A Feedback Information-Theoretic Transmission Scheme (FITTS) for Modelling Aimed Movements

Julien Gori and Olivier Rioul

firstname.lastname@telecom-paristech.fr

Abstract—We build on the variability of human movements by focusing on how the stochastic variance of the limb position varies over time. This implies analyzing a whole set of trajectories at once rather than a single trajectory. We show, using real data previously acquired by two independent studies, that in a tapping task, the positional variance profiles are unimodal. The first phase, where positional variance increases steadily, is followed by a second phase where positional variance decreases until it reaches some small level. We show consistency of this two-phase description with two-component models of movement of the literature.

During the second phase, the problem of aiming can be reduced to a Shannon-like communication problem where information is transmitted from a “source” (determined by the distance between current and target position), to a “destination” (the movement’s endpoint) over a “channel” perturbed by Gaussian noise, with the presence of a feedback information from the current position. We obtain an optimal solution to this problem, re-derive the so-called Elias scheme, and determine that the fastest rate of decrease of variance during the second component is exponential. This leads to a new, “local” Fitts’ law, from which the classical “global” Fitts’ law is also re-derived. The validity of the model is assessed on real data; the rate at which variance is decreased, i.e., at which information is transmitted over the channel, is about 5 bit/s on average.

I. INTRODUCTION

It has since long been observed that people routinely adapt their speed so as to reliably perform precise movements such as pointing or grasping. This so-called speed-accuracy tradeoff that occurs in aimed movements has been studied for more than a century by different communities, such as experimental psychology [1]–[6], human-computer interaction [7]–[9], cybernetics [10, 11], and neuroscience [12, 13].

Despite the complexity and the diversity of human movements, recurrent characteristics are known and described in the literature:

a) Human movement is inherently variable: If one is repeatedly given the same pointing task, both his trajectories and summary performance measures can be strikingly different between trials. Variability affects practically all kinematic profiles, yet the overall performance is improved due to the presence of feedback. The transition between intermittent and continuous control is probably the result of training and learning [1], [23], [29].

b) Human movement relies on feedback: Humans can’t function properly without feedback, see e.g., Wiener’s account [18, p.95] on two patients suffering from ataxia and tabes dorsalis. Movement generation often relies on visual feedback mechanisms; this is also observed for most animals (see e.g., experiments on kitten [19]). Various experiments on occlusion and removal of light [20], [21] or removal of cursor [22] show an effect of visual feedback on accuracy, movement time, and generally speaking on all kinematic quantities. Visual feedback can have effect on movements as short as 100 ms [21], [23], [24].

c) Human movement can be decomposed into submovements, indicating intermittent control: Movements can be segmented into submovements [4], [5] or into two components [23]. Woodworth [1] was the first to suggest that aiming was comprised of a first distance-covering phase followed by a second homing-in phase. During the second half of the twentieth century, when recording trajectories with precision became accessible, researchers noticed that the velocity vanishes multiple times before the end of the movement. This, they reasoned, marked the transition between one submovement to another. This explains why some theoretic models [4], [5], [25] are derived by segmenting a single movement into several submovements, where each submovement is obtained as the response to a single control “impulse”.

d) Human movement can result from continuous control: Control and feedback effects can sometimes appear continuous [26]–[28]. In that case, no visible changes occur in the kinematic profiles, yet the overall performance is improved due to the presence of feedback. The transition between intermittent and continuous control is probably the result of training and learning [1], [23], [29].

The most influential result regarding human movements is an operational formula known as Fitts’ law, first stated by Fitts [2] as an analogy with the Shannon capacity formula [30] and recently formalized using the tools of Shannon’s information theory [31]. It predicts the time MT needed to
successfully reach a target of width $W$ located at a given distance $D$:

$$MT = a + b \log_2(1 + D/W) = a + b \text{ID}, \quad (1)$$

where $a$ (the intercept) and $b$ (the slope) have to be estimated from empirical data. The base of the logarithm is 2 in order to express the so-called index of difficulty $\text{ID}$ in bits. Although the law predicts execution time for movements in a specific paradigm, Fitts’ law has been found tremendously useful in measuring device performance $[7]$, $[9]$, measuring human performance $[33]–[35]$ or even predicting human performance $[36]$.

Fitts’ law is a very robust empirical law, yet its theoretic basis was often questioned $[3]–[5]$, $[8]$, $[9]$, $[37]–[39]$. Many models have been developed in numerous frameworks to describe human movements, from which Fitts’ law can be re-derived. However, as the next section shows, none of them successfully incorporates the four characteristics $a)–d)$ mentioned above.

The goal of this paper is to propose a model for human movement which accounts for $a)–d)$. Our focus is on the evolution of the stochastic variance of the limb position over time. This implies analyzing a whole set of trajectories (acquired under the same experimental condition) at once, as opposed to the common practice of considering a single trajectory. The remainder of this paper is organized as follows. In Section $II$ we review some existing models. In Section $III$ we build on prior work by Elliott and colleagues to propose a two-phase description that is validated on real data in Section $IV$. In Section $V$ we propose an information-theoretic model for the second phase from which theoretical bounds on movement time are leveraged in Sections $V-C$ and $VI$. Local and Global versions of Fitts’ law are derived in Sections $VII$ and $VII-B$ followed by an empirical validation in Section $VIII$.

II. BACKGROUND FOR AIMED MOVEMENTS

We review some models and results for human aimed movements with which our work shares similarities. It is not the purpose of this section to be exhaustive: the interested reader is referred to $[14]$, $[23]$, $[32]$, $[40]$ for more details.

A. Early Descriptions: A Two-Component Movement

The earliest descriptions of aimed movements go back to the nineteenth century $[41]$, p. 154 $[1]$. It was observed that when speed increases, accuracy diminishes “when the eyes are used” $[1]$, and that for a fixed speed, increasing the distance to be covered leads to a decrease in accuracy. Based on these findings, Woodworth $[1]$ hypothesized that two serial components would constitute aimed movements: an initial adjustment, whose main purpose is to cover distance followed by a current control component, which ensures that accuracy constraints are met.

$^1$This version of the law is due to MacKenzie $[8]$. In Fitts’ original expression, the term inside the logarithm was $2D/W$. Many other modifications have been proposed, see $[32]$ Table 2. Another well-known expression is Welford’s $\text{ID} = \log_2(1/2 + D/W)$ $[8]$.

B. Fitts’ Law

Fitts’ law was proposed in 1954 $[2]$, the most popular formulation used today being Eq. $1$. Fitts made an analogy between the human motor system and a Shannon-like noisy communication channel $[50]$ and identified $D/W$ to the signal-to-noise ratio. Recently, Fitts’ analogy was formalized by a complete information-theoretic model $[31]$ where Fitts’ law derives from the evaluation of the capacity of an amplitude-bounded channel, but which unfortunately cannot account for visual or kinesthetic feedback.

ID in Eq. $1$ is a nominal quantity calculated from the task parameters ($D$ and $W$). Yet, as Zhai observed $[37]$, users often underuse or overuse $W$ for tasks of low or high ID, respectively. A classical solution consists of replacing the index of difficulty $\text{ID}$ by an effective index of difficulty $\text{ID}_e$ given by $[9]$

$$\text{ID}_e = \log_2(1 + D/4.133\sigma), \quad (2)$$

where $\sigma$ is the empirical standard deviation of endpoints. The theoretical basis of this solution is however questionable $[31]$. Another solution that depends on an erasure rate was proposed in $[31]$, $[42]$, which accounts for overuse of $W$ only. Note that the law that uses ID is called the nominal law, while the law that uses ID$_e$ is called the effective law.

C. Crossman and Goodeve’s Deterministic Iterative Corrections (DIC) Model

Crossman and Goodeve $[4]$ proposed a scheme of intermittent proportional correction of position. The scheme takes the form of a discrete-time model where the change of position from one sampling instant to the next is proportional to the current error. This implies that the distance to the target is reduced exponentially. Assuming a fixed time step between each control impulse, they show that the total movement time follows Fitts’ law.

The major limitation of this model is that it is deterministic, which is incompatible with the variability typically found in human motor movement. In fact, the predictions of the DIC model are not confirmed by empirical studies $[40]$, p. 194. Nonetheless, it was the first model to consider intermittent control of position as the result of feedback, which explains why it remained popular for quite some time.

D. Schmidt’s Law

Using a time-constrained rather than a width-constrained task and studying the variability of the human response, Schmidt et al. $[43]$ observed the so-called linear speed-accuracy tradeoff for rapid movements:

$$MT = a' + b'D/\sigma, \quad (3)$$

where MT and $D$ are defined as in Eq. $1$, and $\sigma$ is the standard deviation of endpoints. The discrepancy between Schmidt’s and Fitts’ law is most likely due to the method used by Schmidt and colleagues to determine the end of the movement “which leaves no chance for late discrete control” $[23]$. In practice, Schmidt’s law is often seen as an
operational formula for “ballistic”, i.e., open loop movements of short duration, whereas Fitts’ law is seen as an operational formula for aimed, i.e., closed loop movements of longer duration.

E. Meyer et al.’s Stochastic Optimized Submovements (SOS) Model

Woodworth’s idea of a two-component movement, Schmidt’s linear speed-accuracy tradeoff for ballistic movements and Crossman and Goodeve’s DIC model are combined in the SOS model. Each movement is assumed to begin with a primary submovement which is ballistic, whose role is to cover most of the distance separating the initial point from the target. It is thus similar to Woodworth’s description of the distance-covering component. This primary submovement, of duration \( t_1 \), follows Schmidt et al.’s linear tradeoff Eq. (3) without intercept, meaning that the standard deviation of endpoints at the end of the first submovement is proportional to the average speed reached during the submovement. Once this primary submovement is finished, either the endpoint is inside the target in which case the movement stops, or the endpoint is outside the target and a corrective submovement is needed. This corrective submovement has exactly the same behavior as the primary one, except that its variability is naturally lower because the distance to be covered is usually much shorter; the time needed to perform this secondary submovement is \( t_2 \). By minimizing the sum \( t_1 + t_2 \), the SOS model predicts that movement time is given by

\[
MT = a + b(D/W)^{1/2}.
\] (4)

This model was later extended to the case of \( n \geq 2 \) submovements [40]. It can be shown that when \( n \) grows large, \( (D/W)^{1/2} \) should be replaced by the logarithmic law \( \log_2(D/W) \) [44]. Fitts’ law is thus expressed in SOS as the result of an optimal allocation of time between a ballistic primary submovement and a succession of corrective submovements. In essence, the stochastic optimized submovement model is a stochastic version of Crossman and Goodeve’s model, where each individual submovement follows Schmidt’s law.

As it effectively combines elements of several successful models into a comprehensive account of movement, the SOS is one of the leading explanatory models for Fitts’ law [14], [23]. However, the SOS model suffers from several well-documented deficiencies [5], [45], including some theoretical predictions on submovement that do not match empirical findings [45]. More importantly, the model is unable to account for continuous feedback.

F. Bullock & Grossberg’s Vector-Integration-To-Endpoint (VITE) Model

A neural network model called VITE was proposed [15] on the basis that the complicated synergies between muscle groups exclude a pre-planning (ballistic) strategy. The model builds on three signals: target Position Command (TPC) which is used to locate the target, present Position Command (PPC) which is used to locate the current position of the arm and a GO command, used to modulate the overall speed of the movement. At any time instant, the difference between TPC and PPC, corresponding to the remaining distance to be covered is evaluated into a difference vector (DV) which is then multiplied by the GO signal and integrated to form the new PPC. DV is a vector, as each of its component corresponds to the difference between TPC and PPC for a specific synergetic muscle group. The GO signal on the other hand is non-specific and can assume several shapes, including step functions and sigmoid functions.

Although VITE is capable of explaining many aspects of human aimed movement using a feedback scheme based on the difference between current and target position, the equations describing the model are deterministic differential equations, so that the model fails to account for variability. Furthermore, the model’s behavior is largely dependent on the shape of the GO signal, which is determined \( a posteriori \) to fit existing trajectories, but for which we have no \( a priori \) knowledge.

None of the models above capture the four characteristics a)–d) of human aimed movement described in Section 1.

Deterministic models such as DIC and VITE fail to account for the variability of human movements (a) and the derivation of Fitts’ law in [31] does not include ways to integrate feedback (b). VITE does not account for intermittent control (c), while the celebrated SOS model fails to consider continuous corrections (d), yet characteristic of skilled operators [1], [26].

We will derive a two-component model, similar to the one described by Woodworth, which exploits the difference between target and present position obtained via feedback. Considering the position of the target and the limb as relevant signals for movement is consistent with empirical observations [23] and rationales based on minimizing the computational cost [46], and is in line with the feedback schemes presented above, which all rely on computing the difference between the current position of the limb and the target position. The variability will be accounted for by considering a noisy Shannon-like information transmission scheme, as in [31]. However, whereas most models describe a single trajectory, our aim is to describe how the variability of a set of trajectories varies over time; as a result it will account for both intermittent and continuous control. The model we propose thus successfully accounts for a)–d).

III. A Two-Component Movement Model

Building on extensive experimental accounts, Elliott and colleagues [23], [45] have proposed a description of aimed movement inspired by the two component model of Woodworth [1]:

1) a first planned component, that gets the limb close to the target area (cover distance), in which movement generation is based on internal models and representations but, contrary to e.g., Schmidt’s [43] description, it is not entirely ballistic. Instead, it is associated to veloc-

[2]The word ballistic can refer to different concepts [47, p. 830]; here, by ballistic, we mean that there is no feedback involved at all. A ballistic movement is thus fully determined at the onset by a control impulse.
ity regulation through mostly kinesthetic/proprioceptive feedback.

2) When time permits, a second corrective portion is engaged to reduce any spatial discrepancy between limb and target. This process, highly dependent on foveal (central) vision, involves computing the difference between limb and target position and issuing discrete corrections. With practice, these corrections may appear smooth and continuous.

The discrete corrections that characterize the second component are typically identified from the kinematics of movement by searching for zero-crossings of the velocity, acceleration or peaks of jerk profiles. However, these methods are somewhat unreliable as their efficacy depend on the filtering technique used in post-processing and inertial parameters of the limb involved in the movement. They also fail to capture the second component when movements appear continuous. As we next show, two components can be reliably identified using a positional variance analysis.

A. Unimodality Hypothesis for Positional Variance

As remarked in [17], trajectory variability has “surprisingly received little attention from researchers”. Most studies investigating Fitts’ law have often been limited to the measure of the spread of endpoints [6], [9]. Some work exists concerning whole trajectories. The evolution in time of the entropy of trajectories from a tapping task was evaluated in [50]. Entropy profiles, as well as profiles of standard deviation of position were reported unimodal i.e., they were comprised of an increasing phase, followed by a decreasing phase. Other studies [13], [51] have represented positional variance at specific kinematic markers (peak acceleration, peak velocity, peak deceleration, movement time). Extrapolation of data again suggests unimodal profiles of positional variance. The variability of trajectories produced by elbow flexion (allowing only one degree of freedom) has been more extensively studied [52], [53]; most variance profiles are actually bimodal.

These conflicting results can probably be explained by the differences in the tasks used to study variability, where the tapping task mobilizes a greater number of joints then the elbow flexion task. The following simple reasoning leads us to believe that positional variance profiles in Fitts’ tapping task are nonetheless unimodal:

1) all movements starting from the same position, initial positional variance is null;
2) in the early stages of the movement, positional variance increases [43], [53];
3) if time permits, the target is eventually reached and the movement ends, which implies that the positional variance vanishes asymptotically [54].

We therefore expect a unimodal variance profile as illustrated in Fig. 1. A first variance-increasing phase, for time \( t \in [0, \tau] \), where variance increases from 0 to \( \sigma_0^2 \) is followed by a second variance-decreasing phase, where the variance is decreased to arbitrarily low values and eventually vanishes.

Note that Fig. 1 represents a smooth continuous profile, whereas the notion of intermittent control would suggest an irregular variance profile. Trajectories and control impulses cannot be perfectly synchronized, so that resulting summaries appear asymptotically smooth and continuous. This description in terms of a smooth variance profile is convenient as intermittent and continuous control can then be treated indifferently, see c)–d) in Section I.

B. Phase-Component Identification

We now wonder whether the two-component description of Elliott and colleagues given at the beginning of this Section can be mapped to the two phases of variance just presented. If this is indeed the case, the effects on the distance covered and the speed achieved during the first phase should be primarily due to D, whereas the duration of the second phase should be primarily attributed to accuracy requirements. This leads us to formulating the following testable predictions.

The distance covered at the end of the first phase \( D_{\tau} \):

1) should increase with \( D \),
2) shouldn’t be affected significantly by accuracy constraints.

The average velocity during the first phase:

3) should increase with \( D \),
4) shouldn’t be affected significantly by accuracy constraints.

The duration of the second phase:

5) should depend on \( D \), through the value of \( \sigma_0 \),
6) should increase when accuracy becomes more stringent.

Prediction 5 might be surprising, as what takes times is supposedly decreasing the variance. However, it should be remembered that variance has to be decreased from the initial \( \sigma_0^2 \), which is likely affected by \( D \).

IV. Empirical findings

We evaluate the previous predictions on empirical data. We have re-analyzed existing datasets, as pointing studies on Fitts’ tapping task have been conducted numerous times.
A. Datasets

The first dataset is from a study by Guiard et al.\[55\] (hereafter G-dataset), which uses a discrete version of the tapping task [56]. Pointing was done towards a fixed line located at $D = 150$ mm, perpendicular to the direction of movement. Contrary to most tapping studies, there is no explicit width constraint enforced through a predetermined $W$; instead the participants were instructed to vary their strategy through five conditions: from full speed emphasis (1) to full accuracy emphasis (5). Pointing data was acquired on a high-resolution graphical tablet.

The second dataset is the POINTING DYNAMICS DATASET (hereafter PD-dataset) described in a study by Müller et al.\[48\]. They used the reciprocal version of the tapping task \[2\]. D was taken to be either 212 mm or 353 mm, and $W$ conditions were calculated so as to have conditions for ID = 2, 4, 6, 8 (respectively $W = 70.6, 14.1, 3.32, 0.83$ mm and $W = 118, 23.5, 5.54, 1.38$ mm).

In both datasets, position is represented as a one dimensional real number. The raw data from each dataset was low-pass filtered and re-sampled closest to the average sampling frequency, and individual movements were extracted and synchronized so as to have common time origin. For the G-dataset, 16 participants produced movements for each of the five conditions five times, providing 80 different variance profiles. For the PD-dataset, 12 participants produced movements under 8 ($D, W$) conditions, providing 96 variance profiles. No outliers were removed. Removing them would imply relying on an arbitrary heuristics, and for which we found no satisfying method. We are nonetheless able to find compelling evidence to support our claims.

Fig. 2 displays trajectories of one participant (hereafter P X) of the G-dataset, performing under the condition (3) (balanced speed/accuracy).

B. Investigating Unimodality

The unimodality hypothesis was checked by computing the positional variance profiles for each subset composed of all the trajectories acquired by a single participant under the same condition\[4]\.

We asserted unimodality of a profile by verifying that only one sign change occurred in its derivative. Fig. 3 displays the empirical variance profile of P X, consistent with the theoretical profile given in Fig. 1 as well as its derivative in orange.

We found that 64 out of 80 variance profiles in the G-dataset are unimodal. We also proceeded to a visual check and determined that 4 profiles that were labeled as multimodal had a massive outlier which distorted the variance profile. The analysis of the PD-dataset is less conclusive as 32 out of 96 variance profiles in the PD-dataset were found unimodal. However, the higher the value of ID, the more profiles were found unimodal. For each condition of ID there were 24 profiles, the number of non unimodal profiles were for ID in [2,4,6,8] respectively [13,9,8,2]. We visually checked the 10 non unimodal profiles for ID = 6 and ID = 8; 5 were labeled unimodal due to an outlier. One reason to explain the less convincing results from the PD-dataset is that reciprocal tapping paradigms, such as the one used to gather the PD-dataset, are far less cleaner than the discrete paradigm used e.g., to acquire the G-dataset, as there is extra variability associated to the starting position and the starting time. When tasks are too easy (low value of ID), the unimodality is not systematic anymore, as sometimes variance increases slightly towards the end. This will be discussed later.

Usually, profiles with multiple modes are due to outliers. The secondary modes are very small and the variance profile can still be reasonably well be modeled by a unimodal profile. There is thus substantial evidence to support the unimodality hypothesis of variance profiles in tapping tasks.

C. First Phase of Movement

We now look for evidence in support of predictions 1) to 4). We used the PD-dataset only, as the G-dataset had a fixed D. The results are summed up in Figs. 4 & 5 with corresponding statistics reported Tables I & II.

We notice that:

1) $D_r$ increases with D, this is striking in Fig. 4 on average, $D_r/D = 0.65$ for both values of D. The

\[\begin{array}{ccc}
D & F(1, 88) = 117.384 & 0.000 & 0.564 \\
ID & F(3, 88) = 0.748 & 0.526 & 0.011 \\
DxID & F(3, 88) = 0.160 & 0.923 & 0.002 \\
\end{array}\]

TABLE I

TWO-WAY ANOVA FOR EFFECTS OF D AND ID ON $D_r$

As all traces end at different dates, the number of trajectories available upon which variance can be computed decreases with time; to ensure reliable estimations we stopped computing variance when less than 10 trajectories were available.
The unimodal empirical variance profile, in blue, of PX performing in the balanced condition (3). The mode appears for \( \tau \approx 200 \text{ ms} \). The derivative of the variance profile appears in orange and changes sign only once.

\[
\text{Variance } \sigma^2(t) \quad \text{and} \quad \frac{d\sigma^2}{dt} \quad \text{of the variance profile appears in orange and changes sign only once.}
\]

**Fig. 3.**

The distance covered at the end of the first phase \( D_\tau \) represented for the 8 pairs of \( D \) and \( W \) values. Conditions have been grouped by values of \( D \), so that the four bars in each group correspond to \( ID = 8, 6, 4, 2 \) from left to right. Each bar is represented with its errorbar, and corresponding \( W \) condition is displayed on top.

**Fig. 4.**

Bars: Date of transition \( \tau \) between the two phases represented for the 8 pairs of \( D \) and \( W \) values. Conditions have been grouped by values of \( D \), so that the four bars in each group correspond to \( ID = 8, 6, 4, 2 \) from left to right. Each bar is represented with its errorbar, and corresponding \( W \) condition is displayed on top. Diamonds: average movement time \( MT \) for the entire movement for corresponding conditions.

**Fig. 5.**

3) Fig. 5 shows no strong effect of \( D \) or \( ID \), or \( W \) on \( \tau \). This is confirmed by the two-way ANOVA reported in Tab. II. Only factor \( D \) is statistically significant at \( \alpha = 0.05 \), but the effect size is weak \( (\eta^2 = 0.046) \). \( ID \) and \( D \times ID \) show non-significant and weak effects. In practice, \( \tau \) can then reasonably be considered constant, with an average value of \( \tau = 0.317 \text{ ms} \). We computed the correlation between \( \tau \) and \( W \) and found a non significant slope \( (D_\tau = 0.0001W + 0.1814, \ r^2 = 0.0067, \ p = 0.427) \), which further shows that the effect of \( W \) on \( D_\tau \) is marginal.

This observation is interesting and consistent with the so-called isochrony principle of movements [57], which expresses that there is a tendency for participants to increase the speed of their movements when the distance to cover is increased. If we combine the fact that \( \tau \) is constant with the two previous observations, we naturally get that:

a) the average velocity during the first phase scales with \( D \).

b) the average velocity during the first phase is pretty much invariant with regards to levels of \( ID \) or values of \( W \).

There is thus substantial evidence to confirm prediction[1] to [3], meaning the first phase can be identified to the first component.

**D. Second Phase**

The fact that the first phase has a constant duration provides valuable information concerning the remaining predictions [5] and [6]. The total movement time \( MT \) being predicted by Fitts’ law (Eq. (1)), the duration of the second phase \( MT - \tau \) should also follow Fitts’ law. Fig. 6 confirms predictions [5] and [6], as the duration of the second phase shows high correlation with \( ID \): \( MT - \tau = 0.10 + 0.19 ID, \ r^2 = 0.84, p < .0001 \). This finding is interesting and non-trivial as it attributes the speed-accuracy tradeoff to the variance decreasing phase only.

**E. Link with kinematics**

\( \tau \) is found constant on average across profiles, yet we can compute correlations \( \tau \) from one profile with kinematic
portion followed by a fast decreasing portion; this initial surge that the best linear fit between date of maximum variance and variance and the date of minimal acceleration. Notice however indicating a close proximity between the date of maximum X see Fig. 7. All the data points are close to the date of average minimal acceleration (maximal deceleration), markers appear later, MT = 0 find r
acceleration. Each blue point, labeled Data, corresponds to one participant Fig. 7. Date of maximal variance plotted against the date of minimal r linear model fitted to the data, with corresponding confidence intervals. We start this section by describing a simple functional model for the second component. We will then see that it translates naturally into the formalism of information theory. This description is then leveraged to obtain performance bounds on movement time for aimed movements during the second component.

V. A Model for the Second Component

A. A Simple Functional Model

The model is represented Fig. 8, where notations in bold should be ignored for now. At the beginning of the second phase, the limb extremity is at position \( \theta(\tau) \). We suppose that this position, as well as the position of the target \( \Theta \), is known by the brain. Based on \( \Theta \) and \( \theta(\tau) \), the brain outputs a sample, \( x_1 \), which is sent towards the muscles. On the way through the nervous system, the sample is corrupted by noise. Therefore, the received sample \( y_1 \) may differ from \( x_1 \), the sample that was sent. Finally, the muscles act upon receiving \( y_1 \) by moving the limb extremity to \( \theta(\tau + T) \). This information is fed back to the brain. In general, for \( k > 1 \), we have that \( x_k \) is based on all the information available at the brain \( \{ \Theta, \theta(\tau), \theta(\tau + T), \ldots, \theta(\tau + (k-1)T) \} \) and that \( \theta(\tau + kT) \) is based on all received samples \( \{ y_1, \ldots, y_k \} \). When given enough time, the target is reached, meaning \( \theta(\tau + kT) \) converges towards \( \Theta \).

B. Information-theoretic Model

The functional model presented above, as well as most models in the literature predict one trajectory; however, as explained previously, we want to describe a set of trajectories to handle both intermittent and continuous control.

Asymptotically, i.e., when the set is large enough, the position of the limb extremity (the ‘limb’ in short) is a continuous random variable. At the end of the first phase, we may assume that the position can be well approximated by a Gaussian distribution with some standard deviation \( \sigma_0 \) (see Fig. 1).

Thanks to the feedback, the limb position is known at the brain level. Due to eye-hand coordination and fast eye dynamics, the eye is usually pointing towards the target long before the end of the movement. Hence the position of the target is also known at the brain level. The distance from

\[ \begin{align*}
\text{MT} - \tau &= 0.10 + 0.19 \log(1 + D/W), \text{ with } r^2 = 0.84. \text{ The confidence interval for the regression line is also displayed.}
\end{align*} \]

Fig. 7. Date of maximal variance plotted against the date of minimal acceleration. Each blue point, labeled Data, corresponds to one participant performing under one condition. The orange line, labeled \( X = Y \) is the identity operator, i.e., points close to the orange line have maximum variance occurring simultaneously with the minimal acceleration. The green line is the linear model fitted to the data, with corresponding confidence intervals.

markers from the same profile to find that the date of maximal variance correlates reasonably with various kinematic markers (e.g., date of maximum speed \( r^2 = 0.402 \)), date of the first zero-crossing of speed \( r^2 = 0.503 \), date of minimal acceleration \( r^2 = 0.406 \)). On average, when the kinematic markers appear later, \( \tau \) is also larger, which is not surprising.

An interesting observation is that \( \tau \) is very close to the date of average minimal acceleration (maximal deceleration), see Fig. 2. All the data points are close to the \( X = Y \) line, indicating a close proximity between the date of maximum variance and the date of minimal acceleration. Notice however that the best linear fit between date of maximum variance and date of minimal acceleration is rather far from the identity function \( X = Y \).

In typical acceleration profiles, there is a fast increasing portion followed by a fast decreasing portion; this initial surge is then followed by many fluctuations. It is interesting that the maximum variance coincides with the end of the initial surge. This suggests that the first phase may well be modeled by a bang-bang model, where maximum torque is applied, followed by minimal torque. The fluctuations of acceleration then correspond to the second phase, where reliable aiming takes place. This interpretation is consistent with the observation that visual regulations and compensatory adjustments occur primarily after rapid force impulses.

This is an assumption that is often used, whose strict veracity depends on the conditions in which the movements were produced. Usually, this approximation is good enough as distributions are bell-shaped. In, the empirical entropy of the trajectory was compared with the theoretical entropy of a Gaussian distribution. The difference was never more than .3 bits, throughout the entire trajectory.
limb to target is thus easily evaluated by the brain; in fact it is readily estimated by the eye if the limb is close enough to the target.

Let $A$ be the distance from limb to target; from the above assumptions, $A$ is modeled as a zero-mean Gaussian random variable with standard deviation $\sigma_0$. Moreover, for rapid aiming, the first phase may equally well undershoot or overshoot the target*, and we may assume zero mean: $A \sim \mathcal{N}(0, \sigma_0^2)$. To successfully complete the movement, the brain has to send $A$ to the limb; this is precisely the role of the second phase. We consider the following scheme:

- From $A$ the brain outputs a certain amplitude $X_1$ to be sent to the limb:
  \[ X_1 = f(A), \]
  where $f$ is an unknown function performed by the brain.
- To account for the variability of the human motor system [16], we consider a noisy transmission from brain to limb, where $X_1$ gets perturbed by additive white Gaussian noise (so-called AWGN channel). The output of the channel $Y_1$ is given by
  \[ Y_1 = X_1 + Z_1 \quad \text{where} \quad Z_1 \sim \mathcal{N}(0, N). \]
- Based on the channel output $Y_1$, distance $\hat{A}_1$ is actually covered, which is the result of some unknown function $g$ applied by the motor organs to the received $Y_1$.
- $\hat{A}_1$ is returned to the brain via ideal (noiseless) feedback where it is compared to $A$. From such a comparison a new amplitude $X_2$ is produced by the brain.

The scheme then progresses iteratively for $i = 1, 2, \ldots$ We assume that each step $i$, from the creation of $X_i$ to the reception of $\hat{A}_i$ takes $T$ seconds. Each such step is infinitesimal and thus, the whole process is an intermittent iterative correction model that becomes continuous at the limit.

At iteration $i$, the scheme is described by following equations (see Fig. 8):

1) The brain (the ‘encoder’) produces $X_i$ from $A$ and all received feedback information $\hat{A}_i^{-1}$.
   \[ X_i = f(A, \hat{A}_i^{-1}). \]
2) The motor organs (decoder) receive $Y_i$ contaminated by Gaussian noise:
   \[ Y_i = X_i + Z_i. \]
3) The covered distance $\hat{A}_i$ is a function of all previous received amplitudes:
   \[ \hat{A}_i = g(Y_i). \]  

At this stage, $f$ and $g$ are still undetermined.

In Shannon’s communication-theoretic terms, the aiming task in the second phase can thus be seen as the transmission of a real value from a “source” (distance from target at the end of the first phase) to a “destination” (limb extremity) over a noisy Gaussian channel with noiseless feedback.

### C. Bounds on Transmitted Information

We first recall the following definitions:

- $P_i = \mathbb{E}[X_i^2]$, where $\mathbb{E}$ is the mathematical expectation, is the power of the input.
- The Shannon capacity $C$ [30], [59] of the AWGN Channel under power constraint $P_i \leq P$ and noise power $N$ is given by
  \[ C = \frac{1}{2} \log_2(1 + P/N). \]
- $D_n = \mathbb{E}[(A - \hat{A}_n)^2]$ is the distortion, and is the mean square error of the estimation of $A$ by $\hat{A}_n$ after $n$ iterations of the scheme.

**Theorem 1.** Consider a transmission scheme with a feedforward AWGN channel of Shannon capacity $C$ and ideal feedback. For a zero-mean Gaussian source $A$ with variance $\sigma_0^2$, we have that:

\[ \frac{1}{2} \log_2 \frac{\sigma_0^2}{D_n} \leq I(A, \hat{A}_n) \leq nC. \]

The proof is given in the Appendix. The Theorem expresses that enough information should be transmitted from the brain to the limb to reduce the positional variability from $\sigma_0^2$ to $D_n$, but transmitted information can never exceed $nC$, where $n$ is the number of iterations. For a fixed capacity, sending large amounts of information thus requires increasing the number of iterations of the scheme.

### VI. Achieving Capacity

Everything else being equal, maximizing accuracy is equivalent to minimizing $D_n$; similarly, minimizing time is equivalent to minimizing $n$. Optimal aiming, which consists of...
achieving the best accuracy possible in the least amount of time is thus achieved when
\[
\frac{1}{2} \log \frac{\sigma_0^2}{D_n} = I(M, \hat{M}) = nC.
\] (11)

The goal of this section is to find the scheme that achieves optimality (Eq. (11)).

**Lemma 1.** Optimal aiming can be achieved if, and only if, we have the following conditions:
1. All the random variables considered: \(A, \bar{A}, A - \bar{A}, X^i, Y^i, Z^i\) are Gaussian.
2. The input powers \(P_i = \mathbb{E}[X_i^2]\) are all equal (to, say, \(P\)).
3. The endpoints \(\bar{A}\) are mutually independent
4. The channel outputs \(Y^i\) are independent from the errors \(A - \bar{A}\)
5. \(\tilde{A} = g(Y^i)\) is a sufficient statistic of \(Y^i\) for \(A\).

Working with Gaussian variables considerably simplifies operations, as independence between Gaussian variables is equivalent to decorrelation, and the Minimum Mean Square Error (MMSE) estimator, i.e., the one which minimizes \(D_n\), is linear in the Gaussian setting (we will use both properties). In fact, we will see that both \(f\) and \(g\) are linear, but this is not so surprising as linear functions preserve Gaussianity.

If \(g(Y^i)\) is a sufficient statistic of \(Y^i\) for \(A\), then it does not matter if the feedback comes from the endpoints \(\bar{A}\) or from the outputs of the channel \(Y^i\). Feedback information prior to the motor organs (e.g., kinesthetic feedback) can thus also be accounted for.

By working out the conditions of Lemma 1 (hereafter conditions), we derive the structure of the optimal scheme, namely the expression of \(f\) and \(g\); we first obtain \(g\) by using the following result known as the orthogonality principle.

In estimation theory, where \(x\) is to be estimated from the observed \(y\) by the estimator \(\hat{x}(y)\), the orthogonality principle states that there is an equivalence between the following propositions:
- \(\hat{x}(y)\) is the unique Minimum Mean Square Error (MMSE) estimator and \(\hat{x}(y) = \mathbb{E}[x|y] = \mathbb{E}[xy|\mathbb{E}[y]]^{-1}y\),
- \(\mathbb{E}[(x - \hat{x}(y))(y)] = 0\) and \(\mathbb{E}[x - \hat{x}(y)] = 0\).

**Theorem 2.** For the optimal transmission scheme, \(g(Y^i)\) is the MMSE estimator, \(g(Y^i) = \mathbb{E}[A|Y^i]\).

**Proof.** From condition \(\mathbb{E}[(A - g(Y^i))Y^i] = 0\). The proof is immediately finished by using the orthogonality principle. \(\square\)

The optimal scheme thus yields an endpoint \(\bar{A}_i = g(Y^i)\) obtained as the best least-squares estimation of \(A\) from all the observations of the channel outputs \(Y^i\).

**Theorem 3.** For the optimal transmission scheme
\[
X_i = f(\bar{A}^{i-1}, A) = \alpha_i(A - \bar{A}_{i-1})(12)
\]
\[
= \alpha_i(A - \mathbb{E}[A|Y^{i-1}]), \quad (13)
\]
where \(\alpha_i\) meets the power constraint \(\mathbb{E}[X_i^2] = P\).

The signal sent to the channel is thus simply the difference between the initial message \(A\) and its current estimate \(\bar{A}_{i-1}\), rescaled to meet the power constraint.

The previous two theorems formally define the encoding function \(f\) and decoding function \(g\); both are linear functions, which are well known to be performed by the motor system (e.g., by activating \(\alpha\) and \(\gamma\) channels [14]). The difference in distance can be readily estimated by the eye. The functions \(f\) and \(g\) are thus mathematically simple and biologically feasible. The next result shows that the procedure is incremental, yet optimal at each step, allowing optimal on-line control.

**Theorem 4.** Let \(A_i = X_i/\alpha_i\), the unscaled version of \(X_i\). Then, we have that:
\[
\mathbb{E}[A|Y^{i-1}] = \sum_{j=1}^{i-1} \mathbb{E}[A|Y_j] = \sum_{j=1}^{i-1} \mathbb{E}[A_j|Y_j].
\] (14)

The decoding process is obtained successively; at each step, a message \(A_i\) that is independent from the previous \(A^{i-1}\) is formed. It is then estimated optimally by least-square estimation. We finally obtain Eq. (11) by evaluating the distortion.

**Theorem 5.** The squared error distortion \(D_i = \mathbb{E}(A - \bar{A}_i)^2\) decreases geometrically:
\[
D_i = \frac{\sigma_0^2}{(1 + P/N)^i}. \quad (15)
\]

With this scheme, forward capacity \(C\) is achieved and the distortion decreases geometrically (divided by \((1 + P/N)\)) at each iteration. The scheme successfully make the correspondence between the transmission of one real value using feedback, with that of \(n\) independent feedforward transmissions. The equations that we obtain are identical to that given in [60] who discussed a scheme by Elias [61]. The constructive approach given here, as well as its use to model human aimed movements, is to our knowledge new.

The scheme is implemented in Fig. 10. The \(A_i\)'s, given by the difference between the target position \(A\) and current position \(\bar{A}_{i-1}\), represent the distance that remains to be covered. This distance can readily be evaluated by the eye; because of eye-hand coordination and fast eye dynamics, the eye is usually pointing towards the target, giving high fidelity.

![Fig. 9. Linear decrease of the logarithm of standard deviation of position over time for participant 3 of the G-dataset, performing in the balanced (3) condition.](image-url)
or in an expression that looks more like Fitts’ law

\[ t = 1/C'D/W \approx 1/C'D/W, \]  

where \( i_d = \log_2 \frac{\sigma_0}{\sigma(t)} \) is defined as the local index of difficulty, and \( C' \) the capacity in bit/s. Note that this relationship holds between any two dates in the second phase, so that, taking \( t \) and \( \Delta t \geq 0 \), we have that

\[ \log_2 \sigma(t + \Delta t) = \log_2 \sigma(t) - C'\Delta t. \]  

Eq. (18) is reminiscent of Eq. (1), but without intercept (a).

B. Global Version of Fitts’ Law

The local formulation obtained above can be exploited theoretically in the context of Fitts’ paradigm and yields Fitts’ law. The ensuing derivation of Fitts’ law depends on the model that we choose for the first component. Developing a model for the first component in the same spirit as what we have just done for the second component proves out of the question for now as the first component probably follows from a mixed strategy between an internal representation of movements, prediction and noisy feedback [62, 63].

However, Fitts’ task is highly stereotyped, and as such we have shown that the duration of the first phase could reasonably be considered to be constant.

Second, for very short movements, Schmidt’s law can be assumed [5], [43]; namely, \( \sigma_0 = kD \), where \( k \) is some constant and \( \sigma_0 \) is the standard deviation at the end of the first component. Now, if the first component is assumed to cover a fraction of the total distance, as found in Section IV then we have that \( \sigma_0 = kD \). We thus get, using Equation (18), with \( a \) the constant duration of the first component:

\[ MT = a + 1/C'D/W + \log_2 k'; \]  

which is very close to the version of the effective Fitts’ law, see Eq. (2), except for the ‘‘+1’’ inside the logarithm.

Now, if we use the fact that participants are able to keep a relative constant error rate across conditions [2, 9], [56], we get that \( \sigma \simeq \sqrt{2/\text{erf}^{-1}(0.96)}W \), where \( \text{erf}^{-1}(x) \) is the inverse Gaussian Error Function (see [31] Appendix 3 for an example of the computation). This leads to

\[ MT = a'' + b' \log_2 D/W, \]  

which is Crossman’s [6] version of the nominal Fitts’ law (equivalent to Fitts’ \( \log_2 (2D/W) \)). This version is known to be very close to the one given by Eq. (1), except for small values of ID.

C. On Small ID Values

Our derivations Eqs. (22) and (21) differ from the nominal and effective Fitts’ law as given in Eqs. (1) and (2), as they both lack the ‘‘+1’’ inside the logarithm. Due to the asymptotic behavior of the logarithm, this difference is only important for low values of ID. As a matter of fact, there exist different
formulations for nominal and effective Fitts’ law than the one given in Eqs. (1) and (2), see e.g., [32] for a list of 12 formulations that have been used since 1954. Most of them differ for small values of ID.

In our datasets, usually the second phase lasted much longer than the first phase, so that it was sufficient to consider the first phase to be of constant duration. In most experiments, low values of ID are obtained with wide targets [64]; in that case the second component is hardly necessary and it is likely that most of the time spent during aiming is spent in the first component. Therefore movement time cannot be predicted by Fitts’ law, that results from the time spent in the second component, and better approximations for the duration of the movement might be useful.

For small values of ID, if we consider the crudest approximation for MT, i.e., that the movement is performed without a second component at all, we get:

\[
MT = a. \tag{23}
\]

This approximation is consistent with an analysis by Crossman & Goodeve [4, Fig. 11], which indicates that the “proportionality” between MT and ID breaks down for ID < 26 before which movement time tends towards a constant. This constant can be read to be between 200 ms and 250 ms, i.e., close to the value of \( a \) estimated from the G-dataset and the PD-dataset. Therefore, differences in ID for low values are likely uninformative.

However, the “\(+1\)” variants are known to have better fitting power than without [8]: how can this be explained?

We get a clue if we consider a finer approximation of MT. For small values of ID, the task is essentially a distance covering task. In that case, movement time is predicted as a linear function of the square root of the distance [47]:

\[
MT = a + b\sqrt{D}. \tag{24}
\]

Note that for small values of \( x \), we have that

\[
\lim_{x \to 0} | \log(x) - \sqrt{x} | \to +\infty \tag{25}
\]

whereas

\[
\lim_{x \to 0} | \log(1 + x) - \sqrt{x} | \to 0 \tag{26}
\]

Stated naively, the “\(+1\)” formulation brings the logarithm much closer to the square root function.

Therefore, adding 1 in the formulation for ID as in Eq. (1) provides a good fit with the square root law of Eq. (24), for low values of ID, while for large values of ID, the 1 is dominated by the ratio D/W, and the indexes with or without “\(+1\)” are equivalent.

Essentially, the “\(+1\)” appears as a tweak to extend the continuity of Fitts’ law in the domain of small ID’s, where the law should not be valid. Discussions about differences in the expression of indices in the range of small values of ID should thus be regarded with suspicion.

\[6\] They considered yet a different version of ID than Eqs. (1) and (22), but their value for ID amounts to the ratio D/W = 2

VIII. EMPIRICAL EVIDENCE

According to the variance analysis conducted previously, positional variance of the trajectories produced under the same condition should reach a maximum after a constant duration. From there, for an optimal participant, it should decrease exponentially until the accuracy constraint is reached. We thus expect the following observations:

- within a log-lin scale of standard deviation plotted against time, the second component should decrease linearly with slope \( C’ \), as shown by Eq. (17).
- \( C’ \) should not depend on the instruction; it is rather an image of the participant’s involvement in the experiment,
- the more the emphasis is placed on accuracy, the longer the duration of the second component.

Note that we will be using the G-dataset for this section as the positional data is acquired with a very high resolution and allows long observation of the second component without quantizing effects as in the PD-dataset. Also note that in a log-lin scale, a linear variance profile will also appear as a linear standard deviation profile. The latter profile is more convenient, as evaluating its slope gives \( C’ \) directly.

A. Linear Decrease of Standard Deviation

Fig. 11 is an example fit of the second component to determine the goodness of fit of the local Fitts’ law and to estimate \( C’ \). The standard deviation profile corresponds to empirical data from P X which was performing under the balanced (3) instruction. This example is typical of other plots, and it is not uncommon to witness equivalent fits, see Fig. 12.

In this example, standard deviation increases during the first 200 ms. From there, it decreases quasi linearly up to about 950 ms. Goodness of fit is high \( (r^2 = 0.984, \text{student t-test for significance of the slope yields } F(1,76) = 4693, \ p = 10^{-16}) \).

We computed the fits for all participants under all conditions; the average goodness of fit is \( r^2 = 0.93 \), and average slope yields \( C’ = 4.52 \text{ bit/s} \). This is close to typical values given in the literature e.g., [65] that use IDc (Eq. 2).

Fig. 12. Summary of goodness of fits (measured by \( r^2 \) values for the second phase of the variance profile) computed for all participants performing under all instructions in Guiard et al. The incentive to emphasize precision provides better goodness of fits.

**B. Effects of Manipulating Instructions**

We ran a oneway ANOVA for the effect of instruction on the duration of the second component: \( F(4, 75) = 25.579, \ p = 0.000, \eta^2 = 0.577 \), showing a strong and significative effect of instruction on the duration of the second component.

We also ran a oneway ANOVA for the effect on instruction on the value of \( r^2 \) : \( F(4, 75) = 9.717, \ p = 0.000, \eta^2 = 0.341 \), which indicates a significant and moderate effect of instruction on the value of \( r^2 \). This can be partly explained by the fact that longer duration of the second component provides more points to be fitted and mechanically higher \( r^2 \) scores. However, some decrease in \( r^2 \) score is simply due to suboptimal decrease of the variance in the second component. One participant actually produced movements in the full speed emphasis condition (1) which were extremely short and would stop right after \( \tau \) i.e., right after the maximum variance was obtained, thereby completely skipping the second component. The fits display higher \( r^2 \) scores when the tasks require greater precision as all but one \( r^2 \) values are above .95 for the full accuracy emphasis (5) and accuracy emphasis (4) conditions, see Fig. [12](#fig:12).

Finally, we excluded the 15 blocks where \( r^2 \) values where below 0.9 and estimated \( C' \) for all remaining blocks. The average values for \( C' \) for the five conditions ranging from ultra-fast (1) to ultra-precise (5) are respectively 4.87, 4.70, 5.09, 4.98 and 4.83 bit/s. Values of \( C' \) show little effect of instruction, as shown by the results of a oneway ANOVA: \( F(4, 60) = 0.227, \ p = .922, \eta^2 = 0.014 \).

**IX. CONCLUSION**

In this paper, we built on the variability of human movements by observing the variance of the position of the limb extremity over time. We showed that, for a tapping task:

1) Variance profiles are unimodal: a first phase where variance increases is followed by a second phase where variance decreases until a required accuracy constraint.
2) We can identify the two variance phases to the two components (distance covering, followed by homing-in phase) as described by e.g., Woodworth [1], Elliott and colleagues [23].
3) The problem of aiming, during the second component, naturally reduces to that of transmitting information from a source (distance from the target the end of the first component) to a destination (limb extremity) over a channel perturbed by Gaussian noise with the presence of ideal feedback information from the limb position.
4) Using a scheme, first described by Elias [61] using parallel Gaussian channels with feedback, which provides a simple yet optimal solution to the aforementioned transmission problem, we show that the variance can decrease at most exponentially during the second component.

Is is interesting to see the information-theoretic framework appears naturally to solve the aiming problem; this reinforces the idea — often battered, see e.g., [66] — that information theory is a useful tool for measurement and quantification of human performance [10], [67]. The signal never needs to be transformed into bits; the content of information simply measures a ratio of two spatial variances and the coding and decoding processes are extremely simple.

During the derivation leading to Theorem 5 we used twice the fact that the source was zero mean. This implies that the positions at the end of the first component should be centered around the target’s center. For most participants performing in the balanced condition, we found that the average trajectory becomes centered shortly after \( \tau \); it was however almost never true for participants performing in the two extreme conditions. For the ultra-fast condition(1), participants would on average overshoot the target, while for the ultra-precise condition(5), users would generally undershoot the target. This could indicate that the model is appropriate only for aiming when the goal is to balance between precision and speed. Luckily, during many everyday tasks, there is no incentive to be either extremely accurate or extremely fast.

When estimating \( \tau \) for the two datasets, we found that \( \tau \approx 300 \text{ ms} \) for the PD-Dataset and \( \tau \approx 200 \text{ ms} \) for the G-Dataset. The main difference between the two paradigms is that Guiard’s experiment is a discrete version, where the participants can take all their time to prepare each movement, whereas the PD-dataset is acquired with a reciprocal (serial) paradigm where the participants move back and forth. It is remarkable that the reciprocal task, which allows less time to prepare for a movement leads to a longer first component, especially considering that the first component consists of planification and prediction of movement [23]. A possibility is that participants had to finish planning the movement during the early stages of movement, making the first component longer. It is also possible that users who simply not putting all their resources in the experiment (see e.g., [68] for a study of resource investment in pointing), as reciprocal tasks are very repetitive.

The two previous points raise an important question regarding how the two components interact. Does one component follow the other like we have assumed until now, or do both components co-exist? Indeed, the first component could be a preprogrammed specification of a trajectory, upon which the corrective component is added. This would entail a trajectory
monitoring role for the second component. The algebraic distance would then be evaluated against the planned trajectory rather than against the target position.

Another interesting prospect is to consider non additive noise and non ideal feedback in a similar scheme. This could prove useful to model situations where feedback is non visual and only kinesthetic. These problems can also be taken into account within the information-theoretic framework.

X. APPENDIX

Proof of Theorem 1 The proof uses well known techniques and inequalities from information-theory [59].

Inequality (a)

\[
I(A; \hat{A}_n) = H(A) - H(A|\hat{A}_n) = H(A) - H(A - \hat{A}_n|\hat{A}_n) \\
\geq H(A) - H(A - \hat{A}_n) \\
\geq H(A) - \frac{1}{2} \log \left( 2\pi e \left( (A - \hat{A}_n)^2 \right) \right) = \frac{1}{2} \log \frac{\sigma_n^2}{D_n} 
\]

Eq. (27) by definition of mutual information; Eq. (28) because of the conditioning by \( \hat{M}_n \); Eq. (29) because conditioning reduces entropy; Eq. (30) because the Gaussian distribution maximizes entropy under power constraints; Eq. (31) by definition of the distortion and the entropy formula for a Gaussian distribution.

Inequality (b)

\[
I(A; \hat{A}_n) \leq I(A; Y^n) = H(Y^n) - H(Y^n|A) = \sum_i \left[ H(Y_i|Y^{i-1}) - H(Y_i|Y^{i-1}, M) \right] = \sum_i \left[ H(Y_i|Y^{i-1}) - H(Y_i|X_i) \right] \leq \sum_i \left[ H(Y_i) - H(Z_i) \right] \leq \sum_i \left[ \frac{1}{2} \log(2\pi eP_i + N) - \frac{1}{2} \log(2\pi eN) \right] \leq nC
\]

Eq. (32) by the data processing inequality, where \( M \rightarrow Y^i \rightarrow g(Y^i) = \hat{A}_i \) form a Markov chain Eq. (33) by definition; Eq. (34) by applying the chain rule to both terms; Eq. (35) because of the feedback scheme; Eq. (36) because conditioning reduces entropy, \( Y_i = Z_i + X_i \) and \( X_i \) and \( Z_i \) are independent; Eq. (37) because the Gaussian distribution maximizes entropy and \( X_i \) and \( Z_i \) are independent (where \( P_i \) and \( N \) are the powers of respectively \( X_i \) and \( Z_i \)); Eq. (38) by the concavity of the logarithm function.

Proof of Lemma 1 The proof consists of finding the conditions that turn the inequalities in the proof of Theorem 1 into equalities. Equality in Eqs. (29) and (32) directly imply condition 4. Equality in Eq. (30) implies that \( A - \hat{A}_i \) are Gaussian. Equality in Eq. (32) implies that \( H(A|Y^i) = H(A|g(Y^i)) = H(A|g(Y^i)) \), so that \( Y^i \rightarrow g(Y^i) \rightarrow \hat{A}_i \) should form a Markov chain, implying condition 5. Equality in Eq. (36) implies condition 3. Equality in Eq. (37) implies that the \( Y_i \)'s are Gaussian. Eq. (38) implies condition 2 by concavity of the logarithm. Finally, \( X_i \) is Gaussian, as the result of the sum of \( Y_i \) and \( Z_i \), both Gaussian. Similarly, \( \hat{A}_i \) is Gaussian as both \( A \) and \( A - \hat{A}_i \) are Gaussian, which finally yields condition 1.

Proof of Theorem 2 On one hand, \( X_i = E[X_i|A, \hat{A}_i] \) is a linear function of \( A \) and \( \hat{A}_i^{i-1} \), because the conditional expectation is linear for Gaussian variables. On the other hand, condition 3 reads that \( \mathbb{E}[A_i, \hat{A}_i^{i-1}] = \mathbb{E}[g(X_i + Z_i)|\hat{A}_i^{i-1}] = 0 \). Because \( Z_i \) is independent from \( X_i \) and \( \hat{A}_i^{i-1} \), and \( g \) is linear, we get \( \mathbb{E}[g(X_i)|\hat{A}_i^{i-1}] = 0 \). Combining the two results, and because \( g \) is linear, we have \( \mathbb{E}[\alpha_i (A - \hat{f}(\hat{A}_i^{i-1}))|\hat{A}_i^{i-1}] = 0 \). The orthogonality principle clearly appears and \( \hat{f} = \mathbb{E}[A|\hat{A}_i^{i-1}] \) is the MMSE estimator.

Proof of Theorem 2 The goal is to evaluate \( \mathbb{E}[A|Y_{i-1}] \). We first use the operational formula for the conditional expectation \( \mathbb{E}[A|Y_{i-1}] = \mathbb{E}[AY_{i-1}]\mathbb{E}[Y_{i-1}|Y_{i-1}]^{-1} \mathbb{E}[Y_{i-1}] \). We get, using the fact that the \( Y_j \) are independent and have power \( P + N \):

\[
\mathbb{E}[A|Y_{i-1}] = \sum_{j=1}^{i-1} (P + N)^{-1} \mathbb{E}[AY_j] Y_j.
\]

Second, it follows from previous computations that \( A - A_i = \mathbb{E}[A|Y_{i-1}] \), which is a function of the observations \( Y_{i-1} \) and therefore independent of \( Y_i \). This leads to \( A - A_i \) being independent of \( Y_i \) and the following equality: \( \mathbb{E}[A_i Y_i] = \mathbb{E}[A_i Y_i] \).

Combining both results, we thus get

\[
\mathbb{E}[A|Y_{i-1}] = \sum_{j=1}^{i-1} \mathbb{E}[A_i Y_j] = \sum_{j=1}^{i-1} \mathbb{E}[A_i Y_j].
\]

Proof of Theorem 3 First notice that we can write \( D_i \) as \( \mathbb{E}[(A_i - \mathbb{E}[A_i|Y_i])^2] \) as \( A \rightarrow \hat{A}_i = A - \hat{A}_i^{i-1} - \mathbb{E}[A_i|Y_i] = A_i - \mathbb{E}[A_i|Y_i] \). Next, we have that

\[
D_i = \mathbb{E}(A_i^2) + \mathbb{E}[\mathbb{E}^2(A_i|Y_i)] - 2 \mathbb{E}(A_i \mathbb{E}(A_i|Y_i))
\]

From the proof above,

\[
\mathbb{E}[A_i|Y_i] = \mathbb{E}[A_i Y_i|(P + N)^{-1} Y_i = \frac{P}{\alpha_i (P + N)} Y_i.
\]

With some calculus and using \( \mathbb{E}(A_i^2) = D_{i-1} = P/\alpha_i^2 \), we get that

\[
D_i = \frac{D_{i-1}}{1 + P/N}.
\]

The proof is finished by applying this equation recursively.
