Abstract—We study the problem of optimally investing in nodes of a social network in a competitive setting, where two camps aim to maximize adoption of their opinions by the population. In particular, we consider the possibility of campaigning in multiple phases, where the final opinion of a node in a phase acts as its initial biased opinion for the following phase. Using an extension of the popular DeGroot-Friedkin model, we formulate the utility functions of the camps, and show that they involve what can be interpreted as multiphase Katz centrality. Focusing on two phases, we analytically derive Nash equilibrium investment strategies, and the extent of loss that a camp would incur if it acted myopically. Our simulation study affirms that nodes attributing higher weightage to initial biases necessitate higher investment in the first phase, so as to influence these biases for the terminal phase. We then study the setting in which a camp’s influence on a node depends on its initial bias. For single camp, we present a polynomial time algorithm for determining an optimal way to split the budget between the two phases. For competing camps, we show the existence of Nash equilibria under reasonable assumptions, and that they can be computed in polynomial time.

Index Terms—Social networks, opinion dynamics, elections, multiple phases, zero-sum games, Nash equilibrium, Katz centrality.

1 INTRODUCTION

The study of opinion dynamics in a society has been of prime importance to understand and influence the processes and outcomes of elections, viral marketing, propagation of ideas and behaviors, etc. In this paper, we consider two competing camps who aim to maximize the adoption of their respective opinions in a social network. In particular, we consider a strict competition setting where the opinion value of one camp is denoted by +1 and that of the other camp by −1; we refer to these camps as good and bad camps respectively. Opinion adoption by a population can be quantified in a variety of ways based on the application; here we consider a well-accepted way, namely, the average or sum of the opinion values of the nodes in the network [1], [2].

The average or sum of the opinion values is of relevance in several applications, for example, a fund collection scenario where the magnitude of a node’s opinion value corresponds to the amount and the sign indicates the camp towards which it is willing to contribute. Another example is when nodes are agents reporting the intensity of an event based on the information they receive individually; this information could be influenced by the camps. Other examples are elections and product purchases, where the bounded opinion value of a node would translate into its probability of voting for a particular party or purchasing a particular product, and so the sum of opinion values would translate into the expected number of votes or purchases in favor of a party or product.

Social networks play a prime role in determining the opinions of the constituent nodes, since nodes usually update their opinions based on the opinions of their neighbors [3], [4]. This fact is exploited by a camp who intends to influence the opinions of these nodes in its favor. A camp could determine nodes whose opinion values it would want to directly influence (without the aid of social network) by investing on them in the form of money, free products or discounts, attention, convincing discussions, etc. Thus given a budget constraint, the strategy of a camp comprises of how much to invest on a given node, in presence of a competing camp who also would invest strategically, so as to maximize its opinion adoption.

As per the popular DeGroot-Friedkin model [5], [6], every node holds an initial bias in opinion which could have formed owing to the node’s fundamental views, its experiences, past information from news and other sources, opinion dynamics in the past, etc. This initial bias plays an important role in determining a node’s final opinion, and consequently the opinions of its neighbors and hence that of its neighbors’ neighbors and so on. If nodes give significant weightage to their biases, the camps would want to influence these biases. This could be implemented by campaigning in multiple phases or rounds, wherein the opinion at the conclusion of a phase would act as the initial biased opinion for the next phase. Such campaigning is often used during elections and product marketing, so as to gradually drive the opinions of nodes. With the possibility of campaigning in multiple phases, a camp could not only decide which nodes to invest on, but also how to split its available budget across different phases.

2 RELATED WORK

The topic of opinion dynamics in social networks has received significant attention in the autonomous agents and multiagent systems community in recent times [7], [8], [9], [10], [11], [12], [13], [14]. Several models of opinion dynamics have been proposed and studied in the literature [14], [15], some of the noteworthy models being DeGroot [16], Voter
The weights could hold any sign, since the influences could be positive or negative. The good camp (opinion value of +1) aims to maximize the sum (or average) of the opinion values of the nodes, while the bad camp (opinion value of −1) simultaneously aims to minimize it.

3.1 Parameters

3.1.1 Initial Bias

As per DeGroot-Friedkin model, every node $i$ holds an initial bias in opinion prior to the opinion dynamics process; we denote it by $v_i^{(0)}$. In the multiphase setting, this acts as the initial bias for the first phase. We denote the opinion value of node $i$ at the conclusion of phase $p$ by $v_i^{(p)}$. This acts as the initial opinion or bias for phase $p+1$. Naturally, we can denote its initial bias for phase $p$ by $v_i^{(p-1)}$. So by convention, we have $v_i^{(0)} = v_i^{(0)}$. We denote the weight that node $i$ attributes to its initial bias by $w_i^{(0)}$.

3.1.2 Network Effect

Let $w_{ij}$ be the weighting attributed by node $i$ to the opinion of its connection $j$. Consistent with DeGroot-Friedkin model, we assume the influence on node $i$ owing to node $j$ in phase $p$, to be $w_{ij}v_j^{(p)}$. So the net influence owing to all of its connections is $\sum_{j \neq i} w_{ij}v_j^{(p)}$. Let $w_{ii}$ denote the weightage attributed by node $i$ to its own current opinion.

3.1.3 Camp Investments

The good and bad camps attempt to directly influence the nodes so that their opinions are pulled towards being positive and negative respectively. We denote the investments made by the good and bad camps on node $i$ by $x_i$ and $y_i$; respectively, and the weightage that node $i$ attributes to them by $w_{ig}$ and $w_{ib}$. Since the influence of good camp (opinion of +1) on node $i$ would be an increasing function of both $x_i$ and $w_{ig}$, we assume the influence to be $+w_{ig}x_i$ for simplicity. Similarly, $-w_{ib}y_i$ is the influence of bad camp (opinion of −1) on node $i$. Let $k_{r}^g$ and $k_{r}^b$ be the respective budgets of the good and bad camps, so the camps should invest such that $\sum_i x_i \leq k_{r}^g$ and $\sum_i y_i \leq k_{r}^b$.

3.1.4 Matrix Forms

Let $w$ be the matrix consisting of the weights $w_{ij}$ for each pair of nodes $(i,j)$. Let $\mathbf{v}^{(p)}$, $w_{ig}^{(p)}$, $w_{ib}^{(p)}$, $\mathbf{x}^{(p)}$, $\mathbf{y}^{(p)}$, $\mathbf{v}^{(0)}$ be the vectors consisting of the elements $v_i^{(p)}$, $w_{ig}^{(p)}$, $w_{ib}^{(p)}$, $x_i^{(p)}$, $y_i^{(p)}$, $v_i^{(0)}$, respectively. Let the operation $\odot$ denote Hadamard product of vectors, that is, $(a \odot b)_i = a_ib_i$.

3.1.5 Weight Constraints

Like standard opinion dynamics models, we have the following condition on influence weights:

$$\forall i : |w_{ii}^{(0)}| + |x_i| + \sum_{j \neq i} |w_{ij}| + |y_i| + |w_{ig}| + |w_{ib}| \leq 1$$

A standard assumption for guaranteeing convergence is

$$|w_{ii}| + \sum_{j \neq i} |w_{ij}| < 1$$

Since we would have weights attributed to influences external to the network (influences due to bias $(w_{ig})^{(p)}$ and campaigning $(w_{ig},w_{ib})$), this assumption is well suited for our model.
3.2 Opinion Update Rule

The opinion update rule in DeGroot-Friedkin model is

$$\forall i : v_i \leftarrow w_i^0 v_i^{(0)} + w_i^1 v_i + \sum_{j \neq i} w_{ij} v_j,$$

or equivalently,

$$\forall i : v_i \leftarrow w_i^0 v_i^{(p)} + w_i^1 v_i + \sum_{j \neq i} w_{ij} v_j.$$  

Generalizing to multiphase setting, the update rule in the $p^{th}$ phase is

$$\forall i : v_i^{(p)} \leftarrow w_i^0 v_i^{(p-1)} + \sum_{j \neq i} w_{ij} v_j.$$  

Taking the investments of the camps into account, it is

$$\forall i : v_i^{(p)} \leftarrow w_i^0 v_i^{(p-1)} + \sum_{j \neq i} w_{ij} v_j - w_i b_i y_i.$$  

$$\implies v_i^{(p)} = w_i^0 v_i^{(p-1)} + w_i^1 v_i + w_g x_i - w_b y_i.$$  

(1)

The static vectors: $x_i(p), y_i(p), v_i(p)$ (weighted by $w_g, w_b, w_0$), are unchanged throughout a phase $p$, while $v_i^{(p)}$ gets updated.

Writing it as a recursion (with iterating variable $\tau$):

$$v_i^{(p)} = w_i^{\tau} v_i^{(p)}(0) + \sum_{q=0}^{\tau-1} w_i^q (w_i^0 v_i^{(p-1)} + w_g x_i - w_b y_i)$$

Now $v_i^{(p)}(0)$ is the opinion at the beginning of phase $p$, which is $v_i^{(p-1)}$. For determining if the process reaches convergence, we see the limiting value when $\tau \to \infty$.

Since $w_i$ is a strictly substochastic matrix (with the sum of each of its rows strictly less than 1), its spectral radius is less than 1. So $\lim_{\tau \to \infty} w_i^\tau = 0$, and $\sum_{q=0}^{\tau-1} w_i^q = (I - w_i)^{-1}$ (2).

Hence as $\tau \to \infty$, the above equation can be written as

$$\lim_{\tau \to \infty} v_i^{(p)} = (I - w_i)^{-1} (w_i^0 v_i^{(p-1)} + w_g x_i - w_b y_i)$$

which is a constant vector. So the dynamics in phase $p$ converges to the steady state

$$v_i^{(p)} = (I - w_i)^{-1} (w_i^0 v_i^{(p-1)} + w_g x_i - w_b y_i)$$  

(2)

4 Problem Formulation

We now formulate the multi-phase objective function, and analyze the two-phase opinion dynamics in further detail.

We first derive an expression for $\sum_i v_i^{(p)}$, the sum of the opinion values of the nodes in the network at the end of phase $p$.

Pemultiplying (2) by $T$ gives

$$1^T v_i^{(p)} = 1^T (I - w_i)^{-1} (w_i^0 v_i^{(p-1)} + w_g x_i - w_b y_i).$$

Let $r = (I - w_i)^{-1}$ then $r^{-1} 1^T = (I - w_i)^{-1} 1 = (1^T (I - w_i)^{-1})^T$.

So the above is equivalent to

$$\sum_i v_i^{(p)} = \sum_i r_i w_i^0 v_i^{(p-1)} + \sum_i r_i (w_i g x_i - w_b y_i).$$  

(3)

Pemultiplying (2) by $(r \circ w_0)$ gives

$$(r \circ w_0)^T v_i^{(p)} = (r \circ w_0)^T (I - w_i)^{-1} (w_i^0 v_i^{(p-1)} + w_g x_i - w_b y_i).$$

Let the constant $(r \circ w_0)^T (I - w) = s^T$. So the above is equivalent to

$$\sum_i r_i w_i^0 v_i^{(p)} = \sum_i s_i (w_i g x_i - w_b y_i).$$

or equivalently,

$$\sum_i r_i w_i^0 v_i^{(p-1)} = \sum_i s_i (w_i g x_i - w_b y_i).$$

Substituting this in (3) gives

$$\sum_i v_i^{(p)} = \sum_i s_i (w_i g x_i - w_b y_i).$$

(4)

Note that $\mathbf{s}$ can be viewed as a weighted extension of $\mathbf{r}$. If $(I - w_i) = \Delta$, then $r_i = \sum_j \Delta ji$ and $s_i = \sum_j r_i w_j \Delta ji$.

Multiphase Katz centrality, $r_i = (I - w_i)^{-1} 1$, resembles Katz centrality of node $i$, capturing its influencing power on other nodes if there are no subsequent phases. However, while selecting optimal nodes for a phase if there are subsequent phases to follow, the effectiveness of node $i$ depends on its influencing power over those nodes ($j$), which would give good weightage ($w_j^0$) to their initial opinion in the next phase, as well as have a good influencing power over other nodes ($r_j$). This is captured by $s_i$, so it can be viewed as two-phase Katz centrality. Let vector $r$ be denoted by $r^{(1)}$ and $s$ by $r^{(2)}$. In general, for an integer $q > 1$, let $r_i^{(q)} = \sum_j r_j^{(q-1)} w_j^0 \Delta ji$ or $r^{(q)} = \Delta^q (w^{(q-1)} 0)$.

Intuitively, $r_i^{(q)}$ is the measure of influence of node $i$ looking $q$ phases ahead; it can be viewed as $q$-phase Katz centrality.

Now the recursion in Equation (4) can be simplified as

$$\sum_i v_i^{(p)} = \sum_i s_i (w_i g x_i - w_b y_i).$$

(5)

Solving the above recursion to eliminate $v_i^{(p-2)}$ gives

$$\sum_i v_i^{(p)} = \sum_i s_i w_i^0 v_i^{(0)} + \sum_i r_i^{(p-2)} (w_i g x_i - w_b y_i).$$

(6)

which is now a function of intrinsic constants and strategies.

If there is only a single phase, we have

$$\sum_i v_i^{(1)} = \sum_i r_i w_i^0 v_i - \sum_i s_i w_i^0 y_i.$$  

We focus on the two-phase campaign in our study.

$$\sum_i v_i^{(2)} = \sum_i s_i w_i^0 v_i^{(0)} + \sum_i s_i w_i^0 x_i^{(1)} - \sum_i s_i w_i^0 y_i.$$  

(7)

Here $(x_i^{(1)}, x_i^{(2)})$ is the strategy of good camp, and $(y_i^{(1)}, y_i^{(2)})$ is the strategy of bad camp. Given an investment strategy profile $(x_1^{(1)}, x_2^{(2)})$, $(y_1^{(1)}, y_2^{(2)})$, let $w_i^g (x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)})$ be the good camp’s utility and $w_i^b (x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)})$ be the bad camp’s utility. The good camp aims to maximize the value of 7, while the bad camp aims to minimize it. So,
\[ u_g((x^{(1)}, x^{(2)}), (y^{(1)}, y^{(2)})) = \sum_i v_i^{(2)} \]
and \[ u_b((x^{(1)}, x^{(2)}), (y^{(1)}, y^{(2)})) = - \sum_i v_i^{(2)} \] (8)

with the following constraints on the investment strategies:
\[ \sum_i (x_i^{(1)} + x_i^{(2)}) \leq k_g, \sum_i (y_i^{(1)} + y_i^{(2)}) \leq k_b \]
\[ \forall i : x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)} \geq 0 \]

The game can thus be viewed as a two-player zero-sum game, where the players determine their investment strategies \((x^{(1)}, x^{(2)})\) and \((y^{(1)}, y^{(2)})\); the good camp invests as per \(x^{(1)}\) in the first phase and as per \(x^{(2)}\) in the second phase, and the bad camp invests as per \(y^{(1)}\) in the first phase and as per \(y^{(2)}\) in the second phase. Our objective essentially is to find the Nash equilibrium strategies of the two camps.

5 Multiphase Strategies

We call a camp farsighted if it computes its strategy considering that there would be a second phase, that is, it considers the objective function \(\sum v_i^{(2)}\) in Equation (7). A camp can be called myopic if it computes its strategy greedily by considering the near-sighted objective function \(\sum v_i^{(1)}\). We now consider cases where both camps are farsighted or myopic, and where one camp is farsighted while the other is myopic.

When both camps are farsighted, the game is as per (6). Here, the optimal strategy of the good camp is to invest the entire budget on node \(i\) with the maximum value of \(\max \{s_i w_{ig}, r_i w_{ig}\}\) if this value is positive (no investment is made if this value is non-positive). If \(\max s_i w_{ig} > \max r_j w_{jg}\), the entire budget is invested in the first phase, while if \(\max s_i w_{ig} < \max r_j w_{jg}\) the entire budget is invested in the second phase (independent between the phases if \(\max s_i w_{ig} = \max r_j w_{jg}\)). The optimal strategy of the bad camp is analogous. Furthermore, the optimal strategies of the camps are mutually independent, since the optimization terms with respect to different variables are decoupled.

When one camp (say the bad camp) is myopic, while the other camp (say the good camp) is farsighted, the optimal strategy of the good camp is the same as above since it is independent of the strategy of the bad camp. Though the actual utility of the bad camp is \(-\sum v_i^{(2)}\), it perceives its utility as \(-\sum v_i^{(1)}\) (see Equation (6)), owing to its myopic nature. The optimal strategy of the bad camp is hence to invest the entire budget on node \(i\) with the maximum value of \(r_i w_{ib}\) in the first phase itself (if positive). The loss to the bad camp owing to its myopic play is thus,
\[ k_b \left( \max \left( \max \{s_i w_{ia}, r_i w_{ib}, 0\} \right) - \max \{s_i w_{ib}, 0\} \right) \]
where \(i = \arg \max r_i w_{ib}\).

Note that when both camps are myopic, their strategies are as per the single phase objective function (6), that is, the good camp invests entirely on a node \(i\) with the highest value of \(r_i w_{ig}\) (if positive) and the bad camp invests entirely on a node \(i\) with the highest value of \(r_i w_{ib}\) (if positive) in the first phase. However, the actual utility would be as per the two phase objective function (8) with \(x_i^{(2)} = y_i^{(2)} = 0, \forall i\).

Case of Bounded Investment per Node. Here we consider the case when there is a bound on investment on every node in either phase, for instance, \(0 \leq x_i^{(1)}, x_i^{(2)}, y_i^{(1)}, y_i^{(2)} \leq 1, \forall i\). Such bounded investments could be owing to discounts which cannot exceed 100%, attention capacity or time constraint of a voter to receive convincing arguments, company policy to limit the number of free samples that can be given to a customer, government policy of limiting the monetary investment by a camp on a voter, etc. Bounded investments would ensure that the opinion values are bounded (from Equation (2)). Bounded opinion values can be associated with voting in elections and product adoption, where a bounded value could be transformed into a probability of voting for a party or adopting a product. For instance, an opinion value of \(v\) could imply that the probability of voting for the good camp (or adopting the good camp’s product) is \((1 + v)/2\) and that of voting for the bad camp is \((1 - v)/2\). The sum of opinion values would thus imply the expected number of votes in the favor of the good camp.

When both camps are farsighted, for computing optimal strategy of the good camp, we consider the set of elements \(\{s_i w_{ig}, r_i w_{ig}\}_{i \in N}\). Until the budget \(k_g\) is exhausted, we choose an element with the maximum value one at a time, which is not already chosen. If the chosen element is \(s_i w_{ig}\), we invest on node \(j\) in the first phase, while if the chosen element is \(r_j w_{jg}\), we invest on node \(j\) in the second phase, subject to a maximum investment of 1 unit. The strategy of the bad camp is analogous. Note again that the optimal strategies of the camps are mutually independent.

The scenario of one camp (say the bad camp) being myopic can be analyzed on similar lines as in the case of no bounds on investment per node, with the exception that instead of the bad camp investing entirely in one node with the highest value of \(r_i w_{ib}\) in the first phase, it would invest on nodes according to decreasing values of \(r_i w_{ib}\), subject to a maximum investment of 1 unit per node. Hence the loss to the bad camp can be determined. The scenario of both camps being myopic can also be analyzed analogously.

Remark 1. When there were no bounds on investment per node, it was optimal for a farsighted camp to invest its entire budget on one node in one phase. The case with the bounds on investment per node requires a farsighted camp to invest on different nodes, possibly in different phases. Such a strategy would result in an outcome in which the camps could split their budget across the two phases. Specifically, the budget allocated by the good camp for the first and second phases would be \(\sum_i x_i^{(1)}\) and \(\sum_i x_i^{(2)}\), respectively, while that allocated by the bad camp would be \(\sum_i y_i^{(1)}\) and \(\sum_i y_i^{(2)}\).

Extension to Multiple Elections Setting. The multiphase study can be directly extended to the multiple elections setting, where the outcome of the first election is in itself valuable. If the immediate outcome holds a weightage of \(\delta_1\) and the future outcome holds a weightage of \(\delta_2\), the objective function now transforms into \(\sum_i (\delta_1 x_i^{(1)} + \delta_2 x_i^{(2)})\). The decision parameter \(s_i\) would then get replaced by \(\delta_1 r_i + \delta_2 s_i\).
6 DEPENDENCY OF \( w_g \) AND \( w_b \) ON INITIAL BIAS

So far, we considered a setting where \( w_g \) and \( w_b \) for a node \( i \), could be any fixed values. However, in several scenarios, more often that not, the initial opinion of a node would impact the effectiveness of the investment made by the two camps. For example, in an election setting, if the initial opinion of a node is highly positive, it is likely to be the case that the investment made by the good camp would make the difference more effective than that made by the bad camp. In other words, such a node is likely to be more easily influenced by (or is more sensitive towards) the investment made by the good camp. That is, \( v_i^{(p-1)} > 0 \) would likely mean \( w_i^{(p)} > w_i^{(p-1)} \).

The fundamental reasoning is similar to that of the bounded confidence model [19], where a node pays more attention to opinions that do not differ too much from its own opinion.

Note also that \( w_i^{(p)} \) would also play a role, since it says how much weightage is given by node \( i \) to its initial opinion. So a theoretical model can be proposed on this line, wherein \( w_i^{(p)} \) is a monotone non-decreasing function of \( w_i^{(p-1)} \), and \( w_i^{(p)} \) is a monotone non-increasing function of \( w_i^{(p-1)} \). Let node \( i \) attribute a total of \( \theta_i \) to the influence weights of the camps (that is, \( w_i^{(p)} + w_i^{(p)} = \theta_i \)), and \( \Theta \) be the vector consisting of elements \( \theta_i \). So one such simple linear model could be

\[
\begin{align*}
\sum \theta_i & = \sum \theta_i \left( 1 - \frac{w_i^{(p-1)}}{2} \right), \quad \sum \theta_i = \left( 1 - \frac{w_i^{(p-1)}}{2} \right) \quad (9)
\end{align*}
\]

The dependency of \( w_g \) and \( w_b \) on the initial opinion is particularly significant in multi-phase campaigning, since the opinion changes across phases, and hence the assumption of \( w_g \) and \( w_b \) being the same across phases, may not be valid (since these values now depend on \( v_i^{(p-1)} \) which would in general be different for different phases). Considering that \( w_g \) and \( w_b \) can be different across phases, Equation (9) can be generalized to

\[
\sum v_i^{(s)} = \sum \sum \left( w_i^{(0)} v_i^{(s)} + \sum \frac{\theta_i}{2} \left( 1 - \frac{w_i^{(p)}}{2} \right) \right) \quad (10)
\]

We now focus on two-phase campaign \( (p = 2) \). Recall that \( \Delta = (I - w)^{-1} \). We now derive the objective function

\[
\sum v_i^{(s)} = \sum \sum \left( w_i^{(0)} v_i^{(s)} + w_i^{(2)} x_i^{(2)} - w_i^{(2)} y_i^{(2)} \right) = \sum \sum \left( w_i^{(0)} v_i^{(s)} + \theta_i x_i^{(2)} - \theta_i y_i^{(2)} \right) \quad (11)
\]

The first term \( \sum r_j w_j v_j^{(s)} \) can be obtained (without \( v_j^{(s)} \)) by premultiplying \( \frac{\theta_i}{2} \) by \( (1 - \frac{\theta_i}{2} \cdot o \cdot w_0 \cdot (1 + \frac{\theta_i}{2} \cdot o \cdot \theta_i^{(2)})^2 \) and using \( \frac{\theta_i}{2} \). Hence we get

\[
\sum v_i^{(s)} = \sum \sum \left( w_i^{(0)} v_i^{(s)} + \theta_i \left( x_i^{(2)} - y_i^{(2)} \right) \right) \quad (10)
\]

Note that unlike the previous setting (Equation (7)), the optimal strategies of the two camps in this setting would be mutually dependent in general, since the optimization terms with respect to different variables are coupled.

6.1 The Case of a Single Camp

First we consider a simplified yet interesting version by considering only one camp (the good camp). Here we would have \( y_i^{(1)} = y_i^{(2)} = 0, \forall i \in \text{Expression} (10) \). For simplicity of notation, denote \( r_j w_j \Delta_j = b_{ji} \) and \( w_i^{(1)} v_i^{(1)} = c_i \). So we have

\[
\sum v_i^{(2)} = \sum \sum \left( c_i \left( x_i^{(2)} \right) + \theta_i \left( x_i^{(2)} - y_i^{(2)} \right) \right) \quad \sum \sum \left( x_i^{(2)} \right) = \sum \sum \left( \theta_i \varepsilon \right) \quad (11)
\]

Deducing from Equations (12) and (13) that the above objective function is a bilinear function in \( x^{(1)} \) and \( x^{(2)} \), we prove the following claim.

**Lemma 1.** It is optimal to exhaust the entire budget \((k_g^{(1)} + k_g^{(2)} = k_g)\), and if not, it is optimal to not invest at all \((k_g^{(1)} = k_g^{(2)} = 0)\). Furthermore, it is an optimal strategy to invest on at most one node in a given phase.

**Proof.** Given any \( x^{(2)} \), Expression (12) can be maximized with respect to \( x^{(1)} \) by allocating \( k_g - \sum x^{(2)} \) to a single node \( i \) that maximizes \( \theta_i (c_i + 1) \sum b_{ji} (1 + \frac{\theta_i}{2} x^{(2)}) \), if this value is positive. In case of multiple such nodes, one node can be chosen at random. If this value is non-positive for all the nodes, it is optimal to have \( x^{(1)} = 0 \). When \( x^{(1)} = 0 \), Expression (13) now implies that it is optimal to allocate the entire budget \( k_g \) in the second phase to a single node \( j \) that maximizes \( \frac{\theta_j}{2} \sum b_{ji} c_i + r_j \), if this value is positive. If this value is non-positive for all the nodes, it is optimal to have \( x^{(2)} = 0 \). This is the case where starting with an \( x^{(2)} \), we arrive at the conclusion that it is optimal to either invest \( k_g - \sum x^{(2)} \) on a single node in the first phase, or invest the entire budget \( k_g \) on a single node in the second phase, or invest in neither of the phases.

Similarly using (13), starting with a given \( x^{(1)} \), we can conclude that it is optimal to either invest \( k_g - \sum x^{(1)} \) on a single node in the second phase, or invest the entire \( k_g \) on a single node in the first phase, or invest in neither phase.

So starting from any \( x^{(1)} \) or \( x^{(2)} \), we can iteratively improve (need not be strictly) on the value of \( x^{(1)} \) by investing on at most one node in a given phase. Furthermore, it is sub-optimal to have \( k_g^{(1)} + k_g^{(2)} < k_g \) unless \( k_g^{(1)} = k_g^{(2)} = 0 \). ■

So there exist optimal vectors \( x^{(1)} \) and \( x^{(2)} \) that maximize (11), such that \( x^{(1)} = x^{(2)} \) or \( x^{(1)} = x^{(2)} \).
0. Now the next step is to find the nodes α and β that maximize \( \text{Expression } (11) \). By incorporating α and β, the expression for \( \sum_i v_i^{(2)} \) can be rewritten as

\[
\sum_{i \neq \alpha} \sum_{j \neq \beta} c_{ij} + \left( \alpha + \frac{\theta_\beta}{2} k^{(1)}_\alpha (c_{\alpha} + 1) \right) \left( b_{\beta \alpha} \left( 1 + \frac{\theta_\beta}{2} k^{(2)}_\beta \right) \right) + \theta_\beta k^{(2)}_\beta \right)
\]

and the corresponding optimal value of \( k^{(2)}_\beta \) hence determine the value of Expression (14) by plugging in the optimal \( k^{(1)}_\alpha \) and \( k^{(2)}_\beta \) and that \( (\alpha, \beta) \) pair. The optimal pair \( (\alpha, \beta) \) can thus be obtained as the pair that maximizes (14).

The above analysis holds when \( k^{(1)}_\alpha + k^{(2)}_\beta = k_g \). From Lemma 1, we need to consider one more possibility that \( k^{(1)}_\alpha = k^{(2)}_\beta = 0 \), which gives a constant value \( \sum_i c_{ij} \) for Expression (14). Let \((0, 0)\) correspond to this additional possibility. It is hence optimal to invest \( k^{(1)}_\alpha \) (obtained using (15)) on node α in the first phase and \( k^{(2)}_\beta \) (obtained using (16)) on node β in the second phase, subject to it giving a value greater than \( \sum_i c_{ij} \) to Expression (14).

Since we iterate through \((n^2 + 1)\) possibilities (namely, \( (\alpha, \beta) \in N \times N \cup \{(0, 0)\} \)), the above procedure gives a polynomial time algorithm for determining the optimal budget split and the optimal investments on nodes in two phases.

Remark 2. Expression (15) indicates that for a given \((\alpha, \beta)\) pair, the good camp would want to invest more in the first phase for a higher \( s_\alpha \). This is intuitive from our understanding of \( s_\alpha \) being viewed as the Katz centrality of node α looking two phases ahead. Similarly, Expression (16) indicates that it would want to invest more in the second phase for a higher \( r_\beta \), since \( r_\beta \) can be viewed as the Katz centrality of node β looking just one phase ahead. Also as per (9), \( w_{ij} \) is an increasing function of \( \theta_i \). Now taking cue from Expression (16), a node with a higher \( w_{ij} \) is likely to be invested on more by the good camp. A similar insight is given by Expressions (15) and (16), where a higher \( \theta_i \) drives the camp to invest in the first phase and a higher \( \theta_\beta \) drives it to invest in the second phase. We further attempt to illustrate the role of \( w_{ij} \) using simulations in Section 7.3.

### 6.2 The Case of Competing Camps

We now analyze the dependency setting with two camps.

Similar to the proof of Lemma 1, we can show that \( \sum_i v_i^{(2)} \) is a multilinear function, since it can be written as a linear function in \( x^{(1)}, y^{(1)}, x^{(2)}, y^{(2)} \) separately. The following lemma can be hence proved on similar lines.

Lemma 2. For either camp, it is optimal to exhaust the entire budget, and if not, it is optimal to not invest at all. Furthermore, it is an optimal strategy to invest on at most one node in a given phase.

Denoting \( r_j w_{jj} \Delta_{jj} = b_{jj} \) and \( w_{ij} v_i = c_i \) as before, from Expression (10), \( \sum_i v_i^{(2)} \) can be expanded as

\[
\sum_{i,j} c_{ij} b_{jj} + \sum_{j} x^{(2)}_{ji} \left( \sum_i c_{ij} b_{jj} + r_j \right) + \sum_{j} y^{(2)}_{ji} \left( \sum_i c_{ij} b_{jj} - r_j \right)
\]

and the corresponding optimal value of \( k^{(2)}_\beta \) is

\[
\min \left\{ \max \left\{ \frac{k_g}{2} + \frac{s_\alpha}{\theta_\beta r_\beta w_{jj}^{(1)} \Delta_{jj}^{(1)}} - \frac{1}{\theta_\alpha w_{jj}^{(1)} \Delta_{jj}^{(1)}} (1 + w_{jj}^{(0)} v_i^{(0)}) \right\}, k_g \right\}
\]

and the corresponding optimal value of \( k^{(2)}_\beta \) is

\[
\min \left\{ \max \left\{ \frac{k_g}{2} - \frac{s_\alpha}{\theta_\beta r_\beta w_{jj}^{(1)} \Delta_{jj}^{(1)}} - \frac{1}{\theta_\alpha w_{jj}^{(1)} \Delta_{jj}^{(1)}} (1 + w_{jj}^{(0)} v_i^{(0)}) \right\}, k_g \right\}
\]

When we assumed \( k^{(1)}_\alpha \) and \( k^{(2)}_\beta \) to be fixed, we had to iterate through all \((\alpha, \beta)\) pairs to determine the one that gives the optimal value of Expression (14). Now, whenever we look at an \((\alpha, \beta)\) pair, we can determine the corresponding optimal values of \( k^{(1)}_\alpha \) and \( k^{(2)}_\beta \) using (15) and (16), and hence determine the value of Expression (14) by plugging in the optimal \( k^{(1)}_\alpha \) and \( k^{(2)}_\beta \) and that \((\alpha, \beta)\) pair. The optimal pair \((\alpha, \beta)\) can thus be obtained as the pair that maximizes (14).
find \((x_{\alpha}^{(1)}, x_{\beta}^{(2)}), (y_{\gamma}^{(1)}, y_{\delta}^{(2)})\), or equivalently, the optimal \(((k_{g}^{(1)}, k_{b}^{(2)}), (k_{b}^{(1)}, k_{b}^{(2)})\) corresponding to such a profile. So by incorporating \(((\alpha, \beta), (\gamma, \delta))\), Expression \((17)\) for \(\sum_{i} v_{i}^{(2)}\) can be simplified as

\[
\sum_{i} \sum_{j} c_{i}b_{ji} + k_{g}^{(2)} \frac{\theta_{\gamma}}{2} \left( \sum_{i} c_{i}b_{ji} + r_{j}\right) + k_{b}^{(2)} \frac{\theta_{\delta}}{2} \left( \sum_{i} c_{i}b_{ji} - r_{j}\right) \\
+ k_{g}^{(1)} \frac{\theta_{\gamma}}{2} (1 + c_{\alpha}) \left( s_{\alpha} + k_{g}^{(2)} \frac{\theta_{\gamma}}{2} b_{\delta\alpha} + k_{b}^{(2)} \frac{\theta_{\delta}}{2} b_{\gamma\alpha}\right) \\
- k_{b}^{(1)} \frac{\theta_{\delta}}{2} (1 - c_{\gamma}) \left( s_{\gamma} + k_{g}^{(2)} \frac{\theta_{\gamma}}{2} b_{\delta\gamma} + k_{b}^{(2)} \frac{\theta_{\delta}}{2} b_{\gamma\gamma}\right)
\]

(18)

First, we consider the case when \(k_{g}^{(1)} + k_{g}^{(2)} = k_{g}\) and \(k_{b}^{(1)} + k_{b}^{(2)} = k_{b}\). Now, for a given profile of nodes \(((\alpha, \beta), (\gamma, \delta))\), we will find the optimal values of \(k_{g}^{(1)}, k_{b}^{(1)}, k_{g}^{(2)}, k_{b}^{(2)}\). In this case, we have \(k_{g}^{(1)} = k_{g} - k_{b}\) and \(k_{b}^{(2)} = k_{b} - k_{b}^{(1)}\). Substituting this in (18) and simultaneously solving \(\frac{\partial \sum_{i} v_{i}^{(2)}}{\partial k_{g}^{(1)}} = 0\) and \(\frac{\partial \sum_{i} v_{i}^{(2)}}{\partial k_{b}^{(2)}} = 0\), we get \(k_{g}^{(1)}\) equal to (letting \(A = \theta_{\beta}\theta_{\gamma}(1 - c_{\gamma})b_{\gamma\gamma}\) and \(B = \frac{1}{2} (\theta_{\beta}\theta_{\gamma}(1 + c_{\gamma})b_{\gamma\gamma} - \theta_{\beta}\theta_{\gamma}(1 - c_{\gamma})b_{\gamma\gamma})\):

\[
\frac{1}{B^2 + \theta_{\alpha}\theta_{\beta}(1 + c_{\gamma})b_{\gamma\gamma}A}
\sum_{i} \left[ s_{\alpha} + (1 + c_{\gamma})b_{\gamma\gamma} - \theta_{\beta}\theta_{\gamma}(1 - c_{\gamma})b_{\gamma\gamma}\right]
\]

We can similarly obtain \(k_{b}^{(1)}\). If the second derivative with respect to \(k_{g}^{(1)}\), that is, \(-\theta_{\alpha}\theta_{\beta}\delta_{\gamma}u_{\gamma\gamma}\Delta_{\gamma\gamma}(1 + w_{\gamma\gamma}^{0}v_{\gamma\gamma}^{0}) < 0\) and that with respect to \(k_{b}^{(2)}\), that is, \(-\theta_{\beta}\theta_{\gamma}\delta_{\gamma}u_{\gamma\gamma}\Delta_{\gamma\gamma}(1 - w_{\gamma\gamma}^{0}v_{\gamma\gamma}^{0}) > 0\), and the obtained solution is such that \(k_{g}^{(1)} \in [0, k_{g}]\) and \(k_{b}^{(1)} \in [0, k_{b}]\), then we have that neither the good camp can change \(k_{g}^{(1)}\) to increase \(\sum_{i} v_{i}^{(2)}\), nor the bad camp can change \(k_{b}^{(1)}\) to decrease \(\sum_{i} v_{i}^{(2)}\). So we can assign this value \(\sum_{i} v_{i}^{(2)}\) to \(u_{g}(\alpha, \beta, (\gamma, \delta))\).

Thus using the above technique, we obtain \(u_{g}(\alpha, \beta, (\gamma, \delta))\) for all profiles of nodes \(((\alpha, \beta), (\gamma, \delta))\) in the case when \(k_{g}^{(1)} + k_{g}^{(2)} = k_{g}\) and \(k_{b}^{(1)} + k_{b}^{(2)} = k_{b}\). From Lemma \(2\) the only other cases to be considered are \(k_{g}^{(1)} = k_{g}^{(2)} = 0\) and \(k_{b}^{(1)} = k_{b}^{(2)} = 0\). Let the profile of nodes \(((\alpha, \beta), (0, 0))\) correspond to \(k_{g}^{(1)} = k_{b}^{(2)} = 0\). Note that when \(k_{g}^{(1)} = k_{b}^{(2)} = 0\), it reduces to the single camp case with only the good camp (Section 6.1). The value of \(\sum_{i} v_{i}^{(2)}\) for \((\alpha, \beta)\) pair can hence be assigned to \(u_{g}(\alpha, \beta, (0, 0))\). Thus we can obtain \(u_{g}(\alpha, \beta, (\gamma, \delta))\) for all profiles of nodes \(((\alpha, \beta), (0, 0))\). Similarly, we can obtain \(u_{g}(\alpha, \beta, (\gamma, \delta))\) for all profiles of nodes \(((\alpha, \beta), (0, 0))\). And from Equation (18), we know that \(u_{g}(0, (0, 0)) = \sum_{i} c_{i}b_{ji}\).

So we have that the good camp has \((n^2 + 1)\) possible pure strategies to choose from, namely, \((\alpha, \beta) \in N \times N \cup \{(0, 0)\}\). Similarly, the bad camp has \((n^2 + 1)\) possible pure strategies to choose from, namely, \((\gamma, \delta) \in N \times N \cup \{(0, 0)\}\). We thus have a two-player zero-sum game, for which the utilities of the players can be computed for each strategy profile \(((\alpha, \beta), (\gamma, \delta))\) as explained above. Though we cannot ensure the existence of a pure strategy Nash equilibrium, the finiteness of the number of strategies ensures the existence of a mixed strategy Nash equilibrium. Furthermore, owing to it being a two-player zero-sum game, the Nash equilibria can be found efficiently using linear programming.

Summarizing, under practically reasonable assumptions \((w_{ij} \geq 0, \forall (i, j))\) and \(w_{ii}^{0} \geq 0, \forall i, \forall v_{i}^{0} \in [-1, 1], \forall i\), we transformed the problem into a two-player zero-sum game with each player having \((n^2 + 1)\) pure strategies, and showed how the players’ utilities can be computed for each strategy profile. We thus deduced the existence of Nash equilibria and that they can be found efficiently using linear programming.

7 SIMULATIONS AND RESULTS

For determining implications of our analytically derived results on real-world networks, we conducted a simulation study on a popular network dataset: NetHEPT (a co-authorship network in the “High Energy Physics - Theory” papers on the e-print arXiv from 1991 to 2003), consisting of 15,233 nodes and 31,376 edges. This network exhibits many structural features of large-scale social networks and is widely used for experimental justifications, for example, in [21], [33], [44].

In our simulations, we consider \(v_{i}^{0} = 0, \forall i\). We transform the original undirected network into a directed one by making all edges bidirectional. Let \(N(i)\) be the set of neighbors of node \(i\) in the network. For a fixed \(w_{ii}^{0}\), we consider \(w_{ij}, w_{ib} > 0\) and \(w_{ij} \geq 0, \forall j \in N(i)\) such that the weights for any node \(i\) sum to 1, that is, \(w_{ij} + w_{ib} + \sum_{j \in N(i)} w_{ij} = 1 - w_{ii}^{0}\). Furthermore, for different values of \(w_{ii}^{0}\), the values of \(w_{ij}, w_{ib}, wij\) are scaled proportional to \(1 - w_{ii}^{0}\). That is, the values \(w_{ij}, w_{ib}, wij\) corresponding to \(w_{ii}^{0}\) and the values \(\hat{w}_{ij}, \hat{w}_{ib}, \hat{wij}\) corresponding to \(\hat{w}_{ii}^{0}\) are such that

\[
\forall i : \frac{1 - w_{ii}^{0}}{1 - \hat{w}_{ii}^{0}} = \frac{w_{ij}}{\hat{w}_{ij}} = \frac{w_{ib}}{\hat{w}_{ib}} = \frac{w_{ij}}{\hat{wij}}, \forall j \in N(i)
\]
For the case of dependency among parameters, where \( w_{ij}^{(q)} = \frac{1}{2}(1 + w_{ij}^{(q-1)}) \) and \( w_{ij}^{(q)} = \frac{1}{2}(1 - w_{ij}^{(q-1)}) \), we let \( \theta_i = \tilde{w}_{ig} + \tilde{w}_{ib} \), where \( \tilde{w}_{ig} \) and \( \tilde{w}_{ib} \) are as above. Furthermore, since we assume \( v_i^{(1)} = 0 \), we would have \( w_{ij}^{(1)} = \tilde{w}_{ij}^{(1)} = \theta_i \). We consider different values of \( w_{ij}^{(0)} \), namely, \( \{0, 0.05, \ldots, 0.95\} \). In our simulation study, we assume that this value is same for all nodes. This allows us to study the effect of the values of \( w_{ij}^{(0)} \) on the two phase strategy of the camps.

**Simulation Results.** Figures (a) and (c) present the optimal amount of budget that should be invested in the first phase as a function of \( w_{ij}^{(0)} \) for the bounded setting (where investment on each node is bounded in either phase) and the dependency setting (where the influence weight of the camp on a node depends on its initial bias), respectively. In our simulations, the optimal values obtained are such that \( k_g^{(2)} = k_g^{(1)} \) and \( k_b^{(2)} = k_b^{(1)} \). For low values of \( w_{ij}^{(0)} \), the optimal strategy of the camps is to invest almost entirely in the second phase. This is because the effect of the first phase diminishes in second phase. The value \( s_j = \sum_i r_{ij} w_{ij}^{(0)} \Delta_{ij} \) of a node \( j \) would be significant only if it influences nodes \( j \) with significant values of \( w_{ij}^{(0)} \). And hence, investing in first phase would be advantageous only if we have nodes which have significant value of \( w_{ij}^{(0)} \). With low values to \( w_{ij}^{(0)} \), we are less likely to have nodes \( j \) with high values of \( s_j \) since it requires them to not only be influential but also to have a high range of \( i \) with significant values of \( w_{ij}^{(0)} \). This also justifies Figure (b) where, if the bad camp acts myopically (spending its entire budget in the first phase), it incurs significantly more loss for lower values of \( w_{ij}^{(0)} \) (higher value of \( \sum_i v_i^{(2)} \) is worse for the bad camp).

Though we have observed that low values of \( w_{ij}^{(0)} \) are detrimental for the values of \( s_j \) and hence for investment in the first phase, the budget allotted to the first phase need not be a monotone function of \( w_{ij}^{(0)} \). It is possible that for a value of \( w_{ij}^{(0)} \), a set of nodes have good values of \( s_j = \sum_i r_{ij} w_{ij}^{(0)} \Delta_{ij} \) and hence are worth investing on in the first phase. However, for a higher range of \( w_{ij}^{(0)} \), the values of \( w_{ij}, w_{ib}, w_{ij} \) scale down, and hence the first phase worth of a node \( j \) \( (s_j w_{ij} \text{ or } s_j w_{ij}) \) may be superseded by the second phase worth of some other node \( j' (r_{j'} w_{ij} \text{ or } r_{j'} w_{ij}) \), thus possibly making it advantageous to invest in the second phase for a higher \( w_{ij} \). In Figure (a), for the setting where the values of \( w_{ig} \) and \( w_{ib} \) do not depend on the initial opinion of node \( i \) (when we consider bounded investment per node), the general observations suggest that a high range of \( w_{ij}^{(0)} \) makes it advantageous for the camps to invest in the first phase, albeit in a non-monotone way owing to the aforementioned reason. In Figure (c), for the dependency setting with single camp (where we consider unbounded investment per node), a high range of \( w_{ij}^{(0)} \) makes it advantageous for the camps to invest in the first phase. Here we point that though we presented a polynomial time algorithm for the dependency setting with two camps, which is of theoretical interest, it is computationally expensive to run on networks larger than a few hundred nodes.

**8 Conclusion**

Using DeGroot-Friedkin model of opinion dynamics, we proposed a framework for optimal multiphase investment strategies for two competing camps in a social network. We focused on two phases and derived closed-form expressions for optimal strategies, and the extent of loss that a camp would incur if it acted myopically against a farsighted competitor. We then studied the setting where the influence of the camps on a node depended on the node’s initial bias. For the case of single camp, we derived a polynomial time algorithm for determining an optimal way of splitting the budget between the two phases. For the case of two camps, we showed the existence of Nash equilibria under reasonable assumptions, and that they can be computed in polynomial time. Our simulations quantified the impact of the weightage that nodes attribute to their initial biases. Notably, higher weightage would necessitate more investment in the first phase, so as to influence these biases for the second (terminal) phase.

As future direction, it would be interesting to study optimal multiphase investment strategies under other models of opinion dynamics in the literature. The two camps setting can be extended to multiple camps. Also, the two phase study can be generalized to multiple phases to see if any important insights or benefits can be obtained. It would be interesting to study the problem with bounds on total investment on a node by the two camps together (such as \( x_i + y_i \leq 1 \)). It is also worth exploring the possibility of more efficient algorithms for the dependency setting with two camps.
