Abstract
In this paper, we present a generic black-box attack, demonstrated against API call based machine learning malware classifiers. We generate adversarial examples combining sequences (API call sequences) and other features (e.g., printable strings) that will be misclassified by the classifier without affecting the malware functionality. Our attack minimizes the number of target classifier queries and only requires access to the predicted label of the attacked model (without the confidence level). We evaluate the attack’s effectiveness against many classifiers such as RNN variants, DNN, SVM, GBDT, etc. We show that the attack requires fewer queries and less knowledge about the attacked model’s architecture than other existing black-box attacks, making it optimal to attack cloud based models at a minimal cost. Finally, we discuss the robustness of this attack to existing defense mechanisms.

Introduction
In this paper, we present a novel query-efficient black box attack against many types of classifiers, including RNN variants. API call sequence based classifiers such as SentinelOne provide state of the art detection performance (Huang and Stokes 2016), however, those classifiers are vulnerable to the generation of adversarial examples. Adversarial examples are correctly classified samples that are perturbed (modified), so they (incorrectly) get assigned a different label. In this paper, we implement our attack on binary classifiers, which are used to differentiate between malicious and benign processes based on API call sequences. We consider the challenging case of cloud prediction, termed machine learning as a service (MLaaS), such as Amazon Machine Learning or Google’s Cloud Prediction where the attacker pays for every query of the target classifier (provides input and gets classification) and therefore aims to minimize the number of queries to such a cloud service while performing a successful attack. Another reason to minimize the queries number is that many queries from the same computer might raise suspicion of adversarial attack attempt, causing the cloud service to stop responding to those adversarial queries (Chau et al. 2010).

Generating adversarial examples for images (Carlini and Wagner 2017) is the main focus of most existing research; this is different from generating adversarial API sequences, which are demonstrated in this paper, in two respects: 1) In adversarial API sequences one must verify that the original functionality of the malware remains intact (thus, one cannot just generate an adversarial feature vector, but must generate the corresponding valid malware binary), and 2) API sequences consist of discrete symbols with variable lengths, while images are represented as matrices with fixed dimensions, and the values of the matrices are continuous. Attacks against RNN variants exist (Hu and Tan 2017, Papernot et al. 2016, Rosenberg et al. 2018), but they require many queries to the target classifier and additional knowledge of the attacked classifier, such as the target classifier features’ encoding. Previous query-minimizing decision-based attacks (Brendel, Rauber, and Bethge 2018) do not target RNNs or the cyber domain, due to its unique challenges. The differences from our attack are described in Section 2.

The contributions of our paper are as follows:
1) This is the first end-to-end decision based black-box adversarial attack against all state of the art classifiers (RNN variants, feed forward DNNs, and traditional machine learning classifiers such as SVM) that minimizes the number of target model queries, in order to handle cloud attack scenarios. We focus on sequence input and the cyber security domain.
2) Our attack doesn’t require target model queries to train a substitute model (Rosenberg et al. 2018) or a generative adversarial network (Hu and Tan 2017) to generate the adversarial example. Thus, it does not require extensive computation power or pre-deployment phase and is easier to deploy on remote hosts than previous attacks.
3) The attack doesn’t require any knowledge about the target classifier, including knowledge about the training set, model type, architectures, hyperparameters, or feature encoding. Only a subset of the features being used is required.
4) The attack is random and therefore renders defense methods against deterministic adversarial attacks, such as gradient masking (e.g., distillation), useless (Brendel, Rauber, and Bethge 2018).

In this paper, we present two simple but effective methods to reduce the number of black box queries for generating an adversarial example: 1) Logarithmic backtracking - Starting with a large ratio of perturbation (added APIs in random
positions in the original sequence to fool the classifier) and rapidly decrease the ratio as long as the sequence remains misclassified, and 2) **Benign perturbation** - Adding API calls from sequences generated by a generative adversarial network (GAN) trained to mimic real benign sequences, instead of random API calls. This concept is similar to biological viruses (malware) which are sometimes composed of human (“benign”) proteins to evade the immune system (malware classifier) of the host. While we focus on malware classifiers (a challenging case), our attack is generic and can be applied to other domains, like text analysis (using word sequences instead of APIs).

**Background and Related Work**

There are three types of adversarial example generation methods:

1) **Gradient based attacks** - In this type of attack adversarial perturbations are generated in the direction of the gradient, that is, in the direction with the maximum effect on the classifier’s output (e.g., FGSM (Goodfellow, Shlens, and Szegedy 2015)). Gradient based attacks are effective but require adversarial knowledge about the targeted classifier’s gradients. These attacks can be conducted on the targeted model if white-box knowledge is available (Grosse et al. 2017). Our research differs from (Grosse et al. 2017) in several ways: 1) (Grosse et al. 2017) didn’t deal with RNNs or dynamic features which are more challenging to add without harming the malware functionality, 2) (Grosse et al. 2017) did not focus on a generic attack which can affect many types of classifiers, as we do, and 3) Our black-box assumption is more feasible than the white-box assumption presented in (Grosse et al. 2017).

RNN GAN, which aims to generate invalid APIs and insert them into the original API sequences, has already been proposed (Hu and Tan 2017). Gumbel-Softmax, a one-hot continuous distribution estimator, was used to deliver gradient information between the generative RNN and substitute RNN. Our research differs from (Hu and Tan 2017) in several ways: 1) While (Hu and Tan 2017) injects arbitrary API call sequences that might harm the malware functionality (e.g., by inserting the ExitProcess() API call in the middle of the malware code), our attack modifies the code such that the original functionality of the malware is preserved. 2) Our approach works in real world scenarios involving hybrid classifiers and multiple feature types, which are not addressed by (Hu and Tan 2017). 3) While (Hu and Tan 2017) only focused on LSTM variants, we also show our attack’s effectiveness against other RNN variants such as GRUs and conventional RNNs, bidirectional and deep variants, and non-RNN classifiers (including both feed forward networks and traditional machine learning classifiers such as SVM), making it truly generic, 4) The use of Gumbel-Softmax approximation in (Hu and Tan 2017) makes this attack limited to one-hot encoded inputs, while in our attack, any word embedding can be used, making it more generic, and 6) The stability issues associated with GAN training (Arjovsky and Bottou 2017) per sample, which might not converge for specific datasets apply to the attack method mentioned in (Hu and Tan 2017), making it hard to rely on and require more target classifier queries. While such issues might not be visible when using a small dataset (180 samples in (Hu and Tan 2017)), they become more apparent when using larger datasets like ours (500,000 samples). We also use GAN for benign perturbations, but it is optional and, if used, needs to be trained only once.

A white-box gradient based attack against RNNs demonstrated against LSTM architecture for sentiment classification of a movie reviews dataset was shown in (Papernot et al. 2016). A black-box variant, which facilitates the use of a substitute model, was presented in (Rosenberg et al. 2018). As shown in Section 4.2, that attacks described in (Papernot et al. 2016) (Rosenberg et al. 2018) require more target classifier queries, more computing power to generate a substitute model and more knowledge about the attacked classifier (API encoding). Moreover, our attack works in the same flow for all samples, and doesn’t require a per-model pre-deployment phase to generate the adversarial sequence (either using GAN, as in (Hu and Tan 2017), or a substitute model, as in (Rosenberg et al. 2018)). In this paper, the generation is done at run time, making it more robust against different classifiers and easier to deploy.

2) **Score based attacks** - These attacks are based on knowledge of the target classifier’s confidence score. The target classifier’s gradient can be numerically derived from the confidence scores of adjacent input points (Chen et al. 2017) and then apply a gradient-based attack, following the direction of maximum impact to generate an adversarial example. However, attacker knowledge of confidence scores (not required by our attack) is unlikely in black-box scenarios.

3) **Decision based attacks** - These attacks use only the label predicted by the target classifier. (Brendel, Rauber, and Bethge 2018) starts from a randomly generated image classified as desired and then adds perturbations that decrease the distance to the source class image, while maintaining the target classification. (Ilyas et al. 2018) uses Natural Evolutionary Strategies (NES) optimization to enable query-efficient gradient estimation, which leads to generation of misclassified images like gradient based attacks. (Suya et al. 2017) uses a Bayesian optimization to minimize the probability of the point has the correct classification.

All of the currently published score and decision based attacks (Brendel, Rauber, and Bethge 2018) (Chen et al. 2017) (Ilyas et al. 2018) differ from our proposed attack in that: 1) They only deal with convolutional neural networks, as opposed to all state of the art classifiers, including RNN variants. 2) They deal with images and don’t fit the attack requirements of the cyber security domain (while changing a pixel’s color i doesn’t “break” the image, modifying an API call might harm a malware’s functionality). In addition, small perturbations suggested in (Brendel, Rauber, and Bethge 2018) (Chen et al. 2017) (Ilyas et al. 2018) are not applicable for discrete API calls (you can’t change WriteFile() to WriteFile()+0.001 in-order to estimate the gradient to perturb the adversarial example in the right direction - you need to modify it to an entirely different API). 3) They did not present an end-to-end attack in the cyber-security domain, and thus might be used for generating adversarial malware feature vectors but not a working adversarial mal-
ware sample. An exception is (Anderson et al. 2018), presenting a decision-based attack of a reinforcement learning agent is equipped with a set of operations (such as packing) that it may perform on the PE file. Through a series of games played against the anti-malware engine, it learns which sequences of operations are likely to result in evading the detector for any given malware sample. Unlike our attack, this attack’s effectiveness is less than 25% (our attack effectiveness is about 90%). It doesn’t handle sequence features and it isn’t query efficient like ours, either.

Methodology

Target API Call Based Malware Classifier

Our classifier’s input is a sequence of API calls made by the inspected code. In order to add API calls without harming the malware functionality, we used a no-op mimicry attack (Wagner and Soto 2002), that is, adding system calls with no effect or adding system calls with an irrelevant effect. Almost any API call can become no-op if provided with the right arguments, e.g., opening a non-existent file. We focus on classifiers using only the API call type and not its arguments or return value, since IDSs that verify the arguments are 4-10 times slower than classifiers that do not verify arguments (Tandon and Chan 2006) and are therefore less common. However, analyzing arguments would make our attack easier to detect, e.g., by considering only successful API calls and ignoring failed APIs or by looking for irregularities in the arguments of the API calls (e.g., invalid file handles, etc.). In order to address this issue, we use valid (non-null) arguments with NOP effect, such as writing into a temporary file handle, instead of an invalid file handle.

API call sequences can be millions of API calls long, making it impossible to train on the entire sequence at once due to training time and GPU memory constraints. Thus, we used a sliding window approach (Rosenberg et al. 2018): Each API call sequence is divided into windows with size \( m \). Detection is performed on each window in turn, and if any window is classified as malicious, the entire sequence is considered malicious. Thus, even cases, such as malicious payloads injected into goodware (e.g., using Metasploit), where only a small subset of the sequence is malicious, would be detected. We use one-hot encoding for each API call type in order to cope with the limitations of sklearn’s implementation of decision trees and random forests, as mentioned [online]. The output of each classifier is binary (malicious or benign). The tested classifiers and their hyperparameters are described in Appendix B.

Black-Box API Call Based Malware Classifier Attack

We present two forms of attack: 1) Linear iteration attack - a simple attack, and 2) Logarithmic backtracking attack - a more complex and efficient attack in terms of target classifier queries. Both attacks can use either random or benign perturbations.

Random or Benign Perturbation Linear Iteration Attack

In order to prevent damaging the code’s functionality we can only add API calls to the malware’s code; we cannot remove or modify API calls. In order to add API calls in a way that doesn’t impact the code’s functionality, we generate a mimicry attack (Section 3.1). Our attack is described in Algorithm 1.

1. **Input:** \( f \) (black-box model), \( x_m \) (malicious sequence to perturb), \( x_b \) (benign sequence to mimic), \( n \) (size of adversarial sliding window), \( D \) (adversarial vocabulary), \( M_w \) (maximum API modifications per window), \( isBenignPerturb \) (use benign perturbation)
2. for each sliding windows \( w_{j,m} \), \( w_{j,b} \) of \( n \) API calls in \( x_m \), \( x_b \):
3. while \( f(w_{j,m}) = \text{malicious} \) and the number of added APIs \( < M_w \):
4. Randomly select an API’s position \( i \) in \( w_m \)
5. Add an adversarial API (\( w_{j,b}[i] \) if \( isBenignPerturb \), else a random API in \( D \)) in position \( i \). # \( w_{j,m}[i..n] \) become \( w_{j,m}[i+1..n+1] \)
6. return \( (perturbed) \) \( x_m \)

Algorithm 1: Linear Iteration Attack

The attacker splits the malicious API call sequence \( x_m \) to windows of \( n \) API calls (line 2), modifying each window in turn, similar to the division done by the classifier (Section 3.1). The adversarial window size \( n \) might be different from the classifier’s window size \( m \), which is not known to the attacker. As shown in Section 4.2, this has little effect on the attack performance. The same division is done for the benign API call sequence \( x_b \). The modification is the addition of either random API calls, a.k.a. random perturbation, or API calls of a benign sequence, a.k.a. benign perturbation (line 5), at random positions in the API sequence (line 4), until the modified sequence \( w_{j,m} \) is classified as benign or more than \( M_w \) APIs are added, reaching the maximum overhead limit (line 3).

\( D \) is the vocabulary of available features. Here those features are all of the API calls recorded by the classifier. Note that \( D \) is not necessarily known to the attacker. The attacker knows \( D' \), which might be a subset or super-set of \( D \). APIs in \( D' - D \) would not be monitored by the classifier and do not assist in camouflaging: they just add API overhead to the modified sequence and waste queries. APIs in \( D - D' \) would not be generated by the attack and therefore decrease the possibilities for generating modified sequences.

The benign sequence \( x_b \) is generated by a special-crafted GAN (Section 3.2.3).

Logarithmic Backtracking Attack

In order to decrease the number of target classifier queries (the number of calls to \( f(\cdot) \)), we use Algorithm 2, the logarithmic backtracking attack. It uses Algorithm 3 (line 3), which is similar to Algorithm 1 for a single API call window, with added API bookkeeping and without querying the target classifier. The idea is that we only query the target classifier in Algorithm 2, after modifying \( M_w \) API calls in Algorithm 3, which should be a large enough perturbation to evade the classifier; then
we start reducing the number of modified API calls by half (lines 8, 10) until the classifier detects the sample again. Finally, we restore the API calls we removed in the last iteration, half every time (line 16), until we reach a successful perturbation with minimal number of added API calls and minimal target classifier queries number.

1. Input: \( f \) (black-box model), \( x_m \) (malicious sequence to perturb), \( x_b \) (benign sequence to mimic), \( n \) (size of adversarial sliding window), \( D' \) (adversarial vocabulary), \( M_w \) (maximum API modifications per window), \( \text{isBenignPerturb} \) (use benign perturbation)

2. for each sliding windows \( w_{j,m}, w_{j,b} \) of n API calls in \( x_m, x_b \):

3. \( w_j^*, \text{addedAPIs} = \) Algorithm 3(\( w_{j,m}, w_{j,b}, n, D', M_w, \text{isBenignPerturb} \))

4. remainingAPIS = \( \text{addedAPIs} \)

5. while \( f(w_j^*) = \text{benign} \):

6. # Remove added APIs until evasion is lost:

7. Randomly split \( \text{remainingAPIs} \) into two equally sized groups: \( \text{remainingAPIs}, \text{deletedAPIs} \)

8. remove \( \text{deletedAPIs} \) from \( w_j^* \)

9. if \( f(w_j^*) = \text{malicious} \):

10. Remove remaining \( \text{APIs} \) instead of \( \text{deletedAPIs} \) from \( w_j^* \)

11. Switch between \( \text{remainingAPIs} \) and \( \text{deletedAPIs} \)

12. \( \text{recoveredAPIs} = \text{deletedAPIs} \)

13. while \( f(w_j^*) = \text{malicious} \):

14. # While there are still added APIs that were removed, add them back until evasion is restored:

15. \( \text{recoveredAPIs} = \)Randomly pick half of the API calls remaining in \( \text{deletedAPIs} \)

16. Add \( \text{recoveredAPIs} \) to \( w_j^* \)

17. Replace \( w_j \) (in \( x_m \)) with \( w_j^* \)

18. return (perturbed) \( x_m \)

Algorithm 2: Logarithmic Backtracking Attack

The attacker chooses the API calls to add and remove randomly. Note that the only API calls that are being removed are those that were added and not the malware’s original API calls, in order to prevent harming its functionality. Since we add or remove half of the API calls every time, we perform \( O(\log n) \) queries in Algorithm 2, instead of \( O(n) \) in Algorithm 1. The exact numbers are shown in Section 4.2. While the proposed attack is designed for API call based classifiers, it can be used for any adversarial sequence generation.

Benign Perturbation: GAN Generated Benign API Call Sequence When we add an API call to our adversarial sequence, we want a maximum impact on the classifier’s output. Thus, Algorithms 1 and 2 takes as input \( x_b \), a benign API sequence to use. One way to generate \( x_b \) is taking the API call sequence of an actual benign sample from our data-set. The downside of this approach is that those hard-coded API calls can be signed by the classifier and detected explicitly. A better approach is to generate different benign sequence each time, using a generative model. One way to do this is to use a generative adversarial network (Goodfellow et al. 2014), with stochastic input and output of API call sequence that is indistinguishable (to the discriminator classifier) from actual benign sequences from the data-set. This approach is rarely used for API call sequence, but has been used for text generation. It has several advantages over other approaches (e.g., VAE): It tends to generate better output, most other methods require that the generator net has some particular functional form (like the output layer being Gaussian), and all of the other frameworks require that the generator net put non-zero mass everywhere. A challenge with this approach is that the discrete outputs from the generative model make it difficult to pass the gradient update from the discriminative model to the generative model. Another challenge is that the discriminative model can only assess a complete sequence. We used SeqGAN (Yu et al. 2017) implementation, where a discriminative model that is trained to mimic a sequence is indistinguishable (to the discriminator classifier) from actual benign sequences from the data-set. For this purpose, we used a discriminative model that is trained to mimic a sequence is indistinguishable (to the discriminator classifier) from actual benign sequences from the data-set. The discriminative model is used to maximize the binary classification loss between real benign API call sequence and generated ones. Besides the pre-training procedure that follows MLE (maximum likelihood estimation) metric, the generator is modeled as a stochastic policy in reinforcement learning (RL), bypassing the generator differentiation problem by directly performing gradient policy update. Given the API sequence \( s = [x_0, x_1, \ldots, x_{t-1}] \) and the next API to be sampled from the model \( x_t \sim (x|s_t) \), the RL algorithm, REINFORCE, optimizes the GAN objective:

\[
\min_{\phi} - \mathbb{E}_{Y \sim p_{\text{data}}} \left[ \log D_{\phi}(Y) \right] - \mathbb{E}_{Y \sim \hat{G}_\theta} \left[ \log (1 - D_{\phi}(Y)) \right]
\]

The RL reward signal comes from the GAN discriminator judged on a complete sequence, and is passed back to the intermediate state-action steps using Monte Carlo search, to compute the Q-value for generating each token, for the sake of variance reduction. We also tried other GAN architectures (e.g., GSGGAN) but SeqGAN outperformed all of them, as shown in Section 4.2.2.
Experimental Evaluation

Dataset and Target Malware Classifiers

We use the same dataset used in (Rosenberg et al. 2018), because of its size: it contains 500,000 files (250,000 benign samples and 250,000 malware samples), faithfully representing the malware families in the wild. Details are shown in Appendix A. Each sample was run in Cuckoo Sandbox, a malware analysis system, for two minutes per sample. The API call sequences generated by the inspected code during its execution were extracted from the JSON file generated by Cuckoo Sandbox. The extracted API call sequences are used as the malware classifier’s features. The samples were run on Windows 8.1 OS, since most malware targets the Windows OS. Like (Rosenberg et al. 2018), anti-sandbox malware were filtered to prevent dataset contamination (see Appendix A). After filtering, the final training set size is 360,000 samples, 36,000 of which serve as the validation set. The test set size is 36,000 samples. All sets are balanced between malicious and benign samples.

There are no commercial trail version or open source API call based deep learning intrusion detection systems available (such commercial products target enterprises and involve supervised server installation). Dynamic models are also not available in VirusTotal. Therefore, we used the malware classifiers used in (Rosenberg et al. 2018), since the dataset is large (in contrast to (Hu and Tan 2017) with a dataset size of 180 samples) and many classifiers are covered, allowing us to evaluate the attack effectiveness against many classifier types.

The API call sequences are split into windows of $m$ API calls each, and each window is classified in turn. Thus, the input of all of the classifiers is a vector of $n = 140$ (larger window sizes didn’t improve the classifier’s accuracy) API call types with 314 possible values (those monitored by Cuckoo Sandbox). We used the same implementation and hyperparameters (loss function, dropout, activation functions, etc.) as (Rosenberg et al. 2018) for all the classifiers (Appendix B). The malware classifiers’ performance and architecture are presented in Appendix B. Basically, all DNNs have an accuracy higher than 95% and all other classifiers - higher than 90%, on the test set. The FP rate of all classifiers varied between 0.5-1%.

Attack Performance

In order to measure the performance of an attack, we consider three factors: The attack effectiveness is the number of malicious samples correctly classified, which adversarial sequences generated by Algorithm 2 (Algorithm 1 has similar results with more queries) were misclassified as benign by the target malware classifier. We also consider the overhead incurred as a result of the proposed attack. The attack overhead is the average number of API calls which were added by Algorithm 2 to a malware sample successfully detected by the target classifier, so that the modified sample will be misclassified as benign (therefore calculated only for successful attacks) by the target model, as a percentage of the total sample API calls number:

$$\text{attack_overhead} = \frac{\text{avg}(|\text{length}(x_{m}^*) - l_m|)}{l_m}$$

(2)

The average length of the API call sequence is: $\text{avg}(l_m) \approx 100,000$. We used a maximum of $M_w = 70$ additional API calls per window of $m = 140$ API calls. While not shown here due to space limits, higher $M_w$ values cause higher attack effectiveness, overhead and queries. Algorithm 2’s performance, is presented in Table 1 (average of five runs). The performance of Algorithm 1 is very similar.

The proposed attack has high effectiveness against all of the tested malware classifiers. The attack effectiveness is lower for traditional machine learning algorithms, e.g., for SVM and logistic regression. This is due to the linear correlations between their features, which cause many APIs in the sequence to have a low weight; modifying them have little impact. In contrast, neural networks have many layers of non-linear correlations between the features, so modifying the correct API would have significant impact on the score.

Finally, we consider the average number of target classifier queries the attacker performs per sample. The attacker aims to minimize this number, since in cloud scenarios, each query costs money and increases the probability of adversarial attempt detection. The number of queries varies by the algorithm we use and appear in Table 2 (average of five runs).

We see that Algorithm 2 results in similar performance using fewer queries. Benign perturbation have an added benefit compared to random APIs. The reason is that the entire sequence gives the classifier the context to determine malicious or benign functionality, so benign APIs can give a more benign context, impacting the classifier.

As mentioned in Section 4.1, $|\text{TestSet}(f)| = 36,000$ samples, and the test set TestSet(f) is balanced, so the attack performance was measured on: $|\{f(x_m) = \text{Malicious}|x_m \in \text{TestSet}(f)\}| = 18,000$ samples.

For simplicity and training time, we used $m = n$ for Algorithm 3, i.e., the sliding window size of the adversary is the same as that used by the target classifier. However, even if this is not the case, the attack effectiveness isn’t degraded significantly. If $n < m$, the adversary can only modify a subset of the API calls affecting the target classifier, and this subset might not be diverse enough to affect the classification as desired, thereby reducing the attack effectiveness. If $n > m$, the adversary would keep trying to modify different API calls’ positions in Algorithm 3, until he/she modifies the ones impacting the target classifier as well, thereby increasing the attack overhead without affecting the attack effectiveness. The closer $n$ and $m$ are, the better the attack performance. For $n = 100, m = 140$, there is an average decrease of attack effectiveness from 87.96% to 87.94% for a LSTM classifier.

We used $D = D'$, except $D'$ did not contain any API type that might harm the code’s functionality. From the 314 API calls monitored by Cuckoo Sandbox, only two API types were omitted: ExitWindowsExt() and NtTerminateProcess().

Comparison to Previous Work There are three published adversarial attacks against RNN variants (attacks the

minimizes the query numbers but works only for images, like (Ilyas et al. 2018; Brendel, Rauber, and Bethge 2018; Suya et al. 2017), are irrelevant. We compared our work against (Rosenberg et al. 2018), since it provides state of the art performance against a wide range of classifiers. The attack implemented by Papernot et al. (Papernot et al. 2016) was compared to (Rosenberg et al. 2018) and found inferior to it in terms of attack overhead (Rosenberg et al. 2018), resulting in more queries. Therefore, outperforming (Rosenberg et al. 2018) suffice. The work of Hu et al. (Hu and Tan 2017) provides inferior attack performance than (Rosenberg et al. 2018), but more importantly the usage of target classifier queries to train a generative adversarial network requires more queries than training a simple substitute model (Rosenberg et al. 2018) due to the GAN’s complexity and convergence issues (Arjovsky and Bottou 2017). Again, (Rosenberg et al. 2018) has the best performance, query-wise - so we focus on comparing our attack to (Rosenberg et al. 2018). The performance of (Rosenberg et al. 2018) and our attack (Algorithm 2) are presented in Tables 1 and 2. While the attack overhead and effectiveness of (Rosenberg et al. 2018) is better, the number of queries in our attack is significantly lower. This is due to the fact that while generating a substitute model allows the attacker to choose the most impactful APIs, resulting in less added APIs, this substitute model creation requires many target classifier queries. Since our main objective in this paper is minimizing the target queries - the proposed attack outperforms existing methods.

**Benign Perturbation GAN Comparison** To implement the benign perturbation GAN, we tested several GAN types, using TexyGEN framework (Zhu et al. 2018) and Tensorflow, using its default parameters. We use MLE training as the pretraining process for all baseline models except GSGAN, which requires no pretraining. In pretraining, we first train 80 epochs for a generator, and then 80 epochs for a discriminator. The adversarial training comes next. In each adversarial epoch, we update the generator once and then update the discriminator for 15 mini-batch gradients. Due to memory limitations, we generated only one sliding window of 140 API calls, each with 314 possible API call types, in each iteration (that is, generating $w_b$ and not $x_b$ in Section 3.2). As mentioned in Section 3.2.3, we tested several GAN implementations with discrete sequence output. We run Algorithm 2 (logarithmic backtracking attack) on the 9,000 generated API call traces by the GAN, trained using 9,000 sequences (half of the benign test set) as a training set and 9,000 sequences (the other half) as a test set. The results for the LSTM classifier (other classifiers behave the same) are shown in Table 3. SeqGAN outperform all other models in all measured factors.

**Handling Multiple Feature Types and Hybrid Classifiers** Combining several types of features might make the classifier more resistant to adversarial examples against a specific
feature type. For instance, some real world next generation anti-malware products are hybrid classifiers, combining both static and dynamic features for a better detection rate. An extension of our attack to handle hybrid classifiers is straightforward: attacking each feature type in turn using Algorithms 1 or 2. If the attack against a feature type fails, we continue and attack the next feature type until a benign classification by the target model is achieved or until all feature types have been (unsuccessfully) attacked. We used the same hybrid malware classifier used in (Rosenberg et al. 2018), combining both API call sequences and printable strings inside a PE file as our static features, as they are commonly used as the static features of state-of-the-art hybrid malware classifiers (Huang and Stokes 2016) and to ease the comparison with prior work, although any other modifiable feature type can be used. Our architecture for the hybrid classifier is: 1) A static branch that contains an input vector of 20,000 Boolean values: for each of the 20,000 most frequent strings in the entire dataset, do they appear in the file or not? (analogous to a similar procedure used in NLP, which filters the least frequent words in a language). 2) A dynamic branch that contains an input vector of 140 API calls, inserted into a LSTM layer of 128 units, followed by two fully-connected layers with 128 neurons. The 256 outputs of both branches are inserted into a fully-connected output layer. All other hyperparameters are the same as in Appendix B. Due to hardware limitations, a subset of the dataset was used as a training set: 54,000 training samples and test and validation sets of 6,000 samples each. The dataset was representative and maintained the same distribution as the dataset described in Section 4.1. Trained on this dataset, a classifier using only the dynamic branch reaches 92.48% accuracy on the test set, a classifier using only the static branch attains 96.19% accuracy, and a hybrid model, using both branches achieves 96.94% accuracy, so combining features helps.

When attacking only the API call sequences using the hybrid classifier, without modifying the static features of the sample, the attack effectiveness decreases to 23.76%, compared to 89.67% against a classifier trained only on the dynamic features, meaning that the attack was mitigated by the use of additional features. When attacking only the printable strings features (again, assuming that the attacker has the knowledge of $D' = D$, which contains the printable strings being used as features by the hybrid classifier), the attack effectiveness is 28.25%, compared to 88.31% against a classifier trained only on the static features. Finally, the combined attack’s effectiveness against the hybrid model was 90.06%. Other classifier types provide similar results which are not presented here due to space limits.

### Conclusions and Future Work

In this paper, we presented the first black-box attack, generating adversarial sequences, which minimizes the number of queries for the target classifier, making it perfect to attack cloud models. We demonstrated it against API call sequence based malware classifiers and verified the attack effectiveness against all relevant common classifiers: RNN variants, feed-forward networks, and traditional machine learning classifiers. This is the first query efficient decision based attack effective against RNN variants and not only CNNs. We also showed that the generation of the adversarial sequences can be done end-to-end, in a generic way at the endpoint, and, unlike previous adversarial attacks, without generating a costly substitute model, both in terms of classifier queries and the computing resources needed to generate it. Finally, we showed that the attack is effective even when multiple feature types are used. Our attack is the first practical end-to-end attack dealing with all of the subtleties of the cyber security domain, without the need for a pre-deployment stage, making it suitable for sophisticated malware performing lateral movement between endpoints with different next generation anti-malware products. While this paper focuses on API calls and printable strings as features, the proposed attack is valid for every modifiable feature type, sequence or not.

To the best of our knowledge, there is currently no published and evaluated method to either detect or mitigate RNN adversarial sequences. Moreover, existing papers on defense mechanisms against non-sequence attacks are focused on gradient based attacks, thus rarely effective against random perturbation attacks. For instance, distillation (Brendel, Rauber, and Bethge 2018) can mask the gradient - but this has no effect on the attack if you choose an API call without calculating the gradient, as done here. Adversarial training (Goodfellow, Shlens, and Szegedy 2015) is also less effective against random attacks, because a different stochastic adversarial sequence is generated every time, making it challenging for the classifier to generalize form one adversarial sequence to another. Those defense methods

will also be a part of our future work.

We used identical implementation details (e.g., dataset, classifiers’ hyper-parameters, etc.) as (Rosenberg et al. 2018) so the attacks can be compared. Thus, in the paper, we omit many of these details, referring the reader to (Rosenberg et al. 2018) instead. Those details are added here, for the reader’s convenience.

An overview of the malware classification process is shown in Figure 1, taken from (Rosenberg et al. 2018).

Figure 1: Overview of the Malware Classification Process

Appendix A: Tested Dataset

As mentioned in Section 4.1, we used the dataset from (Rosenberg et al. 2018), since it is large and includes the latest malware variants, such as the Cerber and Locky ransomware families. Each malware type (ransomware, worms, backdoors, droppers, spyware, PUA, and viruses) has the same number of samples, to prevent a prediction bias towards the majority class. 20% of the malware families (such as the NotPetya ransomware family) were only used on the test set to assess generalization to an unseen malware family. 80% of the malware families’ (like the Virut virus family) samples were distributed between the training and test sets, to determine the classifier’s ability to generalize to samples from the same family. The temporal difference between the training set and the test set is six months (i.e., all training set samples are older than the test set samples), based on VirusTotal’s ‘first seen’ date. The ground truth labels of the dataset were determined by VirusTotal, an on-line scanning service which contains more than 60 different security products. A sample with 15 or more positive (i.e., malware) classifications from the 60 products is considered malicious. A sample with zero positive classifications is labeled as benign. All samples with 1-14 positives were omitted to prevent false positive contamination of the dataset.

It is crucial to prevent dataset contamination by malware that detects whether the malware is running in a Cuckoo Sandbox (or on virtual machines) and if so, quits immediately to prevent reversing efforts. In those cases, the sample’s label is malicious, but its behavior recorded in Cuckoo Sandbox (its API call sequence) isn’t, due to its anti-forensic capabilities. To mitigate such contamination of the dataset, two countermeasures were used: 1) Considering only API call sequences with more than 15 API calls (as in (Huang and Stokes 2016)), omitting malware that detect a VM and quit, and 2) Applying YARA rules to find samples trying to detect sandbox programs such as Cuckoo Sandbox and omitting all such samples. One might argue that the evasive malware that apply such anti-VM techniques are extremely challenging and relevant. However, in this paper we focus on the adversarial attack. This attack is generic enough to work for those evasive malware as well, assuming that other mitigation techniques (e.g., anti-anti-VM), would be applied. Af-
After this filtering and balancing of the benign samples, about 400,000 valid samples remained. The final training set size is 360,000 samples, 36,000 of which serve as the validation set. The test set size is 36,000 samples. All sets are balanced between malicious and benign samples.

Appendix B: Tested Malware Classifiers

As mentioned in Section 4.1, we used the malware classifiers from (Rosenberg et al. 2018), since many classifiers are covered, allowing us to evaluate the attack effectiveness (Equation 2) against many classifier types. The maximum input sequence length was limited to \( m = 140 \) API calls, since longer sequence lengths, e.g., \( m = 1000 \), had no effect on the accuracy, and padded shorter sequences with zeros. A zero stands for a null API in our one-hot encoding. Longer sequences are split into windows of \( m \) API calls each, and each window is classified in turn. If any window is malicious the entire sequence is considered malicious. Thus, the input of all of the classifiers is a vector of \( m = 140 \) API call types in one-hot encoding, using 314 bits, since there were 314 monitored API call types in the Cuckoo reports for the dataset. The output is a binary classification: malicious or benign. An overview of the LSTM architecture is shown in Figure 2(a).

The Keras implementation was used for all neural network classifiers, with TensorFlow used for the back end. XGBoost and scikit-learn were used for all other classifiers.

The loss function used for training was binary cross entropy. Adam optimizer was used for all of the neural networks. The output layer was fully connected with sigmoid activation for all neural networks. For neural networks, a rectified linear unit, \( ReLU(x) = \max(0, x) \), was chosen as an activation function for the input and hidden layers due to its fast convergence compared to \( \text{sigmoid}(x) \) or \( \text{tanh}(x) \), and dropout was used to improve the generalization potential of the network. A batch size of 32 samples was used.

The classifiers also have the following classifier-specific hyper parameters:

- DNN - two fully connected hidden layers of 128 neurons, each with ReLU activation and a dropout rate of 0.2.
- CNN - 1D ConvNet with 128 output filters, stride length of one, 1D convolution window size of three and ReLU activation, followed by a global max pooling 1D layer and a fully connected layer of 128 neurons with ReLU activation and a dropout rate of 0.2.
- RNN, LSTM, GRU, BRNN, BLSTM, bidirectional GRU - a hidden layer of 128 units, with a dropout rate of 0.2 for both inputs and recurrent states.
- Deep LSTM and BLSTM - two hidden layers of 128 units, with a dropout rate of 0.2 for both inputs and recurrent states in both layers.
- Linear SVM and logistic regression classifiers - a regularization parameter \( C=1.0 \) and L2 norm penalty.
- Random forest classifier - using 10 decision trees with unlimited maximum depth and the Gini criteria for choosing the best split.
- Gradient boosted decision tree - up to 100 decision trees with a maximum depth of 10 each.

The classifiers’ performance was measured using the accuracy ratio, which gives equal importance to both FP and FN (unlike precision or recall). The FP rate of the classifiers varied between 0.5-1%.

The performance of the classifiers is shown in Table 1. The accuracy was measured on the test set, which contains 36,000 samples.

As can be seen in Table 1, the LSTM variants are the best malware classifiers, accuracy-wise, and, as shown in the main submission, BLSTM is also one of the classifiers most resistant to the proposed attack.

\(^1\)The FP rate was chosen to be on the high end of production systems. A lower FP rate would mean lower recall either, due-to the trade-off between them, therefore making our attack even more effective.
Appendix C: Tested Hybrid Malware Classifiers

As mentioned in Section 4.2.4, we used the hybrid malware classifier used in (Rosenberg et al. 2018), with printable strings inside a PE file as our static features. Strings can be used, e.g., to statically identify loaded DLLs and called functions, and recognize modified file paths and registry keys, etc. Our architecture for the hybrid classifier, shown in Figure 2(b), is: 1) A static branch that contains an input vector of 20,000 Boolean values: for each of the 20,000 most frequent strings in the entire dataset, do they appear in the file or not? (analogous to a similar procedure used in NLP, which filters the least frequent words in a language). 2) A dynamic branch that contains an input vector of 140 API calls, each one-hot encoded, inserted into a LSTM layer of 128 units, and sigmoid activation function, with a dropout rate of 0.2 for both inputs and recurrent states. This vector is inserted into two fully-connected layers with 128 neurons, a ReLU activation function, and a dropout rate of 0.2 each. The 256 outputs of both branches are inserted into a fully-connected output layer with sigmoid activation function. Therefore, the input of the classifier is a vector containing 20,000 Boolean values and 140 one-hot encoded APIs, and the output is malicious or benign classification. All other hyper parameters are the same as in Appendix B.

Due to hardware limitations, a subset of the dataset was used as a training set: 54,000 training samples and test and validation sets of 6,000 samples each. The dataset was representative and maintained the same distribution as the dataset described in Section 4.1. Trained on this dataset, a classifier using only the static branch attains 96.19% accuracy, and a hybrid model, using both branches (Figure 2(b)) achieves 96.94% accuracy, meaning that using multiple feature types improves the accuracy.
