1 INTRODUCTION

Information networks are ubiquitous in our daily life and different useful information can be extracted by mining them intelligently. Machine learning applications such as node clustering (a.k.a, community detection), visualization, multi-class classification are some of the well-known problems in research community. All these tasks need a set of independent and informative features. Typically a network is represented in the form of a graph. Different types of raw representations like adjacency matrix or adjacency list have been used as a direct input to many machine learning algorithms. Unfortunately it is very difficult for machine learning algorithms to mine useful information from these representations as they belong to a very high dimensional space and also are highly sparse in nature. In the last few years, network embedding has emerged as a central topic of network research. Network embedding maps the high dimensional networks to a low dimensional vector space such that the information loss is minimum in some sense, and also the features used in the representation are discriminative and independent in nature. There are different types of network embedding methods that exist in the literature such as Deepwalk [18], Line [21], node2vec [8], TADW [27], etc.

Learning network representation or embedding has various advantages over mining directly on the network data. There is no need to extend the basic algorithms for different machine learning tasks. Most of the embedding methods are claimed to be generic so that existing machine learning algorithms for classification or clustering can perform well on these embeddings. Network embedding techniques are mostly unsupervised or semi-supervised in nature as it is common to encounter networks with a small number of labelled nodes or without any labelled node. Hence not much supervision is required to learn the embeddings. It is also possible to retain various network properties such as community structure, homophily in the resultant node embeddings.

These properties are naturally associated with each other. Homophily in networks characterizes communities based on the similarity between the nodes involved. Even though such similarity is captured, typically, based on structural properties of the network, combining the semantic content associated with the nodes can help in exploiting homophily better. From an optimization viewpoint better embeddings can be obtained by regularizing the objective based on structural data using semantics and vice versa. Besides, integrating content present in the nodes has been shown to be useful in various mining tasks such as unsupervised ranking of...

Unfortunately, most of the existing network embedding algorithms consider only the network structure such as nodes and the links while learning the low dimensional representation. But in most of the real-world networks, nodes are also associated with rich content in the form of text or images characterizing them. Naturally a network embedding is semantically incomplete without the use of such rich content. Lately there is some effort to fuse structure of the network with content to get better embeddings. We will briefly discuss them in the next section.

Following are the key contributions made in this paper.

- We propose a nonnegative matrix factorization based optimization framework, namely FSCNMF which considers both the network structure and the content of the nodes while learning a lower dimensional vector representation of each node in the network. Our approach successfully exploits the coherence across the network structure and the content of the nodes.
- We further extend the basic FSCNMF to an advanced method, namely FSCNMF++ to capture the higher order proximities in the network.
- We conduct experiments on real world information networks for different types of machine learning applications such as node clustering, network visualization and multi-class classification. The results demonstrate the superiority of our algorithms than the state-of-the-art approaches and improves the performance for all the applications that we consider.

The rest of the paper is organized as follows. Section 2 discusses the state-of-the-art network embedding techniques and detects some research gap there. Next we formally present the problem description in Section 3. The detailed analysis of the optimization framework and the algorithms proposed by us are recorded in Section 4. Section 5 experimentally shows the merit of our approach over the baseline algorithms on multiple real networks. Finally we conclude with the key observations in Section 6.

2 RELATED WORK

In this section, we briefly discuss some of the important related works from different perspective. Detailed survey on network embedding (NE) or Network Representation Learning (NRL) can be found in [9] or [31]. Feature engineering techniques were there for networks for a long time. Conventional feature extraction methods use hand-crafted features based on the domain knowledge related to the networks [7]. Different linear and non-linear unsupervised dimensionality reduction approaches such as PCA [26] and ISOMAP [1] have also been used to map the network to a lower dimensional vector space.

**Sampling based Embedding**: Advancement of the representation learning for natural language modeling has motivated the researchers to adopt them in the domain of information networks. DeepWalk [18] uses the idea of vector representation of words [14] in a document to node representation in networks. A document can be represented by a sequence of words. Similar to that, a network can also be represented by a sequence of nodes. DeepWalk employs a uniform random walk from a node until the maximum length of the random walk is reached. Two different objective functions have been used to capture first and second order proximities respectively and an edge sampling strategy is proposed to solve the joint optimization for node embedding in Line [21]. In node2vec [8], authors have proposed a biased random walk to explore the diverse neighborhood while incorporating first and second order proximities in network representation. All these methods use different sampling strategies or different hyper parameters to obtain the best network embedding for a particular task. Hence it is difficult to find the best strategy which is consistent over different types of networks.

**DL based Embedding**: There are also some network embedding techniques based on deep learning. In [24], authors propose a structural deep network embedding method where they first propose a semi-supervised deep model with multiple layers of non-linear functions. Then second-order proximity is used by the unsupervised component to capture the global network structure. The idea of using convolutional neural networks for graph embedding has been proposed in [16]. Deep learning architecture has also been used for heterogeneous networks [3]. A modified sampling strategy based on different meta-path schemes is used to represent the heterogeneous networks which has been proposed in [6].

**NMF based Embedding**: Nonnegative matrix factorization based network embedding techniques have also been explored in the literature to some extent. A network representation approach based on factorizing higher orders of adjacency matrix has been proposed in [2]. In [23], authors have shown the equivalence of Deepwalk embedding technique to that of a matrix factorization objective, and further combined that objective to a max-margin classifier to propose a semi-supervised network embedding technique. Modularity maximization based community detection method has been integrated with the objective of nonnegative matrix factorization in [25] to represent an information network. In [28], authors have captured different node proximities in a network by respective powers of the adjacency matrix and proposed an algorithm to approximate the higher order proximities. NMF has been successfully used in a variety of soft clustering applications. It was shown to perform a acceptable clustering of the data, specifically it can locate objects present in the images as clusters of pixels.

**Incorporating Content in Embedding**: A major limitation in all of the above works is that they use only the network structure for embedding. But for most of the real-world networks, rich content information such as textual description is associated with the nodes. Fusing such content is not straightforward in any of the above approaches. There is some limited amount of work present in the literature to fuse structure with content for network representation. In [27], authors have presented a matrix factorization based approach (TADW) for fusing content and structure. But their framework directly learns one embedding from content and structure together. In case when there is noise or inconsistency between structure and content, such a direct approach is prone to be affected more. Extending the idea of TADW, a semi supervised approach for node embedding based on matrix factorization which incorporates empirical loss minimization on the labeled nodes has been proposed in [30]. Compared to these existing works, we propose a novel NMF based optimization framework, which derives two representations based on structure and the content of a network, and iteratively minimizes the distance between them in some sense.
3 PROBLEM FORMULATION

An information network is typically represented by a graph as \( G = (V, E, F) \), where \( V = \{v_1, v_2, \ldots, v_n\} \) is the set of nodes (a.k.a. vertices), each representing a data object. \( E \subset \{(v_i, v_j) | v_i, v_j \in V\} \) is the set of edges between the vertices. Each edge \( e \in E \) is an ordered pair \( (v_i, v_j) \) and is associated with a weight \( w_{v_i, v_j} \geq 0 \), which indicates the strength of the relation. If \( G \) is undirected, we have \((v_i, v_j) \equiv (v_j, v_i)\) and \( w_{v_i, v_j} = w_{v_j, v_i} \); if \( G \) is unweighted, \( w_{v_i, v_j} = 1, \forall (v_i, v_j) \in E \). \( F = \{f_j | i \in \{1, 2, \ldots, n\}\} \), where \( f_j \in \mathbb{R}^d \) is the word vector (content) associated with the node \( v_i \). For simplicity we assume the content to be only text in the textual content at the corresponding node. So the dimension of the matrix \( C \) is \( n \times d \), where \( d \) is the number of unique words (after preprocessing) in the corpus. Given \( G \), the task is to find some low dimensional vectorial representation of \( G \) which is consistent both in structure of the network and also to the content of the nodes. More formally, for the given network \( G \), the network embedding is to learn a function \( f : v_i \mapsto y_i \in \mathbb{R}^k \), i.e., it maps every vertex to a \( k \) dimensional vector, where \( k < \min(n, d) \). The representations should preserve the underlying semantics of the network. Hence the nodes which are close to each other in terms of their positional distance or similarity in content should have similar representation. This representation should also be compact and continuous as that would help the machine learning algorithms to perform better.

4 SOLUTION APPROACH

NMF has been shown to be effective to find the underlying semantic in a network. NMF based optimization has also been used in literature in the context of network embedding [23, 27]. In this paper, we propose an optimization framework based on NMF to fuse structure and content of a network with proper regularization. Here adjacency matrix \( A \) is based on the structure of the network, whereas the content matrix \( C \) is based on the textual content in each node of the graph. Hence in a ideal scenario, the representations found solely based on \( A \) would match well with the representations found solely based on \( C \). But in reality, they may differ due to noise and topological inconsistency in the network. But still there should be a strong semantic coherence between the two, and that is what we want to leverage in this framework.

4.1 FSCNMF: The Optimization Formulation

Given \( A \) and \( C \), initially we have the following factorizations available: \( A = B_1B_2 \) and \( C = UV \), where the dimensions of the non-negative matrices \( B_1, B_2, U \) and \( V \) are \( n \times k, k \times n, n \times k \) and \( k \times d \) respectively, where \( k \) is the dimension of the subspace where we want to embed the network.

Suppose after some iteration of the algorithm, we have instances of the matrices \( B_1, B_2 \) and \( C \) for the given value of \( U \) by optimizing the following cost function:

\[
\begin{align*}
D_1(B_1, B_2) &= \frac{1}{2} ||A - B_1B_2||_F^2 + \frac{\alpha_1}{2} ||B_1 - U||_F^2 + \alpha_2 ||B_1||_F + \alpha_3 ||B_2||_F \\
\end{align*}
\]

Hence the updated matrices \( B_1 \) and \( B_2 \) can be obtained as follows.

\[
B_1, B_2 = \arg\min_{B_1, B_2 \geq 0} D_1(B_1, B_2)
\]

Once we get an updated values of \( B_1 \), we want to re-optimize the values of \( U \) and \( V \) by optimizing the following cost function:

\[
\begin{align*}
D_2(U, V) &= \frac{1}{2} ||C - UV||_F^2 + \frac{\beta_1}{2} ||U - B_1||_F^2 + \beta_2 ||U||_F + \beta_3 ||V||_F \\
\end{align*}
\]

Then the updated values of \( U \) and \( V \) are calculated as follows.

\[
U, V = \arg\min_{U, V \geq 0} D_2(U, V)
\]

Here \( \alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2 \) and \( \beta_3 \) are the trade-off constants to regularize different components in the respective optimizations. We have used the Frobenius norm on the argument matrices to control the over-fit and also to get a smooth but compact representation in the lower dimensional space, which can later be used for different machine learning tasks. Our aim is to balance the role of structure and content of the network in the final embeddings.

Because of the joint optimization framework proposed above, one can easily incorporate the prior knowledge of the network quality and semantics. For example, if the content of the network is known to be more informative than the link structure, then one should give more importance on the initial representation in \( U \) than that in \( B_1 \). This can be accomplished by setting a higher value for \( \alpha_1 \) than that of \( \beta_1 \). On the other hand, a higher value of \( \beta_1 \) gives more importance to the structure of the network than the content, and push the overall representation to be more consistent with the structure. This flexibility between the structure and content was not present in most of the existing network embedding literature as discussed in Section 2.

Algorithm 1 FSCNMF - Network Embedding Algorithm

1. Input: The graph \( G = (V, E, F) \), dimension of the embedding space \( k < \min(n, d) \)
2. Output: The matrix \( B_1 \) as the representation of \( G \)
3. Calculate the adjacency matrix \( A \) and the content matrix \( C \) of the graph \( G \)
4. Initialize the matrices \( B_1, B_2, U, V \)
5. While (a termination condition is not satisfied)
6. Iterative approach to solve the optimization problem in Eq. 2 - Alternately update \( B_1 \) and \( B_2 \) as stated in Section 4.2 for a fixed number of times
7. Iterative approach to solve the optimization problem in Eq. 4 - Alternately update \( U \) and \( V \) as stated in Section 4.2 for a fixed number of times
8. End While
Next we discuss the solution for each of the above optimization problems in detail.

### 4.2 Solving the Optimization Problems

We use projected gradient descent method to solve the optimization problem as stated in Equation 2. Clearly the cost function is not convex with $B_1$ and $B_2$ together. But it is convex with respect to $B_1$, keeping $B_2$ fixed, and vice-versa. Hence we use an iterative approach to solve the optimization w.r.t $B_1$ first, keeping $B_2$ as constant, and then solve it w.r.t $B_2$, keeping $B_1$ fixed. To solve each of these steps, we derive the multiplicative update rules as follows.

Let us consider Equation 3 (Equation 1 can also be tackled in the same way$^3$). The basic problem can be stated as follows.

**Update Rules:**

\[
U_{t+1} = U_t \times p_U^t \\
V_{t+1} = V_t \times p_V^t
\]

In the space of ‘U’, this can be further written as follows.

\[
\min_{p_U^t} \frac{1}{2} \|C - U_t V_t p_U^t \|_F^2 + \frac{p_B}{2} \|U_t p_U^t - B\|_F^2 + \frac{p_B}{2} \|U_t p_U^t\|_2^2.
\]

In a scalar space, this leads to the below stated first order conditions.

\[
(C - U_t V_t p_U^t)(-U_t V_t) + p_B(U_t p_U^t - B) U_t + p_B(U_t p_U^t) U_t = 0.
\]

This implies that

\[
(U_t V_t)^2 p_U^t + p_B(U_t p_U^t) + p_B^2 U_t^2 = C U_t V_t + B U_t.
\]

It follows that

\[
p_U^t = \frac{C U_t V_t + B U_t}{U_t^2 V_t^2 + p_B U_t^2 + p_B^2 U_t^2}.
\]

**Vectorization of the above leads to the following.**

\[
U_{t+1} = U_t [U_t]_{ij} \left[ \frac{C U_t^T + p_B U_t}{U_t^2 V_t^T + p_B U_t + p_B^2 U_t} \right]_{ij}.
\]

**Or**

\[
U_{t+1} = U_t [U_t]_{ij} \left[ \frac{C U_t^T + p_B U_t}{U_t^2 V_t^T + p_B U_t + p_B^2 U_t} \right]_{ij}.
\]

On a similar note,

\[
V_{t+1} = [V_t]_{ij} \left[ \frac{U_t C}{U_t^2 V_t^T + p_B U_t + p_B^2 U_t} \right]_{ij}.
\]

Similarly by solving Equation 1, we can have:

\[
B_{1t+1} = [B_{1t}]_{ij} \left[ \frac{A B_{1t}^T + p_A B_{1t}}{B_{1t}^T B_{1t} + p_A B_{1t} + p_A^2 B_{1t}} \right]_{ij}.
\]

\[
B_{2t+1} = [B_{2t}]_{ij} \left[ \frac{B_{2t}^T A_{ij}}{B_{2t}^T B_{2t} + p_B B_{2t}} \right]_{ij}.
\]

To initialize the matrices $B_1$ and $B_2$ in Step 4 of Algorithm 1, we use NMF with nonnegative double singular value decomposition as the initialization method [4] on the matrix $A$. Similarly we initialize the matrices $U$ and $V$ from the matrix $C$. Experimentally we found that using NMF is much superior as an initialization technique compared to random initialization of these matrices.

The summary of the approach FSCNMF is given in Algorithm 1 with the update rules discussed above.

#### 4.2.1 Backtracking and Proof Sketch

Let us define a direction $d_t^U$ as follows in reference to the problem in only $U$ above.

\[
d_t^U = x_t p_U^t - x_t.
\]

Let us define our iterates as follows.

\[
x_t + 1 = x_t + ad_t^U.
\]

To find an optimal $\alpha$, given a scalar problem it then suffices to look into the case below.

\[
\min_{\alpha} \frac{1}{2} \{ c - w v (p - 1) \alpha \}^2 + \{ u + u (p - 1) \alpha \}^2 + \{ u - B + u (p - 1) \alpha \}^2.
\]

Taking the first order conditions, it follows that

\[
2u v \alpha (p - 1) - 2 w (p - 1) (c - u v) + 2 u (p - 1) \alpha + 2 u + 2 u^2 (p - 1) \alpha + 2 u (u - B) (p - 1) = 0.
\]

This further implies that

\[
\alpha = \frac{v (c - u v) - 2 u - B}{u v (p - 1) + 4 u (p - 1)}.
\]

Extending this to matrices,

\[
\alpha = \frac{\| 2 V (C - U V T) - 4 U + 2 B \|_F}{\| U V V T (P - e e^T) + (U + U T) (P - e e^T) \|_F}.
\]

Note that $U$, $V$, and $C$ are all of the appropriate dimensions. Also $e$ is a vector of ones defined appropriately. We note that while the above is easily intuitive, the formal proof is not obvious. We do not provide the same in this version and this is given as a practical numerical enhancement.

**Lemma 1.** Let $U \in \mathbb{R}^{2 \times 2}$ and $C \in \mathbb{R}^{2 \times 2}$. Let additionally, $U$ and $C$ have similar rows (Row 1 == Row 2). Let $p_1 = 0$ and $p_2 = 1$, for simplicity (though not obvious, these can be easily generalized). Then, $p_U^t$ is a direction for multiplicative descent mentioned above.

**Proof.** Let without loss of generality,

\[
C = \begin{bmatrix} c_1 & c_2 \\ c_3 & c_4 \end{bmatrix}, \quad U = \begin{bmatrix} u_1 & u_2 \\ u_3 & u_4 \end{bmatrix}.
\]

Noting the problem only in $U$, it can be observed that

\[
p_U^t = \left[ \begin{bmatrix} c_1 u_1 + c_2 u_2 \\ c_3 u_1 + c_4 u_2 \end{bmatrix} \begin{bmatrix} c_1 u_3 + c_2 u_4 \\ c_3 u_3 + c_4 u_4 \end{bmatrix} \right].
\]

The required portion of the objective in $U$ can be defined as follows.

\[
f(U, C) = \frac{1}{2} \left( c_1^2 + c_2^2 + c_3^2 + c_4^2 + 2 u_1^2 + 2 u_2^2 + 2 u_3^2 + 2 u_4^2 \right) - 2 c_1 u_1 - 2 c_2 u_2 - 2 c_3 u_3 - 2 c_4 u_4.
\]

Similarly,

\[
f(U P_U^t, C) = \frac{1}{2} \left( c_1^2 + c_2^2 + c_3^2 + c_4^2 + \frac{1}{2} \left( (c_1 u_1 + c_2 u_2)^2 + (c_1 u_3 + c_2 u_4)^2 \right) \right)
\]

\[
+ \frac{1}{2} \left( c_3 u_1 + c_4 u_2)^2 + \frac{1}{4} \left( (c_1 u_3 + c_2 u_4)^2 \right) \right)
\]

\[
+ \frac{1}{2} \left( -c_1 (c_1 u_1 + c_2 u_2) - c_2 (c_1 u_3 + c_2 u_4) \right)
\]

\[
+ \frac{1}{2} \left( -c_3 (c_1 u_1 + c_2 u_2) - c_4 (c_1 u_3 + c_2 u_4) \right).
\]
Noting \( R_1 == R_2 \) in both \( C \) and \( U \), it follows that \( u_1 = u_3, u_2 = u_4, c_1 = c_3, \) and \( c_2 = c_4. \) It further follows that,  
\[
 f(U^{t^U}, C) = (c_1 u_1 + c_2 u_2) (c_1 u_1 + c_2 u_2 - c_1 - c_2).
\]
It is also easy to observe that 
\[
 f(U, C) = u_1^2 - 2c_1 u_1 + u_2^2 - 2c_2 u_2.
\]
It is easily observed that for any \( c_i j, U_j \geq 1, \)
\[
 f(U^{t^U}, C) \leq f(U, C).
\]
Our claim follows.

4.3 FSCNMF++

There are different types of proximities that exist in a network as stated in [21]. For example, first order proximity captures the local pairwise proximity between the two nodes. It is characterized by the weight of the edge connecting them. Similarly, second order proximity between two nodes captures the similarity between their respective immediate neighborhoods. Extending that, any higher order proximity between two nodes in a network can be defined by the similarity of their respective higher order neighborhoods. Higher order proximity information can also be useful for learning the network embeddings as it somehow captures the global behavior of the connectivity in a network.

FSCNMF approach discussed above only uses adjacency matrix to leverage the structural information present in the network. It is easy to fetch the 1st order neighborhood (or proximity) information of any node from the adjacency matrix. But it might be difficult for a machine learning algorithm to fetch the higher order proximity information from the adjacency matrix directly. So instead of working with the adjacency matrix, we propose to use different powers of the adjacency matrix as follows.

It is known that different powers of adjacency matrix give global connectivity information about the network. For example, \((i, j)\)th entry of \( A^l \) gives the number of paths\(^2\) of length \( l \) between the nodes \( i \) and \( j \). The use of higher order powers of the adjacency matrix can also be motivated from the equivalence of Deepwalk and matrix factorization as shown in [23, 27]. Because of these two reasons, we propose FSCNMF++, which uses the following matrix instead of adjacency matrix in Algorithm 1.

\[
 M = \frac{A + A^2 + \cdots + A^m}{m}
\]  
(9)

We will call the above version as the FSCNMF++ of order \( m \), where \( m \in \{1, 2, \cdots \} \). As most of the real-world networks are highly sparse, i.e., \( O(E) = O(V) \), computing the matrix \( M \) requires \( O(n^2) \) time. Similarly for sparse networks, complexity of matrix factorization with square loss is proportional to the number of non-zero elements in the matrix \( M \) [29]. Experimental results, provided in the next section, demonstrate the superiority of FSCNMF++ for most of the machine learning applications on the networks.

5 EXPERIMENTAL EVALUATION

In this section, we first discuss the datasets and the baseline algorithms used for the experiments. We conduct different types of experiments on the embeddings and analyze the results in detail.

5.1 Data Sets

Following are the datasets used in this paper:

**Citeseer**\(^3\): It consists of publications from Citeseer digital library. The nodes (publications) are divided into 6 categories, with the citations among them as the edges.

**Pubmed-Diabetes**\(^3\): It has scientific publications from the PubMed database consisting of 3 classes of Diabetes. The edges denote the citations among them.

**Microsoft Academia (MSA)**: It is a directed network consisting of a collection of wikipedia articles from the 4 categories namely Sports, Politics, Music and Medicine with the edges representing the links between the articles. The dataset was constructed by going from the 4 main categories to their sub-categories and further to their sub-subcategories in a Breadth First Search manner, and in the way collecting all the pages in those categories. Since a page can belong to multiple categories, we labeled the page’s category as the main category which is at the least distance from it. For each article, only the Introduction part was taken as the content in the dataset.

A detailed specification of the datasets is given in Table 1.

5.2 Baseline Algorithms Used

We compare the performance of our algorithms against the following state-of-the-art approaches: DeepWalk [18], LINE [21] (advanced version by considering both the 1st and 2nd order of node proximity), node2vec [8] and TADW [27]. Among these baselines, DeepWalk, LINE and node2vec use only network structure, while TADW uses both structure and the content of the nodes for generating the embeddings. We use the default settings (as applicable) given in the publicly available implementations of the respective baselines.

5.3 Experimental Setup and Network Embedding

In this section, we examine the behavior of the optimization algorithms of FSCNMF on real-world datasets. There are few parameters of FSCNMF to be set before the experiments. Based on the values of different components of the cost functions (in Eq. 1), we set \( \alpha_1 \) and \( \beta_1 \) to be 1000, and \( \alpha_2, \alpha_5, \beta_5 \) to be 1. We observed that these values give similar weight to each component of the respective criterion function in optimizations. As a thumb rule, we set the dimension of the embedding subspace as \( k = 10^\cdot\#communities \) for a dataset for most of the experiments if not mentioned otherwise. We use NMF with nonnegative double singular value decomposition as the initialization method for the matrices \( B_1, B_2, U \) and \( V \), as mentioned in Section 4.

\(^3\)https://linqs.soe.ucsc.edu/data
First we use Algorithm 1 for FSCNMF and FSCNMF++. As described in Section 4.2, we proposed a joint additive-multiplicative update rule to optimize each cost function in alternating direction method of multipliers (ADMM) style. We show the convergence of the proposed technique in Figures 1a and 1b. Both the plots depict the fast convergence of FSCNMF++ on Wikipedia dataset. We can also see the significant drop of the cost after outer iteration 1 in Figure 1a. This happens because the updated content matrix $U$ from the optimization in Eq. 4 makes the cost in Eq. 1 go down. Thus we are able to successfully exploit the coherence of structure and content through the proposed optimization framework.

For FSCNMF of order $l$, the adjacency matrix $A$ needs to be raised up to the power of $l$. We use sparse matrix multiplication available in SciPy [11] to compute different powers of $A$. The runtime for different orders of FSCNMF++ to generate the embeddings on the Wikipedia dataset is shown in Figure 1c. We observe that the difference between the runtime of any two consecutive orders of FSCNMF++ is in the range of few minutes.

### 5.4 Applications to Node Clustering

Node clustering is an important unsupervised machine learning task for network analysis. Here we check the performance of the proposed embedding technique for unsupervised discrimination of the individual classes in the dataset. To perform node clustering, we first get the vector embedding of each node using an embedding method. Then we apply spectral clustering [15] on the vector representations to get the clusters in each case. We use this for all the embedding algorithms and on each of the datasets specified in Table 1. As each node has a ground truth label in the datasets, we use unsupervised accuracy to judge the performance of clustering. Following is the definition of the unsupervised clustering: $\text{Acc}(\hat{C}, C) = \max_{P} \frac{\sum_{i} I(P(\hat{C}_i), C_i)}{n}$ Here $C$ is the ground truth labeling of the dataset such that $C_i$ gives the ground truth label of ith data point. Similarly $\hat{C}$ is the clustering assignments discovered by some algorithm, and $P$ is a permutation on the set of labels. As clustering is unsupervised and hence we do not know the exact mapping between the set of labels in the ground truth and that in the clustering, we have to consider all the permutations of the labels and select the accuracy corresponding to the best permutation. We assume $I$ to be the identity function on $\mathbb{R}^2$, defined as $I(a, b) = 1$ if $a = b$ and $I(a, b) = 0$ if $a \neq b$.

We have compared the performance of the proposed embedding methods FSCNMF and FSCNMF++ for node clustering against all the baseline methods. For each embedding, the configurations in the spectral clustering is kept the same. The results are shown in Table 2. FSCNMF++ with different orders turns out to be the best among all the embedding methods. Apart from MSA dataset, FSCNMF remains to be the second best, followed by TADW. For MSA, only structure based embedding methods such as DeepWalk, Line and node2vec perform better than TADW and FSCNMF. This implies that content of the nodes does not play a significant role for the node clustering in MSA. This can be explained by the statistics mentioned in Table 1. In MSA the ratio between the number of links between the communities to the number of links within the communities is only 0.06. This means the communities are well defined by the link structure in the network. Also the content within a node in MSA dataset contains only the title of the paper and few keywords. Hence content does not add much meaningful information for community detection, which is getting reflected in the performance of TADW and FSCNMF.

An important observation is that the spectral clustering algorithm on the embedding given by FSCNMF is faster by a factor of more than 100 compared to that on DeepWalk and LINE embeddings. We further investigate the effect of different orders of FSCNMF++ on node clustering in Figure 2. It can be observed that for a smaller dataset like Citeseer, higher orders of FSCNMF++ do not improve the clustering accuracy. In other words, higher order proximities can actually add noise to the resultant embeddings of a smaller network. Whereas for most of the large networks, clustering accuracies more or less improve up to a certain order of FSCNMF++ and then start decreasing.4

### 5.5 Applications to Network Visualization

In network visualization or graph visualization, the goal is to map the network or its representations to a 2D space, and show if the plot in the 2D space discriminates different classes or communities present in the network. Network visualization is unsupervised as the labels of the nodes are not being used for learning the map, they can be used in the 2D plots for the better understanding of the quality of visualization. We use ISOMAP [22] toolkit present in python Scikit-learn [17] library to convert the network embedding to 2D space. We use same color for the nodes which belong to the same community, and different colors for the different communities. So a good visualization is that where nodes in the same community are near each other and nodes from different communities are separated from each other.

---

4We observe the same phenomenon beyond order 10 for Pubmed-Diabetes dataset.

(a) Optimization in Eq 1 for Wikipedia
(b) Optimization in Eq 3 for Wikipedia
(c) Runtime for FSCNMF++ on Wikipedia

Figure 1: Performance of FSCNMF++ of order 5 on the Wikipedia dataset: Plot (a) shows the updation of $B_1$ and $B_2$ with respect to the cost function in Equation 1. Similarly, plot (b) depicts the updation of $U$ and $V$ with respect to the cost function in Equation 3. The inter-dependencies between $B_1$, $B_2$ and $U$, $V$, as explained in Algo. 1 (Steps 5-8) can be understood using plots (a) and (b). Between any two consecutive segments in Plot (a), the drop in the respective cost function is because of the update of $U$ and $V$ as depicted in Plot (b), and vice-versa. (c) The runtime of different orders of FSCNMF++ on the Wikipedia dataset. The plots depict the advantage of using fast sparse matrix multiplication to compute the matrix $M$ in Eq. 9.

Figure 2: Accuracy of clustering for different orders of FSCNMF++ on all the datasets.

We have shown the visualization results for Pubmed-Diabetes and the MSA datasets in Figures 3 and 4 respectively. Both the datasets have 3 groups in each. We used all the data points from each of the datasets for the completeness of the plots, and still be able to differentiate the classes with the proposed embedding algorithms. Due to page limitation, we omit the plots for FSCNMF (order = 1), but the performance of that is shown in Table 3. We can see that FSCNMF++ performs the best on both the datasets. Hence there is a clear advantage of using the content along with the structure, which is exploited well by FSCNMF. Similar to [24] and [13], we use Kullback-Leibler divergence in Table 3 as a quantitative measure of the projections of the embeddings into the 2D space. KL divergence in this case measures the distance between a joint probability distribution of the embedded pairs in the high dimensional space and that in the 2 dimensional space. Clearly lower is the value of KL divergence, better is the performance of the embedding method. Figures 3 and 4 along with with Table 3 show the superiority of the proposed algorithms over the baselines. Although there is some overlap between the classes in Pubmed-Diabetes dataset, FSCNMF++ is able to bring out the non-overlapping nature of the classes even on a larger dataset like MSA.

5.6 Applications to Multi-class Classification

Multi-Class Classification involves using the embeddings generated by the algorithms to classify a given node into the category it belongs. Here the embedding are used as the features and the community which they belong to as the the true class labels. We have used Random Forest classifier to train the model to classify the embedding of a node into one of the classes. We run the experiments on the Pubmed-Diabetes dataset for different training sizes ranging from 10% to 50%, repeating each such experiment 10 times. Being consistent with the literature, we have also reported the average Macro-F1 and Micro-F1 scores to compare the performance of all the baseline algorithms over different training sizes in Table 4.

Results show the merit of FSCNMF. The improvements compared to the baseline algorithms are even more for smaller training sizes. We also observed that FSCNMF++ of order 1 (which is same as FSCNMF) performed the best among the higher orders of the same algorithm, hence reported the same. TADW and node2vec also perform well among the baseline algorithms. We observed similar results on the other three datasets also, which we are omitting because of the space limitation.

5.7 Parameter Sensitivity

Here we see the effect of the dimensionality (denoted by $k$, in Section 3) of the embedding subspace on the performance of the proposed algorithms. As all the datasets in our experiments have associated ground truth communities, we assume the dimension...
of the embedding subspace to be \( k = \theta \times \# \text{communities} \), where \( \theta \) is a positive integer. We vary \( \theta \) and check the performance of the FSCNMF for node clustering on all the datasets, as shown in Figure 5. It turns out that there is no single value of \( \theta \) which can guarantee the best performance irrespective of any particular network. So further analysis is required to optimally find the best dimension of the embedding subspace for a given network, which can be addressed in future.

6 CONCLUSION AND DISCUSSION

In this paper, we have proposed a novel framework to fuse the link structure and the content of a network to generate the embeddings. We also develop additive-multiplicative update rules to optimize the associated cost functions. Experimental results show that our framework is able to leverage the coherence of structure and content successfully for multiple machine learning tasks on the network.

The smaller runtime taken by spectral clustering algorithm on the embedding generated by FSCNMF needs to be explored further. One reason for this could be that the embedding generated by the FSCNMF is able to capture the underlying community structure of the network. Further, our framework is based on matrix factorization. So, naturally there is a critical trade-off between the use of disk I/O and main memory, which affects the runtime of the algorithms. Hence one can try to design an online version of the same, using approaches similar to those proposed in [19].

Exploiting structure and content to generate an appropriate embedding is quite challenging. If there is a total agreement between the structure and content then TADW or its variants can do a good job. However, in real-life situations, there could be some noise or inconsistency between content and structure. In such situations, FSCNMF is the right choice as it offers a flexible framework to accommodate noise or partial inconsistency between structure and content (refer to Table 3). This flexibility helps it to perform well even when the structure and content are totally consistent.
