A Non-blocking Buddy System for Scalable Memory Allocation on Multi-core Machines

Abstract—Common implementations of core memory allocation components, like the Linux buddy system, handle concurrent allocation/release requests by synchronizing threads via spin-locks. This approach is not prone to scale with large thread counts, a problem that has been addressed in the literature by introducing layered allocation services or replicating the core allocators—the bottom most ones within the layered architecture. Both these solutions tend to reduce the pressure of actual concurrent accesses to each individual core allocator. In this article we explore an alternative approach to scalability of memory allocation/release, which can be still combined with those literature proposals. We present a fully non-blocking buddy-system, where threads performing concurrent allocations/releases do not undergo any spin-lock based synchronization. Our solution allows threads to proceed in parallel, and commit their allocations/releases unless a conflict is materialized while handling its metadata. Conflict detection relies on conventional atomic machine instructions in the Read-Modify-Write (RMW) class. Beyond improving scalability and performance, our solution can also avoid wasting clock cycles for spin-lock operations by threads that could in principle carry out their memory allocation/release in full concurrency. Thus, it is resilient to performance degradation—in face of concurrent accesses—independently of the current level of fragmentation of the handled memory blocks.

I. INTRODUCTION

In standard libraries or in an Operating System (OS), memory allocation is de-facto a shared-data management problem. In fact, allocators deal with the issue of managing memory buffers in face of requests that can be concurrently issued by multiple threads. This requires thread-coordination mechanisms in order to guarantee the coherence of the state of the memory allocator at any time.

A classical coordination approach, which is widely used in allocators, consists in using spin-locks. With this approach, the manipulation of shared data representing the state of the memory allocator is implemented as a critical section, hampering scalability. This is a relevant issue, since the level of concurrency is increasingly exacerbated because of the modern-hardware trend towards multi/many-core technologies.

The historical approach for reducing the impact of thread coordination (and the associated costs) on performance with concurrent memory allocations/releases is based on either:

(a) pre-reserving arenas, namely memory segments, for each individual thread—this is what typically happens in user-space allocators [1], [2]— or

(b) the usage of intermediate allocation services, called cached allocators—as for the case of OS-kernel allocation services based on quick-lists [3].

Both approaches aim to reduce the likelihood of inducing large volumes of concurrent accesses to the core allocator that is in charge of ultimately delivering memory, either logical or physical. As for point (a), this is achieved by resorting to the core allocator only when the thread’s own pre-reserved arena, which is not accessed by other threads, gets exhausted. As for point (b), cached allocation diminishes the pressure of concurrent accesses to the core allocator—e.g. a kernel-level buddy system—by having upper-level allocators destined to serve specific memory requests, such as those associated with a given size and/or memory alignment—this is the classical case of kernel-level page-table allocations or even SLAB allocations. In such a case, concurrent threads performing memory allocations require coordination only when they need to access the same cached allocator instance or when this allocator is exhausted and a new memory segment needs to be taken from the core allocator.

Concurrent allocation/release operations have also been tackled by creating data separation on the core allocator via multi-instance approaches, and redirecting the requests towards different instances. This further increases the likelihood of saving the requests from actual conflicts that may lead one or more of them to be delayed. For instance, this approach is used in OS-kernel physical memory management on large scale NUMA (Non-Uniform-Memory-Access) machines, where multiple disjoint instances of the buddy system are included, each one managing physical frames to be allocated from—or released to—different NUMA nodes.

Generally speaking, literature approaches make memory management be extremely layered: the upper the layer, the more it satisfies specific requests. In this context, we can define back-end and front-end allocators. The former, previously denoted as core allocators, handle the lowest level of memory management. The latter are built on top the back-end allocator with the goal of reducing the pressure of (concurrent) accesses to it and satisfying more specific purposes.

In this article we tackle the issue of scalability of back-end memory allocation, which is an orthogonal approach with respect to reducing the pressure to core allocators by designing front-end allocators, e.g., adopting (a), (b), or multiple-instance approaches. In particular, our contribution is the design of a non-blocking back-end allocator instance implementing the buddy-system specification, where concurrent allocations/releases are not coordinated via spin-locks.

In our approach, coordination and the guarantee of an
always-coherent state of the buddy system are achieved by
only relying on individual Read-Modify-Write (RMW) in-
structions executed along the critical path of allocation/release
operations. These instructions are exploited to detect whether
concurrent requests have conflicted on the same portion of the
allocator metadata. This may lead a few of them to be retried
as in the classical non-blocking algorithmic paradigm devised in [4]. However, if conflicts do not materialize, then our
proposal saves the latency that would be spent by lock-based
approaches, which temporarily block concurrent operations a-
priori of their execution.

Clearly, our non-blocking solution can be used in combina-
tion with any already existing scheme aimed at diminishing
the pressure of concurrent accesses to the back-end allocator,
e.g. by introducing multiple instances or combining it with
front-end allocators. This is because our unique goal is to
provide a memory allocation system that simply optimizes the
management of those concurrent accesses with respect to lock-
based approaches. On the other hand, having a more efficient
back-end allocator can allow to reduce the impact of, e.g., pre-
allocation on actual memory unavailability in scenarios where
there are skewed memory usages by different threads—so that
the pre-reserved memory for a given thread cannot be used for
serving a more memory-demanding one—or by different
cached allocators.

Our buddy-system implementation has been released as free
software and we also provide experimental data demonstrat-
ing the actual scalability of our proposal.

The remainder of this article is structured as follows. In
Section II we discuss related work. The non-blocking buddy
system is presented in Section III Experimental data are
provided in Section IV For space constraints the proof of
safety and progress of our non-blocking buddy system has
been removed from this submission. The reader can anyhow
refer to the report in [25], where we included the proof.

II. RELATED WORK

The seminal literature work providing the base-ground for
non-blocking coordination in the management of shared-data is [4]. This work has opened the path towards the design and
implementation of algorithms that can well fit the scalabil-
ity requirements imposed by modern (large-scale) multi-core
machines. Also, the avoidance of lock-based coordination in
such new algorithmic class has indirectly offered the opportu-
nity to develop coordination algorithms that are more suited
for CPU-stealing contexts such as Cloud-based computing.
In these contexts, the de-schedule of a lock-holding thread
because of CPU-steals can lead to detrimental performance
and waste of energy because of the stretch of the spin-locking
phase by other threads attempting to access the same critical
section. Along this direction, a lot of effort has been spent in
developing non-blocking versions of classical data structures
such as lists or queues [5], [6], hash-tables [7], registers [8], [9]
binary-search trees [10], [11] and priority queues [12], [13].

In any case, while many solutions have been devised in
order to reduce the negative impact of concurrency and syn-
chronization in memory allocation/deallocation by relying on
pre-reserving or caching, no one fully faces the problem of
concurrent accesses to back-end allocators. The work in [14]
provides non-blocking capabilities of memory allocations with
high probability, just depending on the pattern of memory
allocations/releases and overall memory usage. This solution
is in fact based on pre-reserving memory to be delivered to
specific threads (or CPU-cores), and resorts to lock-based
coordinating across the threads whenever the pre-reserved
memory is fully used by a thread and the global state of the
memory allocator needs to be changed in order to provide a
new pre-reserved area. Similar approaches where threads
operate on pre-partitioned heaps—hence on different memory-
allocator instances—have been presented in [15], [16], [17].
Similarly to the previous work, these proposal still does not ad-
dress the problem of avoiding blocking allocations/releases in
scenarios where a same allocator instance can be concurrently
accessed by multiple threads. This issue is partially alleviated
in [19], where a non-blocking stack data structure is used to
post memory across different threads within the pre-reserving
scheme.

The solution in [18] is suited for SIMD systems and
exploits worker threads operating in isolation (on different data
portions) in order to deliver memory to a pool of requesting
threads. The workers do not block each other thanks to pre-
partitioned accesses to the allocator data structures—they actu-
ally operate on different allocators. Hence this approach does
not provide a mechanism to perform non-blocking memory al-
location/release on a same shared instance of the allocator. On
the other hand, this solution looks to be a reasonably scalable
approach for devices such as GPUs where multiple threads
typically do the same kind of operations in parallel, such as
requesting memory to the worker in charge of managing the
allocator—which ultimately delivers a unique memory block,
each portion of which is used by a different requesting thread.

We note that our approach is de-facto orthogonal to any
approach that tries to improve the scalability of memory
allocation via pre-reserving, since we optimize the actual
handling of concurrent operations on the core allocator—a
buddy system in our case—on top of which pre-reserving
is not fully adequate. In particular, cached allocators and multi-
instance approaches do not fully cope with scenarios where pre-reserving or cached allocation could be
be put in place. Furthermore, it allows to cope with
scenarios where pre-reserving or cached allocation could be
fully adequate. In particular, cached allocators and multi-
instance approaches do not fully cope with scenarios where pre-reserving or cached allocation could be
be put in place. Furthermore, it allows to cope with
scenarios where pre-reserving or cached allocation could be
not fully adequate. In particular, cached allocators and multi-
instance approaches do not fully cope with scenarios where pre-reserving or cached allocation could be

https://github.com/HPDCS/NBBS
threads—can give rise to a peak of requests saturating cached allocation and requiring coordinated concurrent accesses to the underlying buddy-system instance.

A solution with goals similar to the ones pointed to by our proposal can be found in [20]. Here the authors present a concurrent non-blocking memory allocator relying on the so called helping strategy—where threads help each other trying to avoid blocking scenarios. This solution is based on a kind of conditional atomic dec instruction which is not currently supported by conventional processors. Conversely, our proposal only relies on machine instructions offered by off-the-shelf CPUs. Moreover, as pointed by the same authors, this solution is not able to early detect memory fragmentation, thus possibly leading to a large amount of false positives and unnecessary retries.

III. THE NON-BLOCKING BUDDY SYSTEM

Before introducing our solution, a preliminary notion of buddy-system specification is given. A buddy system is a memory allocator that divides a contiguous memory region into partitions, namely memory blocks, by splitting recursively it into halves. These partitions are always contiguous in memory, thus minimizing external fragmentation. In order to satisfy a memory allocation request, it searches for a memory block large enough to satisfy the request.

Every memory block has an order, which is an integer ranging from 0 to a specified upper limit. The size of a block of order $n$ is proportional to $2^n$, so that blocks are exactly twice the size of blocks that are at one order lower.

The peculiarity of a buddy system is that memory allocation requests can be satisfied by: i) returning a block if already available; ii) splitting higher-order free blocks into smaller ones; iii) merging lower-order free blocks into a larger one.

The binary arrangement of blocks allows to simplify the exploit of bit-wise operations. For example, given the address of a block of a given order, finding the address of the relative buddy is a simple arithmetic operation and does not need de-referencing pointers.

In the following four sections, we will discuss the metadata used in our solution, the non-blocking allocation and release procedures, and finally a relevant optimization of our proposal.

A. Basics

Our non-blocking buddy system keeps track of the state of the memory segment used for serving allocations by the means of a static complete binary tree. The tree has a predefined depth $d$ and its structure is assumed to be already materialized in memory. The root of the tree corresponds to (and keeps track of the state of) the entire memory segment within which allocations will take place. Each child of a node represents a portion (a half) of the parent’s chunk of memory, while the leaves represent the state of the minimum allocatable memory chunks, called allocation units. In particular, according to the classical buddy-system structure, if a node at level $i$ has size $s$, the children of this node, located at level $i + 1$, have size $s/2$, and the union of the blocks of memory associated with the children form a larger block of memory that exactly corresponds to the parent. This means that, considering an overall size of memory managed by the buddy system equal to $\text{total\_memory}$, the memory size managed by a node at level $i$ is equal to $\text{total\_memory}/2^i$, and the allocation units (corresponding to the leaves of the tree) have size equal to $\text{total\_memory}/2^d$.

In our non-blocking buddy system, each node in the tree embeds a bit-mask with 5 relevant bits, organized as in Figure 1. These are used to represent the state of the node itself—thus of the corresponding memory chunk—and of its sub-trees (if any) according to the following semantic:

- occupied, this flag indicates whether an allocation operation has targeted exactly that node, meaning that an allocation request has been served by a memory chunk corresponding to that node;
- left\_occupied and right\_occupied, these flags indicate if the branches (left and right, respectively) covered by the node are totally or partially occupied. This means that some allocation request has been served by a node in these sub-trees;
- left\_coalescent and right\_coalescent, these flags indicate whether a memory release operation is currently in place in any of the two sub-trees. In other words, these two flags indicate whether the node is currently in a transient state because of memory-release modifications running on the relative sub-trees.

In order to correctly manipulate the status bits while handling concurrent operations, our solution relies on Read-Modify-Write (RMW) instructions offered by conventional architectures, like x86. These instructions are able to atomically retrieve a single-word memory value and (conditionally) modify it contextually to the retrieval. In particular, our operations are based on the Compare-and-Swap (CAS) RMW instruction. This instruction updates a given memory location only if its current value is equal to an input value provided to the instruction; it then returns the success (or the failure) of the operation.

As in common buddy-system organizations, each allocation of a given size $s$ is mapped to its immediately higher size corresponding to $\text{total\_memory}/2^i$ with $i \in [0, d]$. Also, when a node is allocated, its sub-tree is considered to be fully occupied—this is exactly what the occupied flag takes care of signaling. Nevertheless, we do not reflect node occupancy on the lower-level nodes, which helps us saving atomic RMW instructions for updating the corresponding status bits.

We represent the tree of nodes keeping track of the buddy-system state with an array of $2^{d+1} - 1$ elements, which we refer to as $\text{tree}[]$. We place the root node at index 1 and...
exploit the conventional rule that, given a node with index
n, the left child of this node is at index \(n \times 2\) and the right
child is at index \(n \times 2 + 1\). This representation fulfills the
condition that nodes belonging to the same level of the tree are
placed in a contiguous portion of the array, thus simplifying the
search for free chunks of a given size while performing allocations.
In fact, starting from the amount of requested memory \(s\) it is possible to compute the target level—the one containing nodes useful to serve the request based on its size—
as \(\text{level} = \left\lfloor \log_2(\text{total_memory}/s) \right\rfloor\) upper-bounded by the value \(d\). The nodes belonging to this level are those with index \(n \in [2^{\text{level}}, 2^{\text{level}+1} - 1]\).

A graphical representation of this structure is shown in
Figure 2. Denoting with \text{base_address} the start of the memory region (either physical or logical) managed by the allocator, for each node with index \(n\) it is possible to compute the starting address \text{starting}_n and the size \text{size}_n of the corresponding memory chunk, as well as the level associated with the node, according to the following rules:

\begin{equation}
\text{level}_n = \left\lfloor \log_2(s) \right\rfloor \quad (1)
\end{equation}

\begin{equation}
\text{size}_n = \frac{\text{total_memory}}{2^{\text{level}_n}} \quad (2)
\end{equation}

\text{starting}_n = \text{base_address} + (n - 2^{\text{level}_n}) \cdot \text{size}_n \quad (3)

We couple the \text{tree[]} array with another array, called
\text{index[]}[]. This array is used to keep track of the indexes of the
nodes that have been used for serving memory requests, and which have not yet been released. Given the address, we can easily retrieve the index of the node and use this information during a release operation, whose API receives the base address of the to-be-freed node as its unique parameter.

We present our non-blocking allocation/release algorithms by relying on a few additional notations. The maximum reachable level in the tree-based organization is stored in a variable denoted as \text{depth}. Moreover, we denote as \text{min_size} the variable keeping the size of the allocation units associated with the leaves, and as \text{max_size} the variable that keeps track of the maximum amount of memory allocatable with a single
request (available at level \text{max_level})—clearly, \text{max_size} \leq \text{total_memory}.

To extract and manipulate the status bits within the nodes of the tree, the following bit-masks are used:

\begin{align*}
\text{OCC_RIGHT} &= 0x1 \\
\text{OCC_LEFT} &= 0x2 \\
\text{COAL_RIGHT} &= 0x4 \\
\text{COAL_LEFT} &= 0x8 \\
\text{OCC} &= 0x10 \\
\text{BUSY} &= (\text{OCC} | \text{OCC_LEFT} | \text{OCC_RIGHT})
\end{align*}

Each memory allocation/release operation consists in
traversing the tree up to \text{max_level} in order to correctly
manipulate the status bits of the traversed nodes. In fact, these
bits need to be (re)aligned to the new state of the buddy
system, depending on the type of operation that is performed.
In particular, a memory release operation starts from the
node to be released, while a memory allocation operation starts from
whichever node at the target level—this depends on the size
of the memory allocation request.

Given a value \text{val} of the status bits of a given node
and the index \text{child} of the previous node traversed while
moving towards the root, which is a child of the given node,
the following status-bit manipulation functions are offered to
simplify the exposition:

\begin{align*}
\text{clean_coal}(\text{val}, \text{child}) &= \text{val} \& \neg(\text{COAL_LEFT} \gg \text{mod}_2(\text{child})) \\
\text{mark}(\text{val}, \text{child}) &= \text{val} \mid (\text{OCC_LEFT} \gg \text{mod}_2(\text{child})) \\
\text{unmark}(\text{val}, \text{child}) &= \text{val} \& \neg((\text{OCC_LEFT} \mid \text{COAL_LEFT}) \gg \text{mod}_2(\text{child})) \\
\text{is_coal}(\text{val}, \text{child}) &= \text{val} \& (\text{COAL_LEFT} \gg \text{mod}_2(\text{child})) \\
\text{is_occ_buddy}(\text{val}, \text{child}) &= \text{val} \& (\text{OCC_RIGHT} \ll \text{mod}_2(\text{child})) \\
\text{is_coal_buddy}(\text{val}, \text{child}) &= \text{val} \& (\text{COAL_RIGHT} \ll \text{mod}_2(\text{child}))
\end{align*}

\text{clean_coal}(\text{val}, \text{child}) sets to zero the coalescing bit relative
to the branch of the child. \text{mark}(\text{val}, \text{child}) sets to one the
occupancy bit of the branch of the child. \text{unmark}(\text{val}, \text{child})
sets to zero both the coalescing and the occupancy bits
relative to the branch of the child. \text{is_coal}(\text{val}, \text{child}) returns
true if the coalescing bit relative to the child is set to one. \text{is_occ_buddy}(\text{val}, \text{child}) returns true if the occupancy bit
relative to the buddy associated with the child is set to one. \text{is_coal_buddy}(\text{val}, \text{child}) returns true if the coalescing bit
relative to the buddy associated with the child is set to one.
In order to capture whether the child is the right or the left
one, all these functions use a two-modulus operation applied
to the index of the child.

We additionally use the following status-bit management
function to detect whether a node, whose status bits are
embedded within the \text{val} bit-mask, is currently free:
is_free(val) = ~(val & BUSY)

This condition is verified when the node itself has not been reserved for some allocation operation (it is not occupied), and none of its sub-trees (left and/or right) has nodes currently reserved for allocations—none of the sub-trees is partially or fully occupied.

Similarly to most common allocators, our non-blocking buddy system exposes two API functions for either requesting a chunk of memory of (at least) a given size or for releasing some previously allocated memory chunk identified by its address. Both tree[] and index[] are initialized to zero at start-up. Recall that 0 does not correspond to any node of the tree since the initial element of tree[] is associated with index equal to 1. Setting the entries of index[] to zero indicates that none of the possible memory chunks (and of the corresponding addresses) managed by the buddy system at any level has been delivered for usage.

B. Memory Allocation Algorithm

The non-blocking memory allocation operation is divided in two algorithms, NBALLOC() and TRYALLOC(). The pseudo-code of NBALLOC(), which represents the memory allocation API actually exposed to the user, is reported in Algorithm 1. NBALLOC() takes as input the size of the memory allocation request and, if such amount of memory is available as a set of buddies, it returns the address of a memory chunk big enough to fit the request. If the size exceeds the overall memory allocatable by a single invocation, the algorithm fails. Differently, if it is smaller than the minimum amount managed within the buddy system, it is rounded to the allocation unit, namely the size associated with the leaves. In any case, if the request size is legitimate, the target level of nodes to be considered for allocation is obtained by Rule 1 (line A5). Once identified the right level, thus the range of indexes of nodes suitable for the allocation, these nodes are scanned in order to search for a free one. Note that not necessarily such a search has to start from the first node at that level. Rather, starting from scattered points will more likely lead concurrent allocations (bound to that same level) to target different free nodes, if any. When a free node is found (line A12), the allocation operation tries to “reserve” it by invoking the TRYALLOC() procedure. This returns zero upon success. Otherwise, it returns the index of the node that makes the allocation fail. In the latter case, the algorithm moves to the next candidate node by exploiting the index returned by TRYALLOC() (lines A18-A19) to skip the whole sub-tree relative to the node causing the failure. If no node at that level is found to be free, then the allocation operation fails, indicating that the current usage state of the buddy system is not compliant with the issued request.

When the TRYALLOC() procedure succeeds at reserving a node, the relative address with respect to base_address is computed, and the corresponding entry of the index[] array is updated to store the index of the reserved node (lines A15-A16). Then, such memory address is returned, indicating a successful allocation.

Algorithm 1 Allocation - Part A

A1: procedure NBALLOC(size, size) return void *
A2: if size > max_size then
A3: return false
A4: end if
A5: level ← ceil(log2(total_memory / size))
A6: if level > depth then
A7: level ← depth
A8: end if
A9: starting_from ← 2^level - 1
A10: until_to ← 2^level - 1
A11: for i ← starting_from to until_to do
A12: if is_free(tree[i]) then
A13: failed_at ← TRYALLOC(i)
A14: if ¬failed_at then
A15: index[starting_base_address] ← i
A16: return starting;
A17: else
A18: d ← (1 << (level_i - level_failed_at))
A19: i ← (failed_at + 1) * d
A20: end if
A21: end if
A22: end for
A23: return NULL
A24: end procedure

Algorithm 2 Allocation - Part B

T1: procedure TRYALLOC(index n) return index
T2: if ¬CAS(&tree[n], 0, BUSY) then
T3: return n
T4: end if
T5: current ← n
T6: while level_current > max_level do
T7: child ← current
T8: current ← current >> 1
T9: do
T10: curr_val ← tree[current]
T11: if curr_val & OCC then
T12: FREE_NODEINDEX, level(child))
T13: return current
T14: end if
T15: new_val ← clean_coal(curr_val, child)
T16: new_val ← mark(new_val, child)
T17: while ¬CAS(&tree[current], curr_val, new_val)
T18: end while
T19: return 0
T20: end procedure

The pseudo-code of TRYALLOC() is reported in Algorithm 2 and a visual representation of its steps is shown in Figure 4. It takes as input the index of a node (previously observed as free) and tries to (i) occupy this node, and (ii) propagate the information about the occupancy up to the ancestor node belonging to the max_level. The former task is carried out by relying on the CAS machine instruction (see line T2 corresponding to step 1 in Figure 3), which tries to update all the occupancy bits in the status bit-mask of that node, by atomically checking if the status bits are still set to zero. If the CAS fails, it means that something has concurrently changed on the state of the buddy system, affecting the ongoing operation. Therefore, the memory allocation operation needs to be aborted and retried on a different node just as in the spirit of non-blocking coordination algorithms. Conversely, if the CAS instruction succeeds, the procedure continues by traversing the nodes along the path from the one that has been
C. Memory Release Algorithm

A memory release operation is composed by three phases. In the first phase, the ancestors of the node to be released are marked as coalescing, in order to notify that a free operation is in place along the corresponding path of the tree. In the next phase, the node to be released is marked as free by resetting all its occupancy bits. During the last phase, all the nodes previously marked as coalescing are updated again to notify that the sub-tree involving the just released node is actually free—therefore it can serve again memory requests. As hinted before, this last update may conflict with a concurrent allocation operation and fail thanks to the CAS semantic—left/right occupancy bits remain set since the memory has been already reused. The first two steps are implemented by the \texttt{FREENODE()} procedure (see Algorithm \[3\]), while the last one is carried out by the \texttt{UNMARK()} procedure (see Algorithm \[4\]).

The \texttt{FREENODE()} procedure is not directly exposed to the user. It is instead encapsulated by the \texttt{NBFREE()} procedure, which is the actual memory release API in our buddy system. This procedure receives the memory address corresponding to the chunk to be released, computes the relative index of the corresponding node by inspecting the \texttt{index[]} array, and triggers the execution of the \texttt{FREENODE()} procedure.

\texttt{FREENODE()} takes as input the index of the node to be released and an upper-bound, which identifies the upper-level to be reached along the backward traversal associated with its execution. If the \texttt{FREENODE()} procedure is invoked by \texttt{NBFREE()}, the upper-bound is set to \texttt{max_level}, making it traverse the tree up to the level corresponding to the maximum allocatable size. In this case we are releasing a previously allocated node and, thus, the status bits need to be reflected up to the maximum useful level of the tree. Differently, if the procedure is invoked by a failed \texttt{TRYALLOC()} (see line T12), the upper-bound is set to the level of the last node updated by a \texttt{TRYALLOC()}, during an aborted memory allocation. As discussed before, this execution path is related to the need for \texttt{TRYALLOC()} to restore the status bits of nodes that where involved in the traversal towards the maximum level, which was interrupted because of the discovery of an already occupied node.

While traversing all the nodes up to the upper-bound, \texttt{FREENODE()} atomically sets the coalescing bit of the correct position, via CAS instruction (see line F10 in Algorithm \[3\]). A visualization of this phase is shown in Figure \[8\].

If along this path a buddy is detected as occupied by other allocations, the climb is early arrested, since the corresponding sub-tree cannot be considered free—this is the case of Figure \[4\] where the right subtree of the node below the upper-bound is already fragmented. Once the first phase is concluded, \texttt{FREENODE} can start to signaling that the interested node has been released, whose steps are sketched in Figure \[5\]. In particular, the node to be released can be updated by resetting its occupancy bits. This takes place by simply writing zero on its status bits (see line F19 in Algorithm \[3\] corresponding to step 1 of Figure \[5\]).
The last phase is responsible of propagating the release of the interested node up to the upper-bound and, possibly, merging buddies. This is achieved by invoking UNMARK(), which traverses the nodes, from the one to be released, towards the upper-bound, cleaning the coalescing and the occupancy bits of the traversed nodes (see steps 2 and 3 of Figure 5). For each node met, the first step is to verify whether the coalescing bit is still set: if it is not, the procedure returns, finishing the release operation. As hinted before, this scenario is possible if some allocation/release in the same sub-tree of the target node has already occupied/released that coalescing sub-tree.

Conversely, if the coalescing bit is still set, the procedure tries to clean both the coalescing and the occupancy bits atomically. This operation is done via a CAS in a retry-cycle in order to manage the case in which the coalescing bit has been reset by some concurrent operation, meaning that the resource has already been reused/released. If during this procedure some nodes in the same sub-tree have been allocated, the relative occupancy bits have not to be reset. Then, the procedure checks if the buddy occupancy bit is set at each step and, in the positive case, it returns. In fact, similarly to the first phase, if such buddy is occupied, we cannot propagate node releasing and, thus, merge buddies up to the higher level, since the chunks associated with higher level nodes are still fragmented.

Overall, beyond providing non-blocking capabilities while allocating or releasing memory at a given level, our buddy system allows fragmenting and merging operations—which logically move nodes across different levels within the allocation scheme—still in non-blocking fashion. This operation, that usually has to be explicitly performed, here is carried out automatically while performing allocations/releases.

Algorithm 3 Memory Release

```
F1: procedure NBFREE(void *addr)
F2:   n ← index(addr, base_address)
F3:   FREENODE(n, max_level)
F4: end procedure
F1: procedure FREENODE(index n, index upper_bound)

D. 4-Lets Optimizations

In order to execute an atomic RMW instruction, the CPU core takes an exclusive access to the relative memory cache line, delaying its access to other cores. Reducing the number of RMW instructions executed along the critical path of any thread in a non-blocking algorithm is therefore an important aspect in terms of further performance improvements.

In the previously presented solution, a thread that performs a memory allocation or a memory release has to execute a number of RMW instructions equal to at least the depth of the node involved in the allocation/release respect the max_level within the tree. However, since the number of status bits required to represent the state of each node is significantly smaller than the word size—which is 64-bits on nowadays conventional machines—is possible to reduce such amount of RMW instructions by packing a bunch, namely a node and some levels descendant from it, in the same status bitmask. With this organization a thread is able to update at one
time the state of multiple levels with only one RMW atomic instruction. On the other hand, the coherence with the original specification is guaranteed by the fact that all state-update operations are performed via CAS, which succeeds only if the status bit-mask has not changed in the meanwhile.

Another important consideration is that, given a generic node in the tree, its state can be derived by looking at the state of its children, as shown in Figure 6. In fact, the partial occupancy of a node—say its left/right occupancy—can be computed with a logical OR operation on the (partial and full) occupancy of a node. In the same way, occupying two buddies looks to be the same as fully occupying the parent node. This means that, similarly to the partial occupancy, the fully occupancy of a node can be computed with a logical AND operation on the occupied bits of its children.

Such reasoning can be recursively applied to all the ancestors of a node, hence a sub-tree starting from a given node can be represented by the nodes in its lower level. Then, considering a word-size equal to \( w \) bits, and a status bit-mask of size \( s \) bits, we can pack in a single variable a bunch of depth equal to \( d \), with \( 2^d \times s < w \), representing \( 2^{d+1} - 1 \) nodes of the original tree. In our case, we are able to manage 4 levels, namely 15 nodes with 8 nodes in the lower level (40 bits), in a single 64-bit word, reducing the number of atomic RMW operations by a factor of 4. A representation of this transformation is shown in Figure 7.

Of course, this means that, when an operation is performed on a node that is not in a lower level of a bunch, its state has to be decoupled from its descendant in the same bunch. To practically implement the operation in this variant of our data structure, each node in the \( \text{tree}[] \) array stores a pointer to its bunch and its position inside it (computed with the same rule used in the original solution). The algorithms for the 4-level solution are pretty similar to those shown before, with two main differences. First, the direct allocation/release of a node has to be checked and then set the state of all the nodes in the sub-tree in the lower level of the bunch. In particular, given a node \( n \) with depth \( d_n \) and its position inside the bunch \( b_n \), the corresponding bunch-leaf nodes have position \( p \) in the bunch equal to:

\[
p \in [b_n \times 2^{3 - \text{mod}_{4}(d_n)}, (b_n + 1) \times 2^{3 - \text{mod}_{4}(d_n)} - 1]
\]

Second, updates of the bunches up to the root have to be executed with a step of 4 levels in order to update each time the relative bunch-node.

IV. Experimental Results

In our experimental evaluation, the compared allocators do not use pre-reserving, hence they are tested as actual back-end allocation services. This is compliant with our objective, since we focus on improving the efficiency of a back-end memory manager that could be used in combination with any pre-reserving (and thread binding to pre-reserved memory) policy taken from the literature. As already hinted, pre-reserving is an orthogonal technique to improve memory allocation performance with respect to making a back-end allocator more scalable, via non-blocking algorithms as in our approach.

We have compared the performance of our non-blocking buddy system with various alternatives: 1) the buddy allocator in [21] denoted as buddy-s1, which is still based on a tree data structure, but synchronizes concurrent accesses using spin-locks, 2) the Linux buddy system, which is instead based on a multi-list data structure, and exploits spin-locks for handling concurrency. Each back-end allocator has been set up in a single-instance configuration, since we are interested in evaluating the benefits/shortcomings of our approach when concurrent requests can actually insist on the same allocation data structure instance, rather than exploiting data-separation via multi-instances. In our tests we have assessed both the original and the 4-level optimized versions of our buddy system, which we denote as 1lvl-nb and 4lvl-nb, respectively. Also, we include data related to our own data structure with the variant that, rather than using RMW instructions to make it non-blocking, we synchronize the accesses in a blocking manner by using a unique (global) spin-lock. This configuration, named as 1lvl-s1 and 4lvl-s1 for the two different levels’ organizations, respectively, has been included just to study the effects of non-blocking operations against a wider set of blocking solutions, each based on a different implementation.
For the assessment we used 4 different test scenarios, 3 of which have been taken from the literature, and one has been specially devised for this study. The first is the Linux scalability test [22], where threads continuously ex-
execute an allocation/release pattern, with fixed size, for at least \(20 000 000/\text{num\_threads}\) times. The second is the Thread Test presented in [17], where threads carry out \(10 000/\text{num\_threads}\) allocations of a given size, and then release the acquired memory, executing this pattern in a cycle of at least 200 steps. The third is the one by Larson in [23], where the behavior of a Web server is simulated, by having a thread reserving memory for (emulated) operations, and then releasing it for usage by other operations. According to its specification, this test is aimed at assessing the operations throughput over a time window of 10 seconds. The fourth—the one we propose—which we call Constant Occupancy, is based on having each thread initially allocating a pool of chunks of different sizes, with larger amount of allocations bound to smaller chunk sizes, and then it performs \(20 000 000/\text{num\_threads}\) deallocations/allocations by randomly selecting the element to be deallocated—hence the corresponding deallocation size—and using this same size for the subsequent allocation. Compared to the others, this test more prominently uses allocations/deallocations involving chunks of different size, and tends to keep constant the factor of occupancy of the buddy system. All the tests have been carried out on a 64-bit NUMA HP ProLiant server equipped with four 2GHz AMD Opteron 6128 processors and 64 GB of RAM. Each processor has 8 cores, for a total of 32 CPU-cores. The used operating system is Linux, with kernel version 3.2.

In Figures 5-11 we report data for a comparison among all the back-end allocators implemented in user-space. Here, we configured all the tested allocators to manage chunks of minimal size set to 8 bytes, and maximal size set to 16KB. Also, we used different allocation/deallocation sizes ranging from 8 bytes to 1024 bytes. For the Constant Occupancy test these sizes indicate the minimum ones among those managed, while the maximum ones are set to be 16 times larger.

The data show a clear gain of the non-blocking approach when compared to all the other spin-lock-based solutions especially when increasing the thread count. Also, both the 1-level and 4-level organizations of our non-blocking buddy system have good performance, with the 4-level organization providing a few benefits especially in scenarios where a batch of allocations is interleaved with a batch of releases along the execution of a thread, as in some settings of the Thread Test. Rather, in scenarios where a single allocation is followed by a single release, the lower level of fragmentation of the buddy system allows for less conflicting operations when working with RMW instructions at individual levels, as in the 1-level organization. In any case, when running with 32 threads, the non-blocking buddy system provides performance gain ranging from 9% to 95% across all the configurations.

In a second set of experiments, whose results are reported in Figure 12, we compare the performance of the different allocators this time including the buddy system from version 3.2 of the Linux kernel—to the best of our knowledge, the buddy system is essentially the same in later versions of the Linux kernel. To test with such a kernel level allocator, we developed Linux external modules implementing the logic for the tests related to Linux Scalability, Thread Test and Constant Occupancy. This has been done by relying on kernel level threads which interact with the Linux buddy system via \_	ext{get\_free\_pages} and free\_pages kernel services. Given that our target machine has 8 NUMA nodes, and hence the kernel handles 8 instances of a buddy allocator in parallel, to test the access performance to the same allocator instance we set the memory-policy of the threads we activated within the Linux module so as to bind the allocations towards the same buddy-system instance (namely, instance 0). We have configured the user-space allocators to manage the same amount of memory as the kernel level buddy allocator, and with the same granularity of minimum and maximum chunk size. The data in Figure 12 refer to the tests executed when targeting allocations/releases of 128KB chunks (in Constant Occupancy this time the value corresponds to the maximum-size allocatable chunk) with 32 threads. Here, we see that our non-blocking version has performance which is comparable with the Linux buddy system in one case—the Constant Occupancy test—and is definitely better with the other two test settings. In particular, the non-blocking allocator we propose has performance gain that ranges from 71% (as in the 1-level case) to 67% (as in the 4-level case) for Thread Test, and is of the order of 84% for Linux Scalability.

V. Conclusions

We have presented a non-blocking approach for back-end memory allocators based on the well-known buddy-system specification. To date, this is the first practical implementation of a buddy system that jointly supports allocation, deallocation, and coalescing operations, all implemented in non-blocking fashion. Moreover, we have presented an optimization aimed at reducing the number of executed atomic instructions. The experimental assessment has shown the effectiveness of our solution vs both user-space and kernel-space already-optimized allocators. As future work, we plan to embed our solution in front-end allocators allowing them to interact more frequently the back-end allocator, thanks to its increased scalability, and to reduce the memory consumption peak.
REFERENCES

APPENDIX

In this appendix, we provide a sketch proof that our buddy system achieves lock freedom \cite{24}, thus guaranteeing that some allocation/deallocation invocation eventually completes. Informally, it is like saying that if a thread does not make progress this is due to the advancement (so the progress) in the computation of other threads. Our proof proceeds in two steps. First, we give a definition of progress in our algorithm, and then we prove that threads are blocked in a retry loop because of conflicts with other threads which anyhow are making progress.

As explained in Section [11] both NBALLOC and NBFREE show (more than) one phase where they try to mark in some way nodes starting from the freed/allocated one to a predefined ancestor (typically the level associated to \texttt{max_level}). We call such phase a climb from a source node to a destination one.

**Definition 1.** A thread performs a step forward (makes progress) in a climb phase if the number of not-yet visited nodes is decreased by one.

In our code we can identify one loop in the NBALLOC procedure and two nested loops in TRYALLOC, FREE_NODE and UNMARK.

**Lemma A.1.** NBALLOC is lock-free iff TRYALLOC is lock-free.

**Proof.** The unique loop in NBALLOC is a finite loop where at each iteration local values are computed and two functions are invoked: \texttt{is\_free} which contains no loops and TRYALLOC. It follows that NBALLOC completes if and only if TRYALLOC completes.

**Lemma A.2.** NBFREE is lock-free iff FREE_NODE is lock-free.

**Proof.** NBFREE consists only in invoking the FREE_NODE method.

Analyzing the code of TRYALLOC, FREE_NODE and UNMARK, we can see that they contain one occurrence of two nested loops. These loops have a well-defined structure. The outer loop performs a climb from a source to a destination, thus it is finite, while the inner loop is a retry cycle for updating node metadata with a CAS. We refer to such update as a climb step. Consequently, threads can be stuck only in inner loops.

**Lemma A.3.** If a thread fails to update node metadata in an inner loop, another thread has made progress.

**Proof.** From the CAS semantics, we know that for a thread A failing a CAS on metadata of a node \( n \) at level \( N \), there is a thread \( B \) that has successfully updated such metadata. Such update can be performed by three operations: (i) \texttt{T2} (ii) \texttt{F19} or (iii) a climb step.

On one hand, if \( B \) executes lines \texttt{T2} and \texttt{F19} it is clearly making progress, since it will start a new climb phase from the \( (N - 1) \)-th level. On the other hand, if \( B \) completes its inner loop, it makes a step forward along its climb to the destination by moving from the \( N \)-th level to the \( (N - 1) \)-th level.

**Lemma A.4.** TRYALLOC, UNMARK, FREE_NODE are lock-free functions.

**Proof.** Since climbs performed by a function are finite, they are not nested (no threads start a new climb while executing one), and each climb has a finite number of steps, we know from the last lemma that for a thread stuck at level \( i \) there is a thread making progress—it succeeds climbing to level \( i - 1 \). This reasoning can be iterated until there is a thread \( A \) stuck while trying to update the destination node of another thread \( B \), which succeeds and completes its climb. Since threads perform sequential climbs, eventually a thread will complete its last climb and, thus, the function execution.

**Theorem A.1.** NBALLOC and NBFREE are lock-free functions.

**Proof.** The claim follows from Lemma A.1, A.2 and A.4.

In this section we define some safety properties intended as “nothing bad happens” that we believe an allocator should guarantee and consequently we give an informal proof that our non-blocking buddy system satisfies such properties, described as follows:

- **S1.** A successful allocation returns a non-allocated set of memory addresses coherent respect to the requested size.
- **S2.** A correct invocation of a free releases exactly the memory targeted by the request.

To prove that our non-blocking system satisfies the aforementioned safety conditions, we rely on the following axioms derived by the design of our algorithms:

- **AX1:** an NBALLOC returns contiguous memory;
- **AX2:** NBALLOC of level \( H \) returns a base address \( B = k2^H \);
- **AX3:** NBALLOC of level \( H \) returns set of addresses \( S \) such that \( |S| = 2^H \);
- **AX4:** each method execution, that has reached a node \( n \) during a climb, has updated the state of all traversed nodes.

**Lemma A.5.** A successful allocation returns a memory space coherent respect the size requested.

**Proof.** WLOG we consider allocations of size \( 2^H \). A NBALLOC request of size \( s \) computes the target level \( L \) as \( \log_2(s) \) (line A5). Moreover, by AX3 we know that this level contains memory chunks of size \( 2^L \), that is exactly \( s \).

In order to successfully complete, an allocation has to find a free node \( n \) at level \( L \), set its status to fully occupied (line T2), and climb the tree until \texttt{max\_level} traversing only free or partially occupied nodes (line T11). Thus, a successful allocation has set all nodes between the one at level \( L - 1 \) and the one \texttt{at max\_level} (from AX4) as partially occupied.
Lemma A.6. Two different allocated sets of addresses of the same size cannot overlap each other.

Proof. Let \( A = [r_A, r_A + 2^H] \) and \( B = [r_B, r_B + 2^H] \) be two sets of addresses of level \( H \) returned by two successful allocations.

Supposing that the statement is not true, it follows that
\[
r_A < r_B < r_A + 2^H
\]
from AX1 and AX3.

We know from AX2 that \( r_A = k_A 2^H \) and \( r_B = k_B 2^H \).

Since \( r_A \neq r_B \) by hypothesis, it follows that \( k_A \neq k_B \).

WLOG \( k_A + D = k_B \), where \( k_A, k_B, D \in \mathbb{N} \) and \( D > 0 \).

It follows that \( A = [2^H k_A, 2^H k_A + 2^H) \) and \( B = [2^H (k_A + D), 2^H (k_A + D) + 2^H) \).

It follows that
\[
2^H k_A < 2^H (k_A + D) < 2^H k_A + 2^H
\]
\[
k_A < k_A + D < k_A + 1
\]
\[
0 < D < 1
\]
which is a contradiction.

Lemma A.7. Two different node sets are overlapping iff one node is an ancestor of the other.

Proof. \( \Rightarrow \). Suppose that the statement is not true, namely one node \( A \) is not the ancestor of the other \( B \) and \( A \cap B \neq \emptyset \).

In any case, they have at least common ancestor (e.g. the root). Let \( P \) be the lowest level common ancestor at level \( l_P \) such that \( A \subseteq P \) and \( B \subseteq P \). It follows that \( A \) is either a descendant of \( P \) or is exactly one child of \( P \) and \( B \) is either a descendant of \( P \) or is the other child of \( P \). As we know, \( P \) has two child \( L_P \) and \( R_P \) such that \( L_P \cap R_P = P \cap L_P \cap R_P = \emptyset \) by construction. WLOG, we have that \( A \subseteq L_P \) and \( B \subseteq R_P \). Consequently,
\[
(A \cap B) \subseteq (L_P \cap R_P)
\]
\[
(A \cap B) \subseteq \emptyset
\]
\[
(A \cap B) = \emptyset
\]
which is a contradiction.

\( \Leftarrow \). Let \( A \) be a node and let \( A_i \) the set of \( i \)-th descendants of \( A \). It follows,
\[
\bigcup_{a \in A_i} a = A
\]
by construction.

Lemma A.8. An alloc never returns an already allocated, but not freed, set of addresses.

Proof. If the statement is not true, there are at least two successful allocations \( A \) and \( B \) that have allocated two sets, \( S_A \) and \( S_B \), of overlapping addresses, namely \( S_A \cap S_B \neq \emptyset \).

From Lemmas 5 and 6, we know that either a) \( S_A = S_B \) or b) \( S_A \neq S_B \) and one node is the ancestor of the other.

Case a) Both \( A \) and \( B \) allocations have succeeded to flip the occupancy bit on the same node. This is impossible unless the node has been freed, which contradicts the hypothesis.

Case b) WLOG, we assume that \( A \) is an ancestor of \( B \). Since both \( A \) and \( B \) succeeded, they have successfully marked as partially occupied all nodes along their climb to the destination, which is the same for both \( A \) and \( B \) by construction (line T6). It follows that \( B \) has successfully set one of the partial occupancy bits (OCC_LEFT or OCC_RIGHT) of the node \( n_A \) occupied by \( A \). Moreover, \( A \) has successfully set the occupancy bit of \( n_A \). The set of the occupancy bit is performed with a CAS using 0 as old value, thus \( A \) makes the occupancy bit flip from 0 to 1 (00000 \( \rightarrow \) 10011). On the other hand, partially occupancy bits are only set (0_0_0 \( \rightarrow \) 0_1_1) if and only if the occupancy bit is not set (line T11). Since both CASes are atomic, it means that bits have assumed the following values in time:
\[
00000 \rightarrow 10011 \rightarrow 0_0_0 \rightarrow 00011.
\]

It follows that a transition 1 \( \rightarrow \) 0 of the occupancy bit has taken place. This transition is applied only at line T19 of FREE_NODE, while releasing a particular node passed has parameter. Since a successful allocation does not ever call a FREE_NODE during its last iteration, it cannot be applied by \( A \) or \( B \). It follows that a third operation \( C \) has reset the occupancy bit of \( n_A \). In particular, \( C \) is a FREE_NODE invocation on \( n_A \) that contradicts the hypothesis that both sets allocated by \( A \) and \( B \) are not freed.

Theorem A.2. A successful NB_ALLOC satisfies S1.

Proof. It follows from Lemmas A.5 and A.8.

Definition 2. A free \( f \) is invoked correctly iff the allocation of the memory to be released has returned before the invocation of \( f \).

Lemma A.9. An invocation of a free releases the memory targeted by the free request.

Proof. A free operation translates the memory address \( a \), passed as argument to NBFREE, to the index \( n \) of the relative node. Since this index is computed by applying a transformation that is the inverse of the one applied by the NB_ALLOC to compute the address to be returned, we are sure that the node to be free is the same allocated by the method that has returned the memory address \( a \). Since a NBFREE procedure completes only when it finds a node partially occupied by other allocations (line U8), we are sure that all the traversed nodes have been set to 0 from AX4.

Lemma A.10. A correct invocation of a NBFREE does not release a memory space different by the one targeted by the request.

Proof. Considering, by absurd, that the former statement is not true, we have that a thread \( A \) performing a NBFREE \( F_A \) has successfully updated via a CAS (line U12) a node \( n \),
notifying that the relative subtree (the one where \( F_A \) operation is started) is totally released when a sub-portion of this tree is still allocated — if this happens, the state of the node \( n \) could transit in a released state (all status bits set to 0) and then it can serve another allocation. By construction (lines U8-U10), if \( A \) has reached the node \( n \) during an unmarking climb, it means that it has seen the relative son \( s \) of this node with a state equal to 0. Then, a portion of memory in the subtree could be allocated only if there is a concurrent thread \( B \) executing a \texttt{NBAALLOC} that has updated the node \( s \) after \( A \).

At this point there are two possibilities: \( B \) updates the node \( n \) after \( A \); \( B \) updates the node \( n \) before \( A \). In the first case, since the thread \( B \) will update in turn the state of the node, the absurd is not in place (the free appears to precede the allocation). In the second case, the thread \( A \) has reset the relative coalescing bit of \( n \) (lines T15-T17), but this is absurd since \( A \) can succeed updating \( n \) only if the relative coalescing bit is set to 1.

\[\text{Theorem A.3.} \quad \text{A correct invocation of \texttt{NBFree} satisfies S2.}\]

\[\text{Proof.} \quad \text{It follows from Lemma A.9 and A.10.} \quad \blacksquare\]
