Abstract. We unify several seemingly different graph and digraph classes under one umbrella. These classes are all broadly speaking different generalizations of interval graphs, and include, in addition to interval graphs, also adjusted interval digraphs, threshold graphs, complements of threshold tolerance graphs (known as 'co-TT' graphs), bipartite interval containment graphs, bipartite co-circular arc graphs, and two-directional orthogonal ray graphs. (The last three classes coincide, but have been investigated in different contexts.) This common view is made possible by introducing loops. We also show that all the above classes are united by a common ordering characterization, the existence of a min ordering. We propose a common generalization of all these graph and digraph classes, namely signed-interval digraphs, and show that they are precisely the digraphs that are characterized by the existence of a min ordering. We also offer an alternative geometric characterization of these digraphs. For most of the above example graph and digraph classes, we show that they are exactly those signed-interval digraphs that satisfy a suitable natural restriction on the digraph, like having all loops, or having a symmetric edge-set, or being bipartite. (For instance co-TT graphs are precisely those signed-interval digraphs that have each edge symmetric.) We also offer some discussion of recognition algorithms and characterizations, saving the details for future papers.

1 Introduction

A digraph $H$ is reflexive if each $vv \in E(H), v \in V(H)$ ($H$ has all loops); irreflexive if no $vv \in E(H)$ ($H$ has no loops); and symmetric if $ab \in E(H)$ implies $ba \in E(H)$. In this paper, we shall treat both graphs and digraphs; for simplicity we view graphs as symmetric digraphs. (Thus graphs can have loops, and irreflexive graphs are loopless.) Loops will play an important role in this paper, and this is not common in the literature. They will allow us to view several seemingly unrelated graph classes through a common lens.

Our goal in this paper is to promote a class of digraphs (or 0,1-matrices) that is a broad generalization of interval graphs, while retaining some of the appeal of interval graphs. Recall that a graph $H$ is an interval graph if it is the intersection graph of a family of intervals on the real line, i.e., if there exist intervals $[x_v, y_v], v \in V(H)$, such that $uv \in E(H)$ if and only if $[x_u, y_u] \cap [x_v, y_v] \neq \emptyset$. An equivalent definition says $H$ is an interval graph if and only if there exist two mappings $v \rightarrow x_v$ and $v \rightarrow y_v$, such that each $x_v \leq y_v$, and $uv \in E(H)$ if and only if $x_u \leq y_v$ and $x_v \leq y_u$. Either the intervals $[x_v, y_v], v \in V(H)$, or the two mappings $v \rightarrow x_v$ and $v \rightarrow y_v$, are considered to be an interval model of $H$. We note that (according to either definition) an interval graph is reflexive. A related concept for bipartite graphs is as follows. A bipartite graph $H$ with parts $A, B$ is an interval bigraph if there are intervals $I_a, a \in A$, and $J_b, b \in B$, such that $ab \in E(H)$ if and only if $J_b \cap I_a \neq \emptyset$.

Interval graphs are important in graph theory and in applications, and are distinguished by several elegant characterizations and efficient recognition algorithms [3,12,14,17,28,35].
For this reason, there have been attempts to extend the concept to digraphs \[34\], with mixed success. (Much of their appeal was lost.) More recently a smaller class of digraphs has been found to offer a nicer generalization of interval graphs; these are the adjusted interval digraphs \[11\]. A digraph \( H \) is an adjusted interval digraph if there are two families of real intervals \( [x_v, y_v], [x_v, z_v], v \in V(H) \) such that \( uv \in E(H) \) if and only if \( [x_u, y_u] \cap [x_v, z_v] \neq \emptyset \). Equivalently, \( H \) is an adjusted interval digraph if and only if there exist three mappings \( v \to x_v, v \to y_v, \) and \( x \to z_v \) such that each \( x_v \leq y_v, x_v \leq z_v \), and \( uv \in E(H) \) if and only if \( x_u \leq z_v \) and \( x_v \leq y_u \). When each \( y_v = z_v \), adjusted interval digraphs are precisely the interval graphs. An adjusted interval model of \( H \) is the set of intervals \( [x_v, y_v], [x_v, z_v], v \in V(H) \), or, equivalently, the three mappings \( v \to x_v, v \to y_v, \) and \( x \to z_v \). Note that, like interval graphs, adjusted interval digraphs are reflexive.

In addition to interval intersection, adjacency on a set of intervals can also be defined by containment. A graph is a containment graph of intervals \[35\] if there is a family of intervals on the real line such that two vertices are adjacent if and only if one of the corresponding intervals contains the other. A graph is a containment graph of intervals if and only if it and its complement are both transitively orientable, thus if and only if it is a permutation graph \[35\]. For us a more relevant class is a bipartite version of this concept. A bipartite graph \( H \) with parts \( A, B \) is an interval containment digraph \[35\] if there are intervals \( I_a, a \in A, \) and \( J_b, b \in B, \) such that \( ab \in E(H) \) if and only if \( J_b \subseteq I_a \). These graphs have been studied, from the point of view of another geometric representation, as two-directional orthogonal ray graphs \[33\]. A bipartite graph \( H \) with parts \( A \) and \( B \) is called a two-directional orthogonal ray graph if there exists a set \( U_a, a \in A, \) of upwards vertical rays, and a set \( R_b, b \in B, \) of horizontal rays to the right such that \( ab \in E(H) \) if and only if \( U_a \cap R_b \neq \emptyset \). It is known that a bipartite graph is an interval containment graph if and only if it is a two-directional orthogonal ray graph \[26\], or if and only if its bipartite complement is a circular arc graph \[9\].

It is sometimes convenient to view bipartite graphs as digraphs, with all edges oriented from part \( A \) to part \( B \); thus we speak of a biparitite interval containment digraph, a bipartite interval digraph, or a two-directional orthogonal ray digraph. In general, a bipartite digraph is a bipartite graph with parts \( A \) and \( B \) and all arcs being oriented from \( A \) to \( B \).

There is an interesting intermediate concept that uses both intersection and containment of intervals to define adjacency. To describe it we will start with threshold tolerance graphs. A graph \( H \) is a threshold tolerance graph \[31\] if its vertices \( v \) can be assigned weights \( w_v \) and tolerances \( t_v \) so that \( ab \) is an edge of \( H \) if and only if \( w_a + w_b > t_a \) or \( w_a + w_b > t_b \). (When all \( t_v \) are equal, this defines a better known class of threshold graphs \[5\].) Co-threshold tolerance graphs are complements of threshold tolerance graphs. Equivalently, a graph \( H \) is a co-threshold tolerance (‘co-TT’) graph, if there exist real numbers \( x_v, y_v, v \in V(H) \), such that \( ab \in E(H) \) if and only if \( x_a \leq y b \) and \( x_b \leq y_a \). (This is easily seen by letting \( x_v = w_v \) and \( y_v = t_v - w_v \).) The two mappings \( v \to x_v \) and \( v \to y_v \), are called the co-TT model of \( H \). Comparing this definition with the definition of interval graphs we see that formally they are very similar, except there are now intervals whose ‘beginning’ \( x_v \) may come after their ‘end’ \( y_v \). In other words, we may have ‘intervals’ \( [x_v, y_v] \) with \( y_v < x_v \). We may view a co-TT model as consisting of intervals \( [x_v, y_v], v \in V(H) \), some of which go in the positive direction (have \( x_v \leq y_v \)) and others go in the negative direction (have \( x_v > y_v \)). We speak of positive or negative intervals,
and positive or negative vertices that correspond to them. In the literature \[13,15,19,20,31\], the direction is encoded in colours of the intervals: positive intervals, and vertices, are coloured blue, and negative intervals, and vertices, are coloured red. The above definition of adjacency has interesting consequences. Two blue vertices are adjacent if and only if they intersect; in particular, each blue vertex has a loop. Two red vertices are never adjacent; in particular red vertices have no loops. Finally, a blue vertex \(u\) corresponding to a blue interval \([a, b]\) and a red vertex \(v\) corresponding to a red interval \([c, d]\) are adjacent if and only if \([d, c]\) is contained in \([a, b]\) (i.e., \(a \leq d \leq c \leq b\)). We also use the following signed shorthand (that will be useful later): a positive (blue) vertex or interval will be called a \(+\)-vertex or \(+\)-interval respectively, and a negative (red) vertex or interval will be called a \(-\)-vertex or \(-\)-interval respectively. It follows from the above discussion that in a co-TT graph, the \(+\)-vertices induce a reflexive interval graph, the \(-\)-vertices form an independent set, and the edges between the \(+\)-vertices and the \(-\)-vertices form a bipartite interval containment graph.

Note that co-TT graphs are a generalization of interval graphs – if all intervals are blue we obtain interval graphs. In other words, the reflexive co-TT graphs are precisely interval graphs.

We have seen extensions of interval graphs in two different directions. First, by taking two (adjusted) intervals instead of just one interval, we were able to extend the definition from reflexive graphs to reflexive digraphs. Second, by admitting intervals \([a, b]\) that go in the negative direction (have \(b < a\)), we were able to extend the definition from reflexive graphs to graphs that have some vertices with loops and others without. Both these generalizations have proved very fruitful \[13,15,19,20,31\]. In this paper we show that these two extensions can be unified, i.e., there is a class of digraphs that has both these extensions as special cases.

We define a digraph \(H\) to be a signed-interval digraph if there exist three mappings \(v \mapsto x_v, v \mapsto y_v, \) and \(x \mapsto z_v\) such that \(uv \in E(H)\) if and only if \(x_u \leq z_v\) and \(x_v \leq y_u\). We call the three mappings \(v \mapsto x_v, v \mapsto y_v, \) and \(x \mapsto z_v\) a signed-interval model of \(H\). Alternatively, we call a signed-interval model of \(H\) the family of adjusted pairs of intervals \(I_v = [x_v, y_v], J_v = [x_v, z_v], v \in V(H)\). Since it is possible that \(x_v > y_v\) and/or \(x_v > z_v\), we may have negative intervals \([x_v, y_v]\) and/or \([x_v, z_v]\). Even though the pairs of intervals \(I_v = [x_v, y_v], J_v = [x_v, z_v]\) are adjusted, we avoid adding another adjective (‘adjusted’) to the already long term ‘signed-interval digraph’; we view a pair of signed-intervals as naturally adjusted, by definition. Signed-interval digraphs with all intervals positive, are reflexive, and are precisely the adjusted interval digraphs. Signed-interval digraphs with all \(y_v = z_v, v \in V(H)\), are symmetric, and are precisely the co-TT graphs. Signed-interval digraphs that satisfy both conditions, i.e., with all \(x_v \leq y_v = z_v, v \in V(H)\), are precisely the interval graphs. Furthermore, we will show that there are no reflexive signed-interval digraphs other than adjusted interval digraphs, no symmetric signed-interval digraphs other than co-TT graphs, and no reflexive and symmetric signed-interval digraphs other than interval graphs.

The structure of signed-interval digraphs can be described in a language similar to what was done for co-TT graphs. Let \(H\) be a signed-interval digraph and consider a signed-interval model of \(H\) given by the ordered pairs \((I_v, J_v)\) of intervals where \(I_v = [x_v, y_v]\) and \(J_v = [x_v, z_v]\). For \(\alpha, \beta \in \{+, -\}\), we say a vertex \(v\) is of type \((\alpha, \beta)\) if \(I_v\) is an \(\alpha\)-interval and \(J_v\) is a \(\beta\)-interval. The subdigraph of \(H\) induced by \((+, +)\)-vertices is an adjusted interval digraph. The \((-, -)\)-vertices of \(H\) form an independent set. The arcs between the \((+, -)\) and \((-,-)\)-vertices form
a bipartite interval containment digraph. The arcs between the \((-, +)\)- and \((-,-)\)-vertices also form a bipartite interval containment digraph. Similar properties hold for the other parts and their connections.

We emphasize that our definition of co-TT graphs differs from the standard definition \([13,15,31]\). In the standard definition the condition \(ab \in E(H) \iff x_a \leq y_b \text{ and } x_b \leq y_a\) is applied only for \(a \neq b\), and so the graphs have no loops. Thus a graph under the standard interpretation is co-TT if and only if with a suitable addition of loops it is co-TT under our definition above. This difference is not important as it was shown in \([14]\) that if a graph \(H\) is co-TT (in the standard sense), then it has a co-TT model with red intervals for all simplicial vertices without true twins and all other intervals blue. Thus there is an easy translation between the co-TT graphs as defined here and the standard irreflexive co-TT graphs: namely, loops are to be placed on all vertices other than simplicial vertices without true twins.

Interestingly, interval graphs, adjusted interval digraphs, co-TT graphs, and two-directional orthogonal ray digraphs all share a common ordering characterization. A min ordering of a digraph \(H\) is a linear ordering \(<\) of the vertices of \(H\), so that \(ab \in E(H), a'b' \in E(H)\) and \(a < a', b < b'\) implies that \(ab' \in E(H)\). Interval graphs, adjusted interval digraphs, co-TT graphs, and two-directional orthogonal ray digraphs all have min ordering \([8,11,22,33]\).

Min orderings are a useful tool for graph homomorphism problems. A homomorphism of a digraph \(G\) to a digraph \(H\) is a mapping \(f : V(G) \rightarrow V(H)\) such that \(f(u)f(v) \in E(H)\) whenever \(uv \in E(G)\). If a digraph \(H\) has a min ordering, there is a simple polynomial-time algorithm to decide if a given input graph \(G\) admits a homomorphism to a fixed digraph \(H\) \([16,23]\). In fact, the algorithm is well known in the AI community as the arc-consistency algorithm \([23]\); it is easy to see that it also solves list homomorphism problems, where we seek a homomorphism of input \(G\) to fixed \(H\) taking each vertex of \(G\) to one of a ‘list’ of allowed images. In fact, many (but not all) homomorphism and list homomorphism problems that can be solved in polynomial time, can be solved using arc-consistency with respect to a min ordering.

We will prove that a digraph has a min ordering if and only if it is a signed-interval digraph. We will also give another geometric characterization of signed-interval digraphs, as bi-arc digraphs. We will show that a reflexive signed-interval digraphs are precisely adjusted interval digraphs, that symmetric signed-interval digraphs are precisely co-TT graphs, that reflexive and symmetric signed-interval digraphs are precisely interval graphs, and that bipartite signed-interval digraphs are precisely two-directional ray graphs.

### 2 Min ordering

In this section we prove the following general result.

**Theorem 1.** A digraph admits a min ordering if and only if it is a signed-interval digraph.

Before embarking on the proof we offer an alternate definition of a min ordering. Consider any linear ordering \(<\) of \(V(H)\), and denote by \(O(a)\) the last vertex \(b\) (in the order \(<\)), such that \(b\) is an out-neighbour of \(a\) (i.e., such that \(ab \in E(H)\)). Similarly, for each vertex \(b\), we denote by \(I(b)\) the last vertex \(a\) such that \(a\) is an in-neighbour of \(b\) (i.e., such that \(ab \in E(H)\)).
**Proposition 1.** A linear ordering $<$ of $V(H)$ is a min ordering of a digraph $H$ if and only if the following property holds:

$$ab \in E(H) \text{ if and only if } a \leq I(b) \text{ and } b \leq O(a).$$

**Proof.** Suppose first that $<$ is a min ordering of $H$. If $ab \in E(H)$, then by the definition of $O(a), I(b)$ we have $a \leq I(b)$ and $b \leq O(a)$. On the other hand, let $a \leq I(b)$ and $b \leq O(a)$. Note that if $a = I(b)$ or $b = O(a)$ we have $ab \in E(H)$ also by definition. Therefore we it remains to consider vertices $a, b$ such that $a < c = I(b)$ and $b < d = O(a)$. Then $ad, cb \in E(H)$ and the min ordering property implies that $ab \in E(H)$. This proves the property.

Conversely, assume that $v <$ is a linear ordering of $V(H)$ in which the property holds. We claim it is a min ordering of $H$. Otherwise some $ab \in E(H), a'b' \in E(H), a < a', b < b'$ would have $ab' \not\in E(H)$. This is a contradiction, since we have $a < a' \leq I(b')$ and $b' < b \leq O(a)$. □

We proceed to prove the theorem.

**Proof.** Suppose $<$ is a min ordering of a digraph $H$. We represent each vertex $v \in V(H)$ by the mappings $v \mapsto v, v \mapsto O(v), v \mapsto I(v)$. In other words, $v$ is represented by the two intervals $[v, O(v)]$ and $[v, I(v)]$. It follows from Proposition 1 that $ab \in E(H)$ if and only if $a \leq I(b)$ and $b \leq O(a)$. Thus $H$ is a signed-interval digraph.

Conversely, suppose we have the three mappings $v \mapsto x_v, v \mapsto y_v, v \mapsto z_v$, such that $ab \in E(H)$ if and only if $x_a \leq z_b$ and $x_b \leq y_a$. Without loss of generality we may assume that the points $x_v, y_v, z_v$ are all distinct. Then we claim that the left to right ordering of the points $x_v$ yields a min ordering $<$ of $H$. (Specifically, we define $a < b$ if and only if $x_a$ precedes $x_b$.) Consider now $ab \in E(H), a'b' \in E(H)$, with $a < a', b < b'$. This means that $x_a < x_{a'} \leq z_{b'}$ and $x_{b'} < x_b \leq y_a$, whence we must have $ab' \in E(H)$. This completes the proof of the theorem. □

## 3 An alternate geometric representation

It turns out that digraphs that admit a min ordering (also called min-orderable digraphs) have another geometric representation. Let $C$ be a circle with two distinguished points (the poles) $N$ and $S$, and let $H$ be a digraph. Let $I_v, v \in V(H)$ and $J_v, v \in V(H)$ be two families of arcs on $C$ such that each $I_v$ contains $N$ but not $S$, and each $J_v$ contains $S$ but not $N$. We say that the families $I_v$ and $J_v$ are consistent if they have the same clockwise order of their clockwise ends, i.e., if the clockwise end of $I_a$ precedes in the clockwise order the clockwise end of $I_b$ if and only if the clockwise end of $J_a$ precedes in the clockwise order the clockwise end of $J_b$. Suppose two families $I_v, J_v$ are consistent; we define an ordering $<$ on $V(H)$ where $a < b$ if and only if the clockwise end of $I_a$ precedes in the clockwise order the clockwise end of $I_b$; we call $<$ the ordering generated by the consistent families $I_v, J_v$.

A bi-arc model of a digraph $H$ is a consistent pair of families of circular arcs, $I_v, J_v, v \in V(H)$, such that $ab \in E(H)$ if and only if $I_a$ and $J_b$ are disjoint. A digraph $H$ is called a bi-arc digraph if it has a bi-arc model.

**Theorem 2.** A digraph $H$ admits a min ordering if and only if it is a bi-arc digraph.
Proof. Suppose $I_v, J_v$ form a bi-arc model of $H$. We claim that the ordering $<$ generated by $I_v, J_v$ is a min ordering of $H$. Indeed, suppose $a < a'$ and $b' < b$ have $ab, a'b' \in E(H)$. Then $I_{a'}$ spans the area of the circle between $N$ and the clockwise end of $I_a$, and $J_b$ spans the area of the circle between $S$ and the clockwise end of $J_{b'}$. (See Figure 1.) This implies that $I_a$ and $J_{b'}$ are disjoint: indeed, the counterclockwise end of $I_a$ is blocked from reaching $J_{b'}$ by $J_b$ (since $ab \in E(H)$), and the counterclockwise end of $J_{b'}$ is blocked from reaching $I_a$ by $I_{a'}$ (since $a'b' \in E(H)$). (The clockwise ends are fixed by the ordering $<$.)

Conversely, suppose $<$ is a min ordering of $H$. We construct families of arcs $I_v$ and $J_v$, with $v \in V(H)$, as follows. The intervals $I_v$ will contain $N$ but not $S$, the intervals $J_v$ will contain $S$ but not $N$. The clockwise ends of $I_v$ are arranged in clockwise order according to $<$, as are the clockwise ends of $J_v$. The counterclockwise ends will now be organized so that $I_v, J_v, v \in V(H)$ becomes a bi-arc model of $H$. For each vertex $v \in V(H)$, let again $O(v)$ denote the last out-neighbour of $v$, and $I(v)$ the last in-neighbour of $v$, in the order $<$. Then we extend each $I_v$ counterclockwise as far as possible without intersecting $J_{O(v)}$, and extend each $J_v$ counterclockwise as far as possible without intersecting $I_{I(v)}$. We claim this is a bi-arc model of $H$. Clearly, if $b > O(a)$, then $I_a$ intersects $J_b$ by the construction, and similarly for $a > I(b)$ we have $J_b$ intersecting $I_a$. This leaves disjoint all pairs $I_a, J_b$ such that $a \leq I(b)$ and $b \leq O(a)$; since $aO(a), I(b)b \in E(H)$, the definition of min ordering implies that $ab \in E(H)$, as required.

\[ \square \]

**Corollary 1.** The following statements are equivalent for a digraph $H$.

- $H$ has a min ordering
- $H$ is a signed-interval digraph
- $H$ is a bi-arc digraph.

4 0,1-Matrices and bipartite graphs

It turns out that graphs (without loops) with at least one edge do not admit a min ordering. This follows from Corollary 4 in the next section, but it is also easily derived from the definition. (Take the edges $ab$ and $ba$ and derive that at least one of the loops $aa$ or $bb$ must be present.)
Thus a symmetric digraph without loops, i.e., a graph, only admits a min ordering if it has no edges.) However, in the special case of bipartite graphs, a version of min ordering has been studied, and yielded interesting examples. We will describe that version below, but we first want to explain how to view that definition as a special case of min ordering as defined here.

A useful perspective on min orderings is obtained by considering 0,1-matrices. Square 0,1-matrices naturally correspond to adjacency matrices of digraphs. Let \( L \) be the two by two matrix with rows 01 and 11, and let \( K \) be the two by two matrix with rows 01 and 10. (These have been given other names in the literature, up to a simultaneous permutation of rows and columns they are the gamma matrix, and the identity matrix.) A matrix \( M \) is called \( K,L \)-free if it does not contain \( K \) or \( L \) as a submatrix. If \( M \) is the adjacency matrix of a digraph \( H \), and if the rows and columns of \( H \) are in the order \(<\), then \( M \) is \( K,L \)-free if and only if \(<\) is a min ordering. (This follows from straight the definition of a min ordering.) We call a \( M \) a min-orderable matrix if its rows and columns can be simultaneously permuted to produce a \( K,L \)-free matrix. Now a digraph has a min ordering if and only if its adjacency matrix is min-orderable.

Therefore we can say much about matrices that are min-orderable.

**Theorem 3.** A square 0,1-matrix is min-orderable if and only if it is the adjacency matrix of a signed-interval digraph.

Another natural interpretation of a 0,1-matrix is that it represents adjacencies in a bipartite graph, with rows corresponding to one part and columns to the other part. The bi-adjacency matrix of a bipartite graph \( H \) with marts \( A,B \) has its \( i,j \)-th entry is 1 if and only if the \( i \)-th vertex in \( A \) is adjacent to the \( j \)-th vertex in \( B \). Note that for this interpretation it is not required that the matrix be square. For matrices that are not necessarily square, we can still ask for independent permutations of rows and columns, to produce a \( K,L \)-free matrix. This suggests a definition of min ordering for bipartite graphs as follows. A min ordering of a bipartite graph \( H \) with parts \( A,B \) is a linear ordering \(<_A \) of \( A \) and a linear ordering \(<_B \) of \( B \) so that for any \( a,a' \in A, b,b' \in B \) such that \( ab \in E(H), a' b' \in E(H) \) and \( a < a', b < b \) we have \( a b' \in E(H) \). This is the definition that has been used in the literature; it is clear how it avoids the problems of the general definition.

There is a simple transformation that connects the two interpretations of 0,1-matrices. For a matrix \( M \) with \( k \) rows and \( \ell \) columns, we define the \((k + \ell)\) by \((k + \ell)\) square matrix \( M^+ \) to contain the matrix \( M \) in the first \( k \) rows and the last \( \ell \) columns, with 0 everywhere else. Then a simultaneous row/column permutation of \( M^+ \) corresponds to independent row and column permutations of \( M \). Note that the square matrix \( M^+ \) is an adjacency matrix of the digraph obtained from \( H \) by directing all edges from \( H \) from the first part to the second part. Thus to view the special definition of a min ordering for bipartite graphs as a particular case of the general definition, it suffices to view bipartite graphs as digraphs with all edges oriented from the first part to the second part. We shall say that \( H \) is a bipartite digraph if it is obtained from a bipartite graph in this way.

A robust class of bipartite graphs is relevant for our discussion. A bipartite graph \( H \) with parts \( A \) and \( B \) is called a two-directional orthogonal ray graph if there exists a set \( U_a, a \in A, \) of upwards vertical rays, and a set \( R_b, b \in B, \) of horizontal rays to the right such that \( a b \in E(H) \),
if and only if $U_a \cap R_b \neq \emptyset$. Note that we may, if needed, view a two-directional orthogonal ray graph as a bipartite digraph, with all edges oriented from (say) rays to horizontal rays.

The following theorem is obtained by a combination of results from [9,26,33].

**Theorem 4.** The following statements are equivalent for a bipartite graph $H$.

- $H$ is a two-directional orthogonal ray graph
- the complement of $H$ is a circular arc graph
- $H$ is an interval containment graph.

Matrices that can be permuted to avoid small submatrices have been of much interest [1,27,29]. This of course corresponds to characterizations of digraphs by forbidden ordered subgraphs [6,21]. Our focus was on $K,L$-free matrices. Let the matrix $\Gamma$ be obtained from $L$ by simultaneously exchanging the rows and columns; i.e., $\Gamma$ has rows 11, 10. Let $I$ be the two by two identity matrix. It is easy to see that considering $I,\Gamma$-free matrices is equivalent to considering $K,L$-free matrices, as the permutation that simultaneously reverses rows and columns of matrix $M$ transforms a $I,\Gamma$-free matrix to a $K,L$-free matrix and vice versa. Matrices that are $\Gamma$-free have been intensively studied [1,29], cf. [35]. A bipartite graph $H$ is chordal bipartite if it contains no induced cycle other than $C_4$. A reflexive graph is strongly chordal if it contains no induced cycle or induced trampoline. (A trampoline is a complete graph on $v_0, v_1, v_2, \ldots, v_{k-1}, k > 2$ with vertices $u_i, i = 0, 1, \ldots, k - 1$, each only adjacent to $v_i, v_i + 1$, subscripts computed modulo $k$.) The adjacency matrix of a reflexive graph $H$ can be made $\Gamma$-free by simultaneous row / column permutations if and only if $H$ is strongly chordal; the bi-adjacency matrix of a bipartite graph $H$ can be made $\Gamma$-free by independent permutations of rows and columns if and only if $H$ is chordal bipartite [1]. These results amount to forbidden structure characterizations of matrices that are permutable (by simultaneous or independent row and column permutations) to a $\Gamma$-free format. Algorithms to recognize such matrices efficiently have been given in [29,32]. For $L$-free matrices, or equivalently, for $I$-free matrices a forbidden structure characterization is given in [20]. An $O(n^2)$ recognition algorithm is claimed in [2], cf. [33].

5 Special cases

We now explore what min orderings look like in the special cases we have discussed, namely reflexive graphs, reflexive digraphs, undirected graphs, and bipartite graphs. The results are all corollaries of Theorem [1] and Proposition [1].

**Corollary 2.** A reflexive graph $H$ is a signed-interval digraph if and only if it is an interval graph.

**Corollary 3.** A reflexive digraph $H$ is a signed-interval digraph if and only if it is an adjusted interval digraph.

Next we focus on symmetric digraphs, i.e., graphs.

**Corollary 4.** A graph $H$ is a signed-interval digraph, i.e., has a min ordering, if and only if it is a co-TT graph.
Proof. Consider a co-TT model of $H$, given by the mappings $v \mapsto x_v, v \mapsto y_v$, setting the third mapping $v \mapsto z_v$ with each $z_v = y_v$, yields a signed-interval digraph model of $H$. Conversely, assume $H$ is a graph, i.e., a symmetric digraph, that is a signed-interval digraph. Let $<$ is a min ordering of $H$; we again have $O(v) = I(v)$ for all vertices $v$. We claim that the mappings $v \mapsto x_v = v, v \mapsto y_v = O(v)$ define a co-TT model. Indeed, from Proposition 1 we have $ab \in E(H)$ if and only if $a \leq O(b) = y_b$ and $b \leq O(a) = y_a$, as required. □

Finally, for bipartite graphs we have the following result, stated for convenience in the language of bipartite digraphs. Note that this has only one consequence, that is, when we consider an edge $ab \in E(H)$ we always assume $a \in A$ and $b \in B$.

Corollary 5. A bipartite digraph $H$ is a signed-interval digraph, i.e., has a min ordering, if and only if it is a two-directional orthogonal ray graph.

Note that two-directional orthogonal ray graphs themselves have two other equivalent characterizations in Theorem [4]. The characterization of two-directional orthogonal ray graph by the existence of a min ordering is also observed in [22,33].

Proof. Suppose $H$ has a signed-interval model given by the three mappings $v \mapsto x_v, x \mapsto y_v, x \mapsto z_v$ such that $ab \in E(H)$ if and only if $x_a \leq z_b$ and $x_b \leq y_a$. We construct a two-directional ray model for $H$ as follows. For each $a \in A$, we take an upwards vertical ray starting in the point $P_a$ with $x$-coordinate equal to $y_a$ and with $y$-coordinate equal to $x_a$. For each $b \in B$, we take a horizontal ray to the right, starting in the point $Q_b$ with $x$-coordinate $x_b$ and $y$-coordinate $z_b$. Now $P_a$ intersects $Q_b$ if and only if $x_b \leq y_a$ and $x_a \leq z_b$, i.e., if and only if $ab \in E(H)$ as required.

Now suppose that $H$ has a two-directional model, i.e., upwards vertical rays $U_a, a \in A$, and horizontal rays to the right $R_b, b \in B$, such that $ab \in E(H)$ if and only if $U_a \cap R_b \neq \emptyset$. We will prove that $H$ has a min ordering, whence it is a signed-interval digraph by Theorem [1]. We will define the orders $<$ on $A$ and on $B$ as follows. Assume the starting point of the vertical ray $U_a$ has the $(x,y)$-coordinates $(u_a, v_a)$, and the starting point of the horizontal ray $R_b$ has the $(x,y)$-coordinates $(r_b, s_b)$, for $a \in A$, and $b \in B$. It is easy to see that we may assume, without loss of generality, that all $u_a, a \in A$, and $r_b, b \in B$ are distinct, and similarly for $v_a, a \in A$ and $s_b, b \in B$. We define $a < a'$ in $A$ if and only if $v_a < v_{a'}$, and define $b < b'$ in $B$ if and only if $r_b < r_{b'}$. We show that these is a min ordering of the bipartite digraph $H$. Otherwise, some $ab \in E(H), a'b' \in E(H), a < a', b' < b$ have $ab' \not\in E(H)$. There are two possibilities for $ab' \not\in E(H)$; either $u_a < r_{b'}$ or $u_a > r_{b'}, v_a > s_{b'}$. In the former case, $U_a \cap R_{b'} = \emptyset$, in the latter case $U_a \cap R_{b'} = \emptyset$, contradicting the assumptions. This concludes the proof. □

6 Algorithms and characterizations

Interval graphs are known to have elegant characterization theorems [12,28], cf. [14,35], and efficient recognition algorithms [3,4,17]. Thus one might hope to be able to obtain similar results for their generalizations and digraph analogues. This is true for all the generalizations described in this paper, at least to some degree. In this section we summarize what is known.
The prototypical characterization of interval graphs is the theorem of Lekkerkerker and Boland [28]. In our language, it states that a reflexive graph $H$ is an interval graph if and only if it contains no asteroidal triple and no induced $C_4$ or $C_5$. An asteroidal triple consists of three non-adjacent vertices such that any two are joined by a path not containing any neighbours of the third vertex. An equivalent characterization by the absence of a slightly less concise obstruction is given in [11]. A reflexive graph $H$ is an interval graph if and only if it contains no invertible pair. An invertible pair is a pair of vertices $u, v$ such that there exist two walks of equal length, $P$ from $u$ to $v$, and $Q$ from $v$ to $u$, where the $i$-th vertex of $P$ is non-adjacent to the $(i+1)$-st vertex of $Q$ (for each $i$), and also two walks of equal length $R, S$ from $v$ to $u$ and $u$ to $v$ respectively, where the $i$-th vertex of $R$ is non-adjacent to the $(i+1)$-st vertex of $S$ (for each $i$). It is not difficult to see that an asteroidal triple is a special case of an invertible pair. A number of variants of the definition of an invertible pair have arisen [11,19,20,22], and they have proved useful to give characterization theorems for various classes. It is proved in [11] that a reflexive digraph is an adjusted interval digraph if and only if it contains no directed invertible pair. A directed version of an invertible pair is defined in [11] in a manner similar to the above definition of an invertible pair. With yet another labeled version of an invertible pair, we have the following obstruction characterization of co-TT graphs: a graph is a co-TT graph if and only if it contains no labeled invertible pair [19]. For bipartite graphs, an analogous bipartite version of an invertible pair yields the following result. A bipartite graph is a two-directional orthogonal ray graph if and only if it contains no bipartite invertible pair [22]. In fact, in [9] a stronger version is shown: there is a bipartite analogue of an asteroidal triple, called an edge-asteroid, and a bipartite graph is a two-directional orthogonal ray graph if and only if it contains no induced 6-cycle and no edge-asteroid. Finally, there is an obstruction characterization for a signed-interval digraphs, which is a little more technical than just an invertible pair, [25]. A digraph is a signed-interval digraph if and only if it contains no invertible circuit. Roughly speaking, while an invertible pair $u, v$ has suitable walks from the ordered pair $(u, v)$ to the ordered pair $(v, u)$ and back to $(u, v)$; an invertible circuit $u_0, u_1, \ldots, u_k$ has similar walks from the pair $(u_0, u_1)$ to $(u_1, u_2)$, then from $(u_1, u_2)$ to $(u_2, u_3)$, and so on, until a walk from $(u_k, u_0)$ to $(u_0, u_1)$ [25].

There is a long history of efficient algorithms for the recognition of interval graphs, many of them linear time, starting from [3] and culminating in [4]. A polynomial time algorithm for the recognition of adjusted interval digraphs is given in [11]. It is not known how to obtain a linear time, or even near-linear time algorithm. An $O(n^2)$ algorithm for the recognition of two-directional orthogonal ray graphs follows from Theorem 4 and [30]. A more efficient algorithm in this case is also not known. On the other hand, an $O(m \log n)$ algorithm for the recognition of co-TT graphs will be given in [19]. We also claim a polynomial time algorithm for the recognition of signed-interval digraphs, cf. [25].
