagement and the predicted labels of videos are correlated with the manual labels. This dataset creation is an effort to facilitate research in various e-learning environments such as intelligent tutoring systems, MOOCs and others.

I. INTRODUCTION

The paper proposes an automatic pipeline for predicting user’s engagement, while they are watching educational videos such as the ones in Massive Open Online Courses (MOOCs). A new ‘in the wild’ video-based database (Figure 1) is also proposed. User engagement analysis is of importance to learning environments, which involves interaction between humans and machines. Generally, a course instructor is able to assess the engagement of students in a classroom environment based on their facial expression. However, this assessment becomes tricky, when students are watching study material such as videos, on their computers and mobile phones in different environments. These different environments can be their room, office, cafeteria or outside etc.

engagement is defined as a connection between a user and a resource, which comprises of emotional, cognitive and behavioral nature at any point in time [1]. Various examples of environments in which the engagement of user is an important key component are: e-learning, health sector such as conducting autism-related studies, analyzing driver engagement in automated cars and so on.

Surveys such as [2] [3] discuss the important work done in the field of affective computing. Based on the knowledge in affective computing, researchers have recently tried to predict user engagement. El Kaliouby et. al. [4] argue that user engagement prediction is a challenging problem and has many applications in autism-related studies. Furthermore, Tawari et. al. [5] found that a car driver’s affective state recognition in terms of the engagement level provides important cues in detecting drowsiness levels while driving. Navarathna et. al. [6] proposed an interesting pipeline for analyzing a movie’s affect by predicting viewer’s engagement in the movie. User engagement level recognition is inevitable in e-learning and is useful in detecting states such as fatigue, lack of interest and difficulty in understanding of the content.

Automatic engagement prediction can be based on various kinds of data modalities. It is argued that the student response can be used as an indicator of engagement in intelligent tutoring systems [7]. Another approach is based on features extracted on the basis of facial movements [8], [9]. Automated measures such as response time of a student to problems and test quizzes is used in ITS [10]. Physiological and neurological measures, requiring specialized sensors, such as electroencephalogram, heart rate and skin response have been used to measure engagement [11]–[13].

The vital aspect here is to study the pattern of user engagement across online video lectures. It can give various interesting insights such as- for how long users concentrate,
at which point in a lecture video the user loses interest etc. This is useful for successful delivery of educational content and deciding evaluation criteria for user engagement [1]. In the research community many datasets are released to study the problems such as object detection in an image and video [4], segmentation [15]. The number of datasets related to user engagement in the online learning environment released are very limited [16]–[18]. With the advent of deep learning frameworks, larger sized databases representing diverse settings are required.

The availability of datasets related to user engagement especially student engagement in online courses would help in understanding the problems faced by students such as- loss of interest, fatigue, boredom etc in online learning environment. A student engagement database is proposed in the report [19].

In this paper we introduce a database for common benchmarking and development of engagement assessment in diverse ‘in the wild’ conditions. ‘in the wild’ conditions here refer to different background, illumination and poses etc. Video level engagement prediction task is modeled as a weakly labeled learning problem. Multiple Instance Learning (MIL) is followed as the paradigm for this weakly supervised learning. MIL has been found extensively useful for tasks, in which the dataset has weak or noisy labels [20] and has been recently used in affect analysis tasks such as facial expression prediction [21] and image emotion prediction [22]. MIL assumes that the data could be presented with the help of a set of sub-instances or bag of sub-instances as \( \{X_i\} \), where each bag consists of sub-instances \( \{x_{ij}\} \) and the weak labels \( \{y_i\} \) are present at the bag level only [23].

Our work is based on Deep Multi-Instance Learning (DMIL) framework which makes use of complex features that can be learned by deep neural networks along with MIL technique for a weakly supervised problem. This technique has been successfully used in vision tasks like image/video classification, object detection [23], [24] medical image processing in the form of mammography for breast cancer detection [25] and molecular activities of drugs [26]. Sikka et. al. [27] studied pain localization in a video in a weakly supervised fashion using the MIL framework. Tax et. al. [21] proposed an MIL based framework to select the concept frames using clustering multi-instance learning.

The main contribution of this work is to formulate student engagement prediction and localization as an MIL problem and derive the baseline scores based on DMIL. The rationale behind MIL is that labeling of engagement at frequent intervals in user videos is expensive and noisy. The rest of the paper is organized as follows: In Section II we introduce the dataset and details about data collection and annotation. In Section III we discuss the methodology used for student engagement prediction and localization. In Section IV and V we describe the experimental setup and the results obtained respectively. Finally we conclude in Section VI.

II. DATA COLLECTION

In this section, we discuss the data recording paradigm in this study. The experiment contained two parts: i) Video recordings of the subjects, while they watched the stimuli videos (each video around 5 minutes long) and ii) A verbal feedback section, in which the subject was given 15 seconds to speak about the video. In those 15 seconds the subjects are asked to express their views about the video, especially if they found the video interesting?, would they like to watch the video again?, which part of the video was most/least engaging?, any comments/suggestions on how the video could have been made more engaging etc. Based on the content of the stimuli videos, we choose two purely educational videos Learn the Korean Language in 5 minutes and a pictorial video (Tips to learn faster). This was aimed to capture both focused and enjoyable settings which allow natural variations. In the experiment section, as a baseline, we had explored the video signal only.

The dataset has 75 subjects (25 females and 50 male participants) in total. The age range of the subjects is 19-27 years. A total of 102 videos are collected, each approximately 5 minutes long. The dataset is collected in unconstrained environment i.e. at different locations such as computer lab, hostel rooms, open ground, via Skype etc. In order to introduce the effect of different environments, we included a video conferencing based setup. In this, the subject, watched the stimuli on their computer (full) screen and in parallel a Skype-based video session was setup. We captured the video region of the Skype application at the other end of the Skype videocall. It was made sure that the subject was not disturbed by the Skype recording. The usefulness of recording over Skype is that network latency and frame drop can help in simulating different environments.

The videos are captured at a resolution of 640 x 480 pixels at 30 fps using a Microsoft Lifecam wide-angle F2.0 camera (excluding the Skype-based recordings). The audio signal is recorded using a wideband microphone, which is part of the camera. Apowersoft Screen Recorder software is used to capture the Skype videos.

The dataset and it’s accompanying baseline code will be made publically available to facilitate open research. The consent of the subjects has been taken following the due process. To the best of our knowledge, this would be one of the first publically available user engagement datasets being recorded in such diverse conditions.

A. Data Annotation

After video recording, the next step is to label the subject’s video for perceived engagement. A team of 5 annotators viewed and rated the videos for the engagement intensity. The labelers were instructed to label the videos on the basis of their engagement intensity (from facial expressions) ranging from 0 to 3. Audio for the videos was turned off during labeling. The engagement categories are inspired by the work of Whitehill et. al. [18]. The engagement intensity mapping is as follows: Engagement intensity 0 means that the subject is completely
Fig. 2: The proposed deep multi-instance network pipeline. First, LBP-TOP features are extracted from facial video segments. Second linear regression using DNN is employed and instance level responses are ranked. Finally, max and mean pooling are used to predict the subject engagement intensity for a given video.

Fig. 1: Example images for engagement labels. The dataset along with the annotations would be made publicly available for the research community.

III. ENGAGEMENT LOCALIZATION AND PREDICTION

The framework performs subject’s engagement detection and localization (in time). The steps of the pipeline are as follows: The face and facial landmark (eyes, chin, nose, mouth) positions [28] are localized in each frame. The video is then sub-sampled into small segments (instances) as discussed in detail in Section III-A. LBP-TOP features are extracted for a window of frames. The window then slides, next set of frames are extracted to compute LBP-TOP. This stage is discussed in Section III-B. The engagement prediction and localization are computed with the deep MIL network using mean and top-k pooling for regression. The details are discussed in Section III-C.

A. Pre-Processing

Let \( v = [f_1, f_2, f_3, \ldots, f_n] \) be a video clip of a subject in response to different stimuli, where \( f \) denotes a video frame and \( n \) are the total number of frames. The OpenFace library [28] is used to track the facial landmarks first in order to register the facial region, which is then cropped to a final resolution of 112 \times 112. The videos in the database are captured at 30 fps, the change in facial expression in consecutive frames can be minimal. In order to speed up the experiments, each video is therefore sampled at a frame rate of 6 fps such that \( v_s = [f_1, f_2, \ldots, f_k] \) represents the sampled video.

B. LBP-TOP Feature Extraction

We are interested in computing spatiotemporal features to capture the changes in the facial region. Local Binary Patterns from Three Orthogonal Planes (LBP-TOP) [29] is a standard spatiotemporal texture descriptor and is used in our work. The LBP-TOP descriptor concatenates the local binary patterns computed from three orthogonal planes: XY, XT and YT of a video sequence. In the experimental evaluation, LBP-TOP features were extracted in two ways:

1) Full video: The complete video \( v_s \) is considered and LBP-TOP features are extracted from it.
2) Shorter segment: A sliding window \( v_f = [f_1, f_2, \ldots, f_k] \) of \( k \) frames is taken at a time and LBP-TOP features are extracted. A smaller value of \( k \) would fail to efficiently approximate the entire expression while a larger value of \( k \) would yield results with poor frame-wise specificity. We therefore deem \( k = 20 \) (approx. 3 seconds in the sampled video) as the appropriate length of each window for expression recognition. After extracting features for the first \( k \) frames, the sliding window is moved by \( l \) frames. The value of \( l \) is empirically set to 10 (overlap of 50%) as it was found to provide adequate accuracy.

C. Deep Multi-Instance Network for Engagement Localization and Prediction

Leveraging the insights from the success of LBP-TOP features in approximating facial expressions efficiently, we design a deep multi-instance network for the task of user engagement level prediction and localization. Fig. 2 shows the proposed
network architecture with multiple dense regression layers, one ranking layer and one multi-instance loss layer. Pooling functions play an important role in MIL deep networks to fuse instance-level outputs. Two pooling schemes are employed for combining multiple instances, i) the top k-pooling based multi-instance learning taking only the largest ten elements (k = 10) from the ranking layer and ii) mean-pooling based multi-instance learning taking mean of all the elements. The details of these schemes are given later in the section.

In the MIL paradigm the training data is in the form of bags \( B = \{X_i, y_i\}_{i=1}^{N} \), where \( X_i = \{x_{ij}\}_{j=1}^{M} \), \( y_i \in Y \), \( M \), the number of instances in \( X_i \) and \( Y \) \in \{0,1,2,3\} are the labels for the bags. \( M \) is same across all the videos and is equal to 150. Such a problem is common in computer vision where it is easier to label the bag compared to individually labeling the instances. The goal of our work is to efficiently predict engagement intensity for the whole video and localize the most engaging/disengaging segments within a given stimuli video.

Given the segment-wise LBP-TOP features \( x_{ij} \), multiple dense regression layers and a ranking layer are designed to regress the output between values 0 and 3. Let \( r_{ij} \) of range \([0,3]\) denote the engagement intensities of instance \( x_{ij} \). Ranking layer of each bag is represented as \( R_i = \{r_{ij}\}_{j=1}^{M} \) corresponding to \( X_i = \{x_{ij}\}_{j=1}^{M} \).

1) Top-k Pooling based Multi-instance Learning: A general MIL framework for classification problems defines two kinds of bags, positive and negative. In MIL atleast one instance is positive then the bag is assigned a positive label \([26]\). This assumption holds good for binary classification problems like malignancy detection \([25]\), pain detection \([27]\) and image classification \([23]\) etc.

In our dataset, since the ground truth labels are given for the entire video spanning 5 minutes, we take the first \( k \) largest intensities of instances from the ranking layer, instead of adopting the general multi-instance learning assumption of considering the largest contributing instance. The hyper-parameter \( k \) has been chosen from the following set of values \( k \in \{1,5,10,20,30\} \) and is empirically set as 10. Let \( R'_i \) be the rankings of \( i^{th} \) bag in descending order such that \( R'_i = \{r_{ij}\}_{j=1}^{M} \). Finally average of highest \( k \) values of the ranking layer i.e. \( \frac{1}{k} \sum_{j=1}^{k} r_{ij} \) is taken as the predicted intensity score for \( i^{th} \) bag.

2) Mean Pooling based Multi-instance Learning: The engagement intensity fluctuates among various instances over the span of the video. We adopted another scheme of pooling in which the final predicted intensity for \( i^{th} \) bag is taken to be the mean of all the intensities from the ranking layer i.e. \( \frac{1}{M} \sum_{j=1}^{M} r_{ij} \).

IV. EXPERIMENTS

The details about the dataset which was used for experimentation can be found in Section \( \text{III} \). We followed 8-fold cross-validation for dataset split. The training and test sets are subject independent. In this section, we discuss the two approaches followed to predict the engagement level of individuals and result comparisons are shown in Section \( \text{V} \).

A. Baseline machine learning approaches

We have explored two approaches of extracting LBP-TOP features as explained in Section \( \text{III-B} \). In first approach, features for the entire video are extracted as a single vector \( x_{i} \) \( \in \mathbb{R}^{N} \), where \( x_{i} \in \mathbb{X} \) and \( y_{i} \in \mathbb{Y} \).

In second approach a temporal scanning window is taken and features are extracted for each window segment of the video. The training data is in the form of bags \( B = \{X_i, y_i\}_{i=1}^{N} \), where \( X_i = \{x_{ij}\}_{j=1}^{M} \), \( y_i \in \mathbb{Y} \) and \( M \) (number of instances) is equal to 150.

The segments obtained for each sequence are labeled using the following two approaches:

1) Noisy/Weak Labeling: All the segments in the training data are assigned the same label as that of their corresponding video sequence. This strategy is similar to that employed in previous works \([30][31]\).

2) Relabeling segments using Kmeans clustering: Initially, we assigned the labels to segments using the noisy labeling method. Now segments are divided into \( k \) clusters using the Kmeans clustering. The hyper-parameter \( k \) is selected from the following set of values \( k \in \{5,10,15,20,25,30,35,40\} \). Segments falling in a cluster are relabeled as follows:

i) All the segments in a cluster are relabeled by the mode of the labels in that cluster.

ii) All the segments in the cluster are relabeled by the mean of the labels in that cluster.

Finally, we tried two different techniques: Support Vector Regression (SVR) and Dynamic Neural Network (DNN). The average pooling rule is employed to assign a label to the entire video corresponding to the segment-wise predicted labels.

B. Deep Multi Instance Learning

The architecture for Deep MIL approach is shown in Fig. 2 Here a video sequence is first divided into 150 segments and LBP-TOP features are extracted from each segment. These features are then passed to a neural network with four dense layers, obtaining a single feature for each segment. To obtain a single label for the entire video, segment-wise features are then passed through a Deep MIL loss layer using two pooling schemes, namely Top-k and Mean as mentioned in Section \( \text{III-C} \).

In Top-k pooling, intensities of the top ten contributing instances are evaluated and their mean is finally assigned as the predicted intensity value for the video. In mean pooling, the average of intensities of all the instances of the video is assigned as the final intensity for the video.

We also evaluated two activation functions: 1) Rectified Linear Unit (ReLU): \( f(x) = \text{max}(0,x) \) is the most frequently used activation function as it allows gradient flow for all positive values. 2) Swish activation function: \( f(x) = x . \text{sigmoid} (\beta x) \), recently proposed by Ramachandran \text{et. al.} \([32]\). Here \( \beta \) is a trainable parameter. It is argued to be smoother and non-monotonic and was found to perform better than ReLU at certain instances.
V. RESULTS AND DISCUSSIONS

In this paper, we have advocated the efficacy of DMIL in handling multiple segments in a video compared to the baseline ML algorithms. Our results show a significant performance improvement using Deep MIL approach to affirm our proposition. Table I shows the mean squared error, Pearson’s correlation coefficient (PCC) and coefficient of determination/ R squared (R^2) for baseline ML approaches and gives a clear view of the different relabeling techniques discussed in Section IV-A. It is observed that Kmeans clustering performs better than noisy labeling.

Table II shows the performance of our network using mean squared error, Pearson’s correlation coefficient (PCC) and coefficient of determination/ R squared (R^2) as measures for regression. Our results show an improved performance using mean pooling scheme and swish activation function.

User Engagement Localization: Instance level engagement intensities \( R_i = \{r_{ij}\}_{j=1}^{M} \) corresponding to \( X_i = \{x_{ij}\}_{j=1}^{M} \) (see Section III-C) are extracted from the penultimate layer before MIL pooling. In Fig. 3 we show 4 cases (two from each stimuli video) to highlight the ability of our algorithm to localize engagement. The visualization compares the instance/segment-wise engagement intensity levels over the entire video for a sample subject. By analyzing the results obtained from the entire dataset, we can efficiently localize disengaging parts in a video (shown in red circles in Fig. 3) corresponding to dips in engagement level of individuals. Our experiments are likely to show promising results in applications where the goal is to foster student engagement e.g. in MOOCs and ITS.

VI. CONCLUSION

In automatic engagement, many of the current techniques used- like self-reports, teacher introspective evaluation are cumbersome and lack the ability to localize student engagement. In this paper, we have devised a multi-instance learning-based method to automatically predict the engagement level of a subject from their facial expressions and thereby localize...
the most/least engaging parts in the stimuli video. In prior literature, other modalities such as student response, audience movie rating, psychological and neurological sensor readings etc (see Section I) have been used for engagement prediction, however, our deep MIL based approach performs very strongly. Further, to the best of our knowledge this is the first attempt to localize student engagement over the course of a video. The proposed method can be extensively used in designing study material for MOOCs and ITS to substantially decrease the dropout rates.
