Flux-driven Josephson traveling-wave parametric amplifier

A. B. Zorin

Physikalisch-Technische Bundesanstalt, Bundesallee 100, 38116 Braunschweig, Germany

We have developed a concept for a traveling-wave parametric amplifier driven by a magnetic-flux wave. The circuit consists of a serial array of symmetric DC SQUIDs coupled inductively to a separate superconducting LC-transmission line carrying the pump wave. The adjusted phase velocity of the pump flux-wave of frequency \( \omega_p \) ensures amplification of the signal (\( \omega_s \)) and the idler (\( \omega_i \)) waves, with frequencies obeying the relation \( \omega_s + \omega_i = \omega_p \). The advantage of the proposed flux-driven linear circuit includes an adjustable phase matching yielding large gain in a wide frequency range and overcoming of the pump depletion problem. Unlike the conventional traveling-wave amplifiers, the signal and pump in the proposed circuit are applied to different ports, what can greatly simplify the whole measurement setup. The experimental parameters and characteristics of this amplifier have been evaluated and show promise for applications in quantum information single-photon circuits.

1. INTRODUCTION

Josephson parametric amplifiers (JPAs) are among the most useful tools in the field of quantum technology (see, for example, Refs.\(^{1–10}\)). However, the quantum-limited performance of these devices is often combined with a fairly limited bandwidth and small dynamic range. The limitation of the bandwidth is primarily due to an amplifier cavity that enhances the interaction between the signal and the pump, thereby ensuring a large parametric gain. For this reason, JPAs that are based on traveling microwaves (i.e., that have no cavity, and are thus free from the gain-bandwidth trade-off) have been extensively explored in the past several years.\(^{11–25}\) Moreover, the lack of a cavity enables a larger dynamic range in these amplifiers.\(^{15}\)

The traveling-wave JPAs (TWJPAs) have an architecture of a microwave transmission line made of periodically repeated sections, including either single Josephson junctions\(^{14,15}\) or various types of SQUIDs.\(^{16–20}\) Most of these amplifiers operate in the four-wave mixing mode (i.e., when \( \omega_s + \omega_i = 2 \omega_p \), where \( \omega_s \), \( \omega_i \), and \( \omega_p \) are the signal, idler and pump frequencies, respectively). This mode is possible due to the natural Kerr-like nonlinearity of the Josephson inductance \( L_J = \partial \Phi(I)/\partial I \). This inductance, has a quadratic dependence on the reason-

\[ L_J(t) \approx \left[ 1 + 0.5I^2(t)/I_c^2 \right] L_{J0} \tag{1} \]

Here the parameter \( L_{J0} = \varphi_0/I_c \) is the linear (small-signal) inductance, \( \varphi_0 = \hbar/2e \) is the reduced flux quantum, and \( I_c \) is the critical current.

The non-hysteretic rf-SQUID having linear geometrical inductance \( L \) and dimensionless screening parameter \( \beta_L \equiv L_c/\varphi_0 < 1 \) (or, alternatively, by using an asymmetric SQUID having a Josephson inductance in one branch).\(^{10,18,21,22}\) Compared to the TWJPA with four-wave mixing exploiting Kerr nonlinearity, this TWJPA was almost free of self- and cross-modulation effects. So, the corresponding wave numbers \( k_s \), \( k_i \), \( k_p \) did not depend on the pump power \( P_p \), which may otherwise cause a significant phase mismatch \( \Delta k = k_p - k_s - k_i \neq 0 \) and require careful dispersion engineering (resonant phase matching).\(^{14,15}\)

Both these types of TWJPA were based on the Josephson nonlinearity, i.e., dependence of the Josephson inductance \( L_J(\tau) \) on current \( I(t) \), enabling time-variation of \( L_J(t) \) with the pump frequency \( \omega_p \) or the double pump frequency \( 2 \omega_p \) in the three-wave and four-wave mixing regimes, respectively. The later is the very principle of operation of the optical-fibre (as well as the superconducting kinetic-inductance based) traveling-wave parametric amplifier, where a large pump ensures modulation of the refraction index of optical medium (or kinetic inductance of the wire in the microwave transmission line) with weak Kerr nonlinearity and, hence, enabling a growth of a signal. Unfortunately, in the Josephson parametric amplifiers, the pump power \( P_p \) (more specifically, the pump current \( I_p \)) is limited by the critical current of the junctions, \( \sqrt{P_p} \propto |I_p| \lesssim 0.5 I_c \). In addition to this, the pump power is progressively depleted due to conversion into the signal \( P_s \) and the idler \( P_i \) powers. This sets a limitation on the length and, therefore, on the gain of the TWJPA. Thus, similar to the cavity-based JPAs, the pump depletion reduces the compression point and limits the dynamic range of the TWJPA.\(^{13,17,27}\) Finally, the nonlinearity may cause unwanted leakage of the pump power by converting it into the power of higher harmonics.\(^{14,17}\)

In this paper, we propose an alternative concept for a realization of the TWJPA in which these problems can be mitigated. Our TWJPA exploits the principle of straightforward modulation of the Josephson element (DC SQUID) by means of an external flux drive \( \Phi_{\text{ext}}(t) \).
applied via a separate pump-line. In this case, the Josephson nonlinearity is no longer exploited for mixing the modes, so the parametric circuit can operate in the regime with time-varying linear inductance $L_J(t)$ (cf. Eqs. (1,2) and Eq. (3)) and, hence, have a larger dynamic range.

This fundamental principle of parametric amplification (see, for example, Refs. 28, 29) was realized earlier by Yamamoto et al. 30 in the cavity-based JPA by directly modulating the flux threading the DC SQUID at twice the resonator frequency. The SQUID in this inherently linear circuit played the role of a flux-dependent inductor terminating a superconducting transmission-line $\lambda/4$-resonator. The great advantage of this JPA was that the pump and the signal ($\omega_s \approx 0.5 \omega_p$) were applied to different ports of the circuit, so the separation of the output signal from the pump was straightforward. Lately, these flux-driven cavity-based JPAs were successfully applied, e.g., for the microwave photon generation 31, 32 and ultra-sensitive thermal microwave detectors 33, 34 and squeezing of vacuum fluctuations 35, 36, etc. The nonlinear effects in flux-driven SQUID-based circuits were studied in Refs. 37, 38. Another variant of a flux-modulated JPA with high gain was based on serially-connected eight SQUIDs which were embedded in a lumped-element $LC$-circuit and driven in-phase by an RF current in the common coupling loop 39.

However, the traveling-wave case is unique in that it requires the flux-drive phases on the individual cells of the SQUID-based transmission line to be properly adjusted. Only then the parametric amplification of a traveling signal becomes possible. Below, we will show that such flux drive is possible with the help of a separate pump transmission line; because this pump line is inductively (weakly-) coupled to the signal line over its full length, the flux drive can be realized in the desired traveling-wave fashion. Importantly, in the case of sufficiently small coupling of two lines, the power transmitted in the isolated pump line is no longer limited by the critical current of the Josephson junctions (SQUIDs) inserted in the signal line, but it is only limited by tolerance of the cryogenic setup to a generated Joule heat. Therefore, sufficiently large pump power can ensure almost depletion-free pump regime of parametric amplification. In this case, each elementary cell in the signal line provides maximum possible gain.

II. WAVE EQUATION AND FLUX DRIVE

The electric diagram of our superconducting microwave circuit with nominally vanishing losses is shown in Fig. 1. The circuit consists of two inductively coupled ladder-type transmission lines: a signal line and a pump line. Similar to the design of the cavity-based JPA explored in Ref. 1, the cells of our signal line include symmetric DC SQUIDs ($L_{\perp 1} = L_{\perp 2} = I_0$) with small geometrical inductances of the loops. In this case, the effective critical current $I_c = 2I_0 |\cos(\Phi/2\varphi_0)|$ and corresponding linear inductance of each SQUID, $L_{\perp 0}^{-1} = (2I_0/\varphi_0) |\cos(\Phi/2\varphi_0)|$, can be efficiently controlled by magnetic flux $\Phi = \Phi_{dc} + \Phi_{ac}$. These SQUIDs are interleaved with identical ground capacitances $C$ (Fig. 1b). The pump transmission line consists of $LC$ sections with inductances $L'$ and ground capacitances $C'$ $\approx C$; its impedance $Z_0 = \sqrt{L'/C'}$ $\approx 50 \Omega$. The coupling inductances between SQUIDs and inductors $L'$ are equal to $M$ ($\ll L'$) and enable AC flux drive in the SQUIDs.

The flux offset $\Phi_{dc}$ is set by means of an external static field $B$ and ensures the SQUID critical current $I_c \sim I_0$ and, hence, the SQUID inductance $L_{\perp 0}(\Phi_{dc}) \sim L_0 \equiv \varphi_0/I_0$. Then, as shown in Fig. 2, the AC component of the flux $\Phi_{ac}$ can result in sufficiently large modulation of the inductance, i.e., $0 < L_{\perp 0}^{-1} < 2L_0^{-1}$. Therefore, the efficient three-wave mixing is possible in such a SQUID without exploiting the nonlinear properties of its inductance. Fine “tuning” the flux $\Phi_{dc}$ and, therefore, the SQUID inductance $L_{\perp 0} \approx L'$, allows adjustment of fre-
amplitude completed and presents a traveling flux wave having constant flux bias. The shaded band corresponds to the ±20% deviation from the optimal value \(1/L_0 \approx 1/L'\) allowing both sufficiently large flux-modulation of the inductance and sufficiently wide range for fine adjustment of the phase velocities in two lines (see Eq. (5)).

keeping the signal-line impedance \(\sqrt{L_{0}/C} \approx \sqrt{L'/C'} \approx 50\, \Omega\) Neglecting for the moment small dispersion, relation (5) ensures that the phase velocities of the waves in the signal line,

\[ v_s = a\omega_0, \]  

and in the pump line,

\[ v_p = a\omega'_0, \]  

are equal, where \(a\) is the size of the cells in each transmission line. Therefore, the spatial phase matching is possible, i.e., \(\Delta k = k_p - k_s - k_i \approx 0\).

Generally, the dynamics of the electrical circuit shown in Fig. 1a is described by the set of coupled equations for the values of fluxes \(F_n\) on the nodes of the pump line and fluxes \(\Phi_n\) on the nodes of the signal line (see Fig. 1b). These equations are derived in Appendix A. In the case of sufficiently small dimensionless coupling, i.e.,

\[ \kappa = M/L' \ll 1, \]  

and sufficiently large power \(P_p\), the pump remains undepleted and presents a traveling flux wave having constant amplitude \(A_{\phi_0} \propto \sqrt{P_p}\). Then, the equations for these two transmission lines decouple. Eventually, the equation of motion for the signal line in the continuum limit (valid for \(\omega \ll \omega_0, \omega_f\)) reads

\[
\frac{\partial^2 \phi}{\partial t^2} - \omega_0^2 \frac{\partial^2 \phi}{\partial t^2} + \omega_f^2 \frac{\partial^4 \phi}{\partial t^2 \partial x^2} - \gamma \frac{\partial}{\partial x} \left[ \left( \frac{\partial \phi}{\partial x} \right)^3 \right] + \frac{\partial}{\partial x} \left[ m \sin(k_p x - \omega_p t) \frac{\partial \phi}{\partial x} \right] = 0. \tag{9}
\]

Here, \(x\) is the dimensionless coordinate normalized on the cell size \(a\); the normalized magnetic flux \(\phi(x, t)/\phi_0\), where the continuous flux variable \(\Phi(x, t)\) coincides with flux values \(\Phi_n\) on the nodes \(x = n\). Frequency

\[ \omega_f = 1/\sqrt{L_{0}C_f} \]  

is the plasma frequency of the SQUID that has total capacitance \(C_f = C_{f_1} + C_{f_2}\) (see Fig. 1b) and effective inductance \(L_{0}\). The dimensionless wave numbers of the pump wave in the pump line, \(k_p\), and of any wave (including signal \(\omega_s\) and idler \(\omega_i\)) in the signal line, \(k\), obey the dispersion relations (see Appendix A)

\[ k_p \approx \frac{\omega_p}{\omega_0} \left(1 + \frac{\omega_p^2}{24\omega_0^2} \right) \approx \frac{\omega_p}{\omega_0} \ll 1 \]  

and

\[ k \approx \frac{\omega}{\omega_0} \left(1 + \frac{\omega^2}{2\omega_0^2} \right) + \frac{\omega^2}{24\omega_0^2} \approx 1, \]  

respectively. The latter relation includes the small term \(\omega^2/2\omega_0^2\) which stems from the Josephson plasma resonance in the SQUIDs. The small terms \(\omega_0^2/24\omega_0^2\) and \(\omega^2/24\omega_0^2\) entering into Eqs. (11) and (12), respectively, are the consequence of the fact that the transmission lines are made of lumped elements. In the practical case of \(\omega_s^2 \leq \omega_0^2\) these small terms can be omitted.

The fourth, on the right-hand side of Eq. (9), Kerr-like term (with coefficient \(\gamma = 1/6\)) describes nonlinear effects

\[ \omega^2/2\omega_0^2 \]  

which are normally negligibly small (unless the signal amplitude or, more specifically, the Josephson phase deviation on the SQUIDs approaches appreciable values, \(\varphi(x) = k_s, \Phi(x)/\phi_0 \sim 1\), see Section V for more details). For reasonably small input signal, the signal wave can approach such large amplitude only at the transmission-line output. So, counting of this term is only important for evaluation of the gain compression.

The fifth term on the right-hand side of the wave equation (9) stems from the time-dependent distributed inductance \(L(x, t)\), which is varied in the traveling-wave fashion,

\[ L^{-1}(x, t) = [1 + m \sin(k_p x - \omega_p t)]L_{0}^{-1}. \]  

The dimensionless coefficient \(m\),

\[ m = \frac{\kappa}{2} A_{\phi_0} k_p \tan \frac{\Phi_{dc}}{2\varphi_0} \approx \kappa \frac{\sqrt{\varphi_0 P_p}}{2\varphi_0} \tan \frac{\Phi_{dc}}{2\varphi_0}, \]  

determines the depth of the inductance modulation and depends on the strength of coupling \(\kappa\) and the pump power \(P_p\). Here the product \(A_{\phi_0} k_p\) is equal to \(A_{\phi_0} \omega_p/\phi_0 = V_p/\phi_0 \omega_0\), where \(V_p = \sqrt{2Z_\alpha P_p}\) is the voltage amplitude in the pump wave.
The time-dependent inductance \[ \frac{\phi}{L}\text{ enables parametric amplification of the signal} \]

\[ G = \frac{P_{\text{out}}}{P_{\text{in}}} = \cosh^2(gN) \approx \frac{1}{4} e^{2gN}, \]  

(15)

\[ G_i = \frac{P_{\text{out}}^i}{P_{\text{in}}^i} = \frac{\omega_i}{\omega_s} \sinh^2(gN) \approx \frac{\omega_i}{4\omega_s} e^{2gN}, \]  

(16)

where both the direct power gain \( G \) (\( \gg 1 \)) and the intermodulation power gain \( G_i \) (\( \gg 1 \)) depend exponentially on length \( N \) and the gain factor \( g \propto m\omega_p/\omega_0 \). Its inverse value,

\[ g^{-1} = N_g, \]  

(17)

is, therefore, the \( e \)-folding length of the amplitude gain.

### III. PHASE MATCHING CONSIDERATION

In the general case, an inherently broadband flux-driven transmission-line allows multiwave mixing processes. Specifically, the basic three-wave mixing process involving conventional idler frequency

\[ \omega_1 = \omega_p - \omega_s, \]  

(18)

can be accompanied by two additional mixing processes (frequency up-conversion) involving the idlers \[ \omega_1 = \omega_p + \omega_s, \]  

(19)

and

\[ \omega_2 = \omega_p + \omega_i = 2\omega_p - \omega_s. \]  

(20)

The latter expression for idler frequency \( \omega_2 \) allows interpreting the process Eq. (20) as a four-wave mixing. These three types of mixing, i.e., (18), (19), and (20), are schematically shown in the diagram in Fig. 3a.

If the processes (19) and (20) are not sufficiently suppressed, they may degrade the system performance. In this general case, the Manley-Rowe relations for the wave powers, i.e.,

\[ \frac{P_s - P_{s,1}^\text{in}}{\omega_s} = \frac{P_1}{\omega_1} = -\frac{P_p - P_{p,1}^\text{in}}{\omega_p}, \]  

(21)

or, equivalently, the relations for corresponding photon numbers,

\[ n_s - n_{s,1}^\text{in} = n_1 = n_{p,1}^\text{in} - n_p, \]  

(22)

take the form

\[ \frac{P_s - P_{s,2}^\text{in}}{\omega_s} = \frac{P_1}{\omega_1} + \frac{P_2}{\omega_2} = -\frac{P_p - P_{p,2}^\text{in}}{\omega_p} - \frac{2P_1}{\omega_1} - \frac{P_2}{\omega_2}, \]  

(23)

or, in terms of the photon numbers,

\[ n_s - n_{s,2}^\text{in} = n_1 - n_1 + n_2 = n_{p,2}^\text{in} - n_p - 2n_1 - n_2, \]  

(24)

where \( P_{1,2} \) and \( n_{1,2} \) are the powers and the photon numbers of the modes \( \omega_{1,2} \), respectively. Due to large photon energies, \( \hbar \omega_{1,2} \gg \hbar \omega_p \), both complementary processes, \( \omega_{s,1} + \omega_p \rightarrow \omega_{1,2} \) and \( \omega_{1,2} \rightarrow \omega_{s,1} + \omega_p \), are possible so the amplified power of the signal/idler flows repeatedly from \( \omega_{s,1} \) to \( \omega_{1,2} \) and vice versa.41,44 This sce-
nario leads to reducing the direct/intermodulation gain $G = \frac{P_{out}}{P_{in}} \left( \frac{G_{c}}{G_{i}} \right)$. As we shall show below, suppression of unwanted modes $\omega_1$ and $\omega_2$ is possible by properly choosing the circuit parameters, i.e., without modification of the circuit architecture.

Using expression (11) for wave number $k_p$ and expression (12) for wave numbers $k_s$, $k_i$, and $k_2$ of the waves $\omega_s$, $\omega_i$, $\omega_1$, and $\omega_2$, respectively, the corresponding phase mismatches for the processes (18), (19), and (20) can be written as

\[
\Delta k = k_p - k_i - k_s = -\left( 1/3 + \delta^2 \right) \eta, \quad (25)
\]

\[
\Delta k_1 = k_p - k_1 + k_2 = -\left( 13/3 + 3\delta + \delta^2 \right) \eta, \quad (26)
\]

\[
\Delta k_2 = k_p - k_2 + k_i = -\left( 13/3 - 3\delta + \delta^2 \right) \eta. \quad (27)
\]

Here the dimensionless frequency detuning is

\[
\delta = \frac{2\omega_s - \omega_p}{\omega_p} = \frac{\omega_p - 2\omega_s}{\omega_p}. \quad (28)
\]

In Eqs. (25), (26), and (27), we have introduced two small parameters,

\[
\eta = 3\omega_p^3/8\omega_s\omega_j^2, \quad (29)
\]

and

\[
\nu = \omega_p/\omega'_0 - \omega_p/\omega_0 \approx \Delta \omega \omega_p/\omega_0^2, \quad (30)
\]

where $\Delta \omega = \omega_0 - \omega'_0 < \omega_0$ is a small mismatch of the cutoff frequencies in two transmission lines (see Eq. (31)). Therefore, properly designing the plasma frequency of the SQUID $\omega_j$ (see Eq. (11)) and setting a small cutoff-frequency difference, $\Delta \omega > 0$, allow effective control of all three phase mismatches (25), (26) and (27). Specifically, fixing the frequency difference equal to

\[
\Delta \omega = \omega_p^2/8\omega_0^2, \quad (31)
\]

or, equivalently, taking $\nu = \eta/3$, one can achieve nearly perfect phase matching ($\Delta k \approx 0$) in the basic mixing process (18) for frequencies $\omega_s \approx \omega_i \approx \omega_p/2$ (or small detuning $\| \delta \| \ll 1$), while keeping appreciable phase mismatches in unwanted processes (19) and (20), i.e.,

\[
\Delta k = -\delta^2 \eta, \quad (32)
\]

\[
\Delta k_1 = -(4 + 3\delta + \delta^2) \eta, \quad (33)
\]

\[
\Delta k_2 = -(4 - 3\delta + \delta^2) \eta. \quad (34)
\]

The dependencies of these values on the normalized signal frequency are shown in Fig. 3b.

In the case of sufficiently small $|\Delta k|$, or, equivalently, large coherence length $N_c$ in the basic process,

\[
N_c \equiv \frac{\pi}{|\Delta k|} \approx \frac{\pi}{\delta^2 \eta} \gg \frac{1}{g} = N_g, \quad (35)
\]

and sufficiently short coherence lengths $N_{c1,c2}$ in two additional mixing processes, i.e.,

\[
N_{c1,c2} \equiv \frac{\pi}{|\Delta k_{1,2}|} \approx \frac{\pi}{4\eta} \ll \frac{1}{g} = N_g, \quad (36)
\]

The unwanted processes (19) and (20) are safely suppressed. So, amplification of the signal ($\omega_i$) and the idler ($\omega_j$) tones is described by formulas (15) and (16), respectively. This favorable case is illustrated in Fig. 3c.

## IV. SIGNAL GAIN

To quantify the effect of multiwave mixing (shown schematically in Fig. 3a) we apply the coupled-mode equation method\(^{24}\). The solution of Eq. (9) is then found in the form of four waves propagating in the forward direction,

\[
\phi(x,t) = \frac{A_s(x)}{2} e^{i(k_1x - \omega_1t)} + \frac{A_i(x)}{2} e^{i(k_2x - \omega_2t)} + \frac{A_1(x)}{2} e^{i(k_1x - \omega_1t)} + \frac{A_2(x)}{2} e^{i(k_2x - \omega_2t)} + c.c., \quad (37)
\]

where $A_{s,i,1,2}(x)$ are slowly varying complex amplitudes of the signal and three idlers, obeying the condition\(^{12-17}\)

\[
|\frac{\partial^2 A_{s,i,1,2}}{\partial x^2}| \ll k_{s,i,1,2} |\partial A_{s,i,1,2}/\partial x| \ll k_{s,i,1,2}^2 |A_{s,i,1,2}|. \quad (38)
\]

After incorporating Eq. (37) into Eq. (9) with omitted Kerr term ($\chi \gamma$), the coupled linear equations for $A_s$, $A_i$, $A_1$, and $A_2$, take the form

\[
\frac{dA_s}{dx} = \frac{m}{2} k_s A_s e^{i\Delta k x} + \frac{1}{2} k_1 A_1 e^{-i\Delta k_1 x}, \quad (39)
\]

\[
\frac{dA_i}{dx} = \frac{m}{2} k_s A_s e^{i\Delta k x} + \frac{1}{2} k_2 A_2 e^{-i\Delta k_2 x}, \quad (40)
\]

\[
\frac{dA_1}{dx} = -\frac{1}{2} k_s A_s e^{i\Delta k_1 x}, \quad (41)
\]

\[
\frac{dA_2}{dx} = -\frac{1}{2} k_s A_s e^{i\Delta k_2 x}. \quad (42)
\]

The first terms on the right-hand-sides of equations (39) and (40) describe the basic parametric mixing (18)\(^{23}\).

In the case of sufficient suppression of the modes $\omega_1$ and $\omega_2$ (see condition Eq. (38) or, equivalently, the inequality $\pi g/4\eta \ll 1$) small amplitudes $A_{1,2}$ can be omitted and the decoupled pair of equations (39) and (40) for solely amplitudes $A_s,i$ has a simple analytical solution. Specifically, the solution with initial conditions $A_s(0) = A_{s,0}$ and $A_i(0) = 0$ reads\(^{14-17}\)

\[
A_s = A_{s,0} \left[ \cosh(gx) - \frac{i}{2} \frac{\Delta k}{2g} \sinh(gx) \right] e^{i\Delta k x/2}, \quad (43)
\]

\[
A_i = 2 \frac{g\omega_s}{\omega_p} A_{s,0} \sinh(gx) e^{i\Delta k x/2}. \quad (44)
\]

Here the exponential gain factor is

\[
g = \sqrt{(1 - \delta^2)g_0^2 - (\Delta k/2)^2}, \quad (45)
\]

and its maximum value,

\[
g_0 = \frac{mk_p}{4} \approx \frac{m\omega_p}{4\omega_0}. \quad (46)
\]
is achieved at perfect phase matching, $\Delta k = 0$, and zero detuning, $\delta = 0$.

The power gain $G$ of the line of length $N$ is then given by formula\textsuperscript{14}

$$G = \frac{|A_s(N)|^2}{|A_{so}|^2} = \cosh^2(gN) - \left(\frac{\Delta k}{2g}\right)^2 \sinh^2(gN), \quad (47)$$

which for the zero phase mismatch, $\Delta k = 0$, and large gain, $gN \gg 1$, is reduced to Eq. (13) with $g = g_0 \sqrt{1 - \delta^2}$, i.e.,

$$G = \cosh^2(g_0 \sqrt{1 - \delta^2} N) \approx \frac{1}{4} \exp \left(\frac{\omega_p \sqrt{1 - \delta^2}}{2\omega_0} mN\right). \quad (48)$$

The frequency dependence of $\log G$ has a typical semi-circle shape, $y = \sqrt{1 - \delta^2}$, with the maximum at $\delta = 0$.\textsuperscript{21,22} For example, the amplifier with this ideal shape of the power gain with maximum value of 20 dB has the 3 dB bandwidth of $\sqrt{1 - (17/20)^2} \approx 0.5 \omega_p$, which is centered at $\omega_s = 0.5 \omega_p$ (see the dotted line in Fig. 4).\textsuperscript{17,40}

In the case of insufficiently short coherence lengths $N_{c1,2} \approx N_g$, see Eq. (26), i.e., not sufficiently small value of dimensionless parameter

$$\xi = \frac{N_{c1,2}}{N_g} = \frac{\pi g_0 \sqrt{1 - \delta^2}}{4 \eta} \approx \frac{m \omega_p^2 \sqrt{1 - \delta^2}}{2 \omega_0^2} \lesssim 1, \quad (49)$$

the power conversion to the modes $\omega_1$\textsuperscript{19} and $\omega_2$\textsuperscript{20} becomes appreciable. So, redistribution of power between the signal, the idler and the unwanted idler modes $\omega_1$ and $\omega_2$ may lead to substantial suppression of the signal gain. To quantify this effect, which is most pronounced at large detuning, $|\delta| \gtrsim 0.5$, we numerically solved the set of differential equations\textsuperscript{59-62}.

Figure 4 shows the frequency dependence of $\log G$ obtained by numerical integration of Eqs. (39)-(42) with initial conditions

$$A_s(0) = A_{so}, \quad A_i(0) = A_1(0) = A_2(0) = 0, \quad (50)$$

for five TWJPAs having different lengths $N$ (the set of solid curves), but nominally the same maximum gain of 20 dB (adjusted by a proper pump power, $P_p \propto 1/N^2$, keeping $m \propto 1/N$). The values of parameter $\xi$ are approximately equal to 0.13, 0.19, 0.27, 0.38, and 0.47 (in the order of curves from top to bottom in the central part of the plot) which cover the range from the relatively small value of 0.13 up to the value 0.47 close to unity. For comparison, the dotted curve illustrates the case of $\xi = 0$, yielding the maximum possible gain given by Eq. (13).

One can see two features in behavior of these circuits. Firstly, the gain suppression in the TWJPAs with relatively small values of $\xi$ ($\xi < 0.3$ or $m < 0.1$) is rather small (< 2 dB) for detuning $|\delta| \lesssim 0.5$, whereas for $0.5 \lesssim |\delta| \leq 1$ the gain suppression is significant. This behavior is due to increase of the phase mismatch $|\Delta k| = \delta \eta$ and, hence, violation of inequality\textsuperscript{63} occurring at relatively large $|\delta|$. Secondly, the signal gain for rather large values of parameter $\xi$ ($\xi > 0.3$ or $m > 0.1$) is notably less than the nominal value given by the dotted line, especially for small detuning, $|\delta| \lesssim 0.5$. Interestingly, that suppression of the gain for larger detuning, $|\delta| \gtrsim 0.5$, is not so dramatic as in the case of small values of parameter $\xi$. So, we can conclude that for our set of characteristic frequencies, the TWJPA length $N$ of about 1000 ensures both sufficiently large bandwidth of about 0.47$\omega_p$ and sufficiently small unwanted power conversion to the high-frequency idler modes.

**V. POSSIBLE CIRCUIT DESIGN**

The design of the practical circuit obviously depends on specific applications of the TWJPA. Below we focus on the set of parameters typical for the TWJPAs (both with three-wave mixing and four-wave mixing) which were earlier developed for the quantum information applications including superconducting qubits\textsuperscript{13,20}. These parameters include the operation frequency of the order of 10 GHz, relatively large Josephson junctions having critical current of the order of several microamperes (and, hence, sufficiently low charging energy $E_c = e^2/2C_J \sim 10^{-3}\varphi_0 I_0$, ensuring classical behavior of the Josephson phase $\varphi$), the standard line impedance of 50 $\Omega$ and the nominal gain of 20 dB.

Taking relatively high target value of the cutoff frequency $\omega_0/2\pi = 100$ GHz and the standard transmission-line impedance $Z_0 = 50$ $\Omega$, we obtain the following basic

![FIG. 4: Signal gain as a function of frequency $\omega_s$ at fixed pump frequency, $\omega_p = 0.2 \omega_0$, and Josephson plasma frequency, $\omega_J = 0.5 \omega_0$ (yielding $\eta \approx 0.012$, see Eq. (29)). Solid curves correspond to several combinations of length $N$ (decreasing order from top to bottom) and modulation parameter $m$ with fixed product $g_0 N = m \omega_p \sqrt{1 - \delta^2}$ (yielding nominal maximum gain of $G = \cosh^2(g_0 N) \approx 10^2$). The dotted curve shows the plot of the ultimate gain versus frequency given by formula (48).](image-url)
circuit-parameters,
\[ C' = C = 1/\omega_0 Z_0 \approx 32 \text{ fF} \] (51)
and
\[ L' = L_{J0} = Z_0/\omega_0 \approx 80 \text{ pH}. \] (52)

For a typical size of elementary cell \( a \sim 30 \mu\text{m} \) (see possible circuit layout, for example, in Ref.45) the phase velocity of microwaves in these transmission-lines \( v_s = \omega_0/\omega \) is reduced to the value about \( 2 \times 10^7 \text{ m/s} \). The wavelength of the pump \( \lambda_p \) for the designed frequency of \( \omega_p/2\pi = 20 \text{ GHz} \) (i.e., \( \omega_p/\omega_0 = 0.2 \)) is equal to the length of \( N_p = 2\pi\omega_0/\omega_p \approx 31 \) elementary cells.

In the optimal working point the constant magnetic flux \( \Phi_{dc}^\text{opt} /2\phi_0 \approx \pi/3 \) yields about 50% suppression of the maximum critical current of the SQUIDs, so the Josephson inductance value (52) corresponds to the critical current of a single junction, i.e., \( I_0 = \phi_0/2L_{J0} \approx 4 \mu\text{A} \) (see Fig. 2). Such Josephson junctions can be fabricated using either multilayer niobium technology (see, for example, Ref.42 and the review43) or shadow-evaporation aluminum technology.44 The Josephson plasma frequency of a bare Josephson junction with critical current density of, say, \( j_c = 3 \mu\text{A}/\mu\text{m}^2 \) and specific barrier capacitance about \( c_J = 50 \text{ F}/\mu\text{m}^2 \) is \( \omega_p/2\pi \approx 70 \text{ GHz} \). Therefore, the plasma frequency of the flux-biased SQUID with a partially suppressed critical current is \( \omega_p/2\pi \approx 70/\cos(\pi/3) \text{ GHz} \approx 50 \text{ GHz} \), i.e., \( \omega_p/\omega_J = 0.4 \). Taking the total number of elementary cells \( N = 1000 \), one can achieve sufficiently large gain in a reasonably large bandwidth (see Fig. 4). Possible deterioration of performance due to imperfect flux setting and inhomogeneity of the transmission line parameters (including those due to regular and irregular inhomogeneities of the critical current density on the chip) should be sufficiently small. The corresponding estimations are given in Appendix B.

According to formula (12), the target value of modulation-parameter \( m = 0.06 \) can be achieved by engineering a reasonably small dimensionless coupling \( \kappa = M/L' \) (for example, on the order of 0.02) and applying sufficiently large pump power,
\[ P_p = 2\cot^2(\pi/3) \frac{(m\varphi_0\omega_0)^2}{k^2 Z_0} \approx -53 \text{ dBm}. \] (53)

This power passing through the superconducting transmission line is not immediately dissipated on the chip, but can cause some heating of cold attenuators installed in the base-temperature stage. However, this level of power is seemingly acceptable for the most of setups with dilution refrigerators.

In the conventional TWJPs operating on wave mixing with the aid of Josephson nonlinearity, a relatively small pump power (limited by the nonlinear-element characteristics, i.e., the critical current value) propagates together with the signal and idler waves in the common transmission line. Due to parametric interaction of these traveling waves the pump power is gradually converted into the signal and the idler. The resulting pump-depletion leads to gradual reduction of the signal gain and, finally, to the gain saturation. This effect dramatically limits the amplifier dynamic range.13,16,17 The important feature of the proposed TWJPA driven by relatively large power \( P_p \) fed into a separate port of an isolated \( LC \)-line and only partly converted into the signal and idler is almost constant pump power, i.e., the absence of pump depletion. This remarkable property enables ultimate mixing in all section of the signal line and, hence, a steady gain. Only at sufficiently large signal amplitude achieved in the output sections of the line (i.e., for AC current amplitude amounted to the value about \( I_0 \)) its further growth is impeded by the SQUID nonlinearity.

To evaluate this effect in the limit of pure three-wave mixing \( |A_{1,2}| \ll |A_{s,i}| \), we derived from Eq. 9 the pair of coupled nonlinear equations for complex amplitudes \( A_s \) and \( A_i \), i.e.,
\[ \frac{dA_s}{dx} = -\frac{m}{2} k_s A_s^* e^{i\Delta k x} + \frac{3}{8} \gamma k_s A_s (k_s^2 |A_s|^2 + 2k_i^2 |A_i|^2), \] (54)
\[ \frac{dA_i}{dx} = -\frac{m}{2} k_i A_i e^{i\Delta k x} + \frac{3}{8} \gamma k_i A_i (k_s^2 |A_s|^2 + 2k_i^2 |A_i|^2). \] (55)

Both the self-Kerr \((\gamma |A_{s,i}|^2 |A_{s,i}|^2)\) and the cross-Kerr \((\gamma |A_{s,i}|^2 |A_{s,i}|^2)\) nonlinear terms cause the effect of phase modulation14 and, hence, phase mismatch \( \Delta k \neq 0 \), rising with the growth of the signal and the idler. As result, the total gain of TWJPA is reduced. We solved

\[ l_0 = 4 \mu\text{A} \]
\[ m = 0.06 \]
\[ \omega_0/2\pi = 100 \text{ GHz} \]
\[ \omega_0/2\pi = 20 \text{ GHz} \]
\[ \omega_0/2\pi = 10.1 \text{ GHz} \]

**FIG. 5:** Growing power of the signal waves of frequency \( \omega_s = 0.508\omega_p \) with input power values of \(-91 \text{ dBm}, -87.7 \text{ dBm}, \) and \(-84 \text{ dBm} \) (solid lines in the order from bottom to top, respectively) as a function of the cell number, found by numerical solving of the coupled-mode nonlinear equations (53) and (54). The actual gain for different input powers is given in the right column. The topmost (red) solid curve corresponds to decrease of the nominal 20 dB gain by 1 dB, which occurs at the input power of \( P_{\text{in}} \approx -84 \text{ dBm} \). For comparison, the dashed lines show the signal-power growth neglecting the nonlinear effects \((\gamma = 0)\), i.e., applying the formula \( P_s = P_s^{\text{opt}} \cosh^2(\varphi_0 N) \) (see Eq. 48).
Eqs. (55)-(55) with initial conditions \( A_{0}(0) = A_{0}^{\text{in}} = \sqrt{2Z_{0}P_{\text{in}}^{\text{in}}/\omega_{0}\varphi_{0}} \) and \( A_{1}(0) = 0 \) numerically and presented the results in Fig. 5.

The plot shows almost exponential growth of the signal power propagating in the array of SQUIDs with the effective critical current value of \( I_{0} = 4 \mu A \) and driven by the flux wave ensuring the modulation-parameter value \( m = 0.06 \). One can see that for sufficiently small input power the amplifier shows the nominal gain of about 20 dB (see the bottom curve, corresponding to \( P_{\text{out}}^{\text{in}} \approx -91 \text{ dBm} \) and \( P_{\text{out}}^{\text{in}} \approx -71 \text{ dBm} \)). For somewhat larger input power values (see, for example, the middle curve with \( P_{\text{out}}^{\text{in}} \approx -88 \text{ dBm} \)) the suppression of the nominal gain is still rather smaller, i.e., about \(-0.2 \text{ dB} \). In this case, the amplitude of current oscillations in the output sections of the signal transmission-line approaches approximately 0.71\( I_{0} \), whereas the Josephson-phase oscillations are about \( \pi/4 \).

The upper solid curve, calculated for the largest input power of \( P_{\text{in}} \approx -84 \text{ dBm} \), exhibits the 1 dB suppression of the nominal gain of 20 dB and, hence, corresponds to the amplifier compression point. In this case, the signal current amplitude in the output sections of the line approaches approximately 0.91\( I_{0} \) leading to the amplitude of the Josephson-phase oscillations of about 1.1 rad. At such large amplitude the cubic approximation of the Josephson nonlinearity in the original wave equation Eq. (9) is no longer strictly valid, so the above-mentioned value of \(-84 \text{ dBm} \) can only be considered as an estimate of the gain compression point. Still, this value is broader than that achievable in the nonlinearity-based TWJPAs having almost similar electrical parameters (both with four-wave mixing and three-wave mixing). For example, the gain compression points reported in Refs.\(^{54,55}\) are \(-98 \text{ dBm} \) (for \( I_{0} = 3.29 \mu A \) and \(-96 \text{ dBm} \) (for \( I_{0} = 5 \mu A \)), respectively.

The reason for the notable improvement of the amplifier dynamic range is almost absence of pump depletion. In the above example, the maximum output signal power is sufficiently small, i.e., \( P_{\text{out}} + P_{\text{out}}^{\text{in}} \approx 2P_{\text{out}} \approx -62 \text{ dBm} \) and is set by saturation in the last sections of the line, as one can conclude from comparison of the solid and dashed lines in Fig. 5. This property allows achieving the signal gain in the most efficient way.

VI. CONCLUSION AND PROSPECTS

We have developed a concept for a flux-driven TWJPA with a large dynamic range. Due to the separate transmission-line, fed through an isolated input port by sufficiently large pump power, the amplifier is practically free of the pump depletion effect. Moreover, the linear regime of its operation ensures small distortions of signal that prevents generation of shock waves.\(^{49}\) Due to good phase matching in a rather broad bandwidth, these properties allow the parametric amplifiers to be designed with rather large number of elementary cells \( N \) and, therefore, larger gain, for example, 40 dB. In combination with ultimately quantum-limited performance in a wide frequency range, such TWJPA can be an indispensable device for amplifying weak signals from quantum sources, including qubits.

When required, even larger output signals can be achieved by using in each elementary cell not a single SQUID, but a group of several serially-connected SQUIDs (like in Ref.\(^{50,51}\) designed with Josephson junctions having larger critical currents, and, therefore, weaker (unwanted) Kerr nonlinearity. In this case, the need for a cold HEMT preamplifier with typical noise figure of several Kelvin, which is usually unavoidable in high-fidelity microwave measurements, is eliminated. The latter feature may be especially useful in quantum information processing and, in particular, in quantum interference and correlation measurements with single microwave photons.\(^{50,51}\)

The proposed circuit may also operate in the quantum regime enabling efficient production of entangled photon pairs. As was recently demonstrated by Lahteenmäki et al.,\(^{52}\) a similar array of 250 DC SQUIDs, embedded in a microwave resonator and pumped by homogeneous alternating flux at the double resonant frequency of \( \omega_{\text{res}} = 2\pi \times 10.8 \text{ GHz} \), gave rise to generation of biphotons at frequencies \( \omega_{a} \) and \( \omega_{b} \). The corresponding photon conversion, \( h\omega_{b} = h\omega_{a} \), was, however, only possible in rather narrow bandwidth of about 200 MHz around \( \omega_{\text{res}} \approx 5.0 \omega_{a} \approx \omega_{b} \). In this experiment, periodic modulation of the refraction index of the SQUID metamaterial embedded in the cavity ensured the photon conversion similar to that occurring in the case of periodic modulation of the resonator boundary impedance (the mirror position) in the microwave-resonator version of the dynamical Casimir effect.\(^{52}\) In our case of pumping by means of a traveling flux-wave, the parametric down-conversion should produce biphotons in a broad frequency range, i.e. like in the recent experiment on production of Casimir photons due to time-varying boundary impedance of a semi-infinite transmission line.\(^{52}\) The generated entangled pairs of photons can be used in quantum sensing circuits, quantum cryptography and other fields of quantum information science.

Finally, the design of our circuit can, possibly, be useful for implementation of the superconducting-circuit analog\(^{54}\) of the event horizon and emission of Hawking radiation.\(^{55,56}\) The step-like pulse propagating in the separate transmission line instead of continuous pump wave can induce a locally-decreased speed of light in the SQUID-array with location of the horizon where the propagation velocities in the two transmission lines coincide. As was proposed by Nation et al.,\(^{52}\) at sufficient steepness of the flux step-like pulse (corresponding to sufficiently high Hawking temperature ensuring visibility of non-classical radiation above the thermal radiation background) the circuit should emit detectable (see a possible measuring strategy in, e.g., Ref.\(^{52}\)) microwave photons in
the two-mode squeezed state.

Appendix A: Equation of motion

1. The circuit Lagrangian

Our circuit consists of the linear $LC$-transmission pump line formed by $N$ identical elements $L'$ and $C'$ and the signal transmission line formed by the identical symmetric two-junction SQUIDs and the identical ground capacitances $C$ (see Fig. 1a). The critical currents and capacitances of the Josephson junctions are nominally identical, $I_{c1} = I_{c2} = I_0$ and $C_{J1} = C_{J2} = 0.5C_J$ (see Fig. 1b). We assume that the geometrical inductions of the SQUID branches $L_{g1,g2}$ are much smaller than the Josephson inductance of the individual junctions ($L_{J0} = \varphi_0/I_0$), and are therefore omitted. Such a SQUID is equivalent to a single junction with a flux-dependent critical current (see, for example, Ref. 22),

$$I_c(\Phi_c) = 2I_0|\cos(\Phi_c/2\varphi_0)|, \quad (A1)$$

and, therefore, with a flux-dependent potential energy,

$$U_{\text{SQUID}}(\Phi_c, \varphi) = -2E_{J0}|\cos(\Phi_c/2\varphi_0)| \cos \varphi, \quad (A2)$$

where $E_{J0} = \varphi_0/I_0$ is the Josephson characteristic energy, $\Phi_c = \Phi_{dc} + \Phi_{we}$ is the total external flux applied to the SQUID loop and $\varphi$ is the phase difference on the SQUID. The kinetic energy of each SQUID is associated with the charging energies of two junctions, i.e.,

$$K_{\text{SQUID}} = \frac{(C_{J1} + C_{J2})V^2}{2} = \frac{C_J(\varphi_0\dot{\varphi})^2}{2}, \quad (A3)$$

where $\varphi_0\dot{\varphi} = V$ is the voltage on the SQUID that has total capacitance $C_J$ (see equivalent electrical circuit in Fig. 1c).

To derive the equations of motion of our electrical circuit with a large number of variables, we apply the Lagrangian mechanics (a similar approach was used, for example, by Wallquist et al. in Ref. 27) and start by constructing Lagrangian $L$ that describes the entire circuit,

$$L = L_p + L_s. \quad (A4)$$

Here $L_p$ and $L_s$ are the Lagrangians of the pump line and the signal line, respectively. In terms of the flux variables associated with the node values $\Phi_n$ and $\Phi_n$ for the pump and signal lines, respectively, these Lagrangians read

$$L_p = \sum_{n=1}^{N} C'n^2 - \frac{(F_{n+1} - F_n)^2}{2L'} \quad (A5)$$

and (see, e.g., the Lagrangian approach to the traveling wave parametric amplifier with the Kerr nonlinearity in Ref. 29),

$$L_s = \sum_{n=1}^{N} \frac{C\Phi_n^2}{2} + \frac{C_J(\Phi_{n+1} - \Phi_n)^2}{2} + 2E_{J0} \left| \cos \frac{\Phi_{dc} + \kappa(F_{n+1} - F_n)}{2\varphi_0} \right| \cos \frac{\Phi_{n+1} - \Phi_n}{\varphi_0}. \quad (A6)$$

Here, the time derivatives $\dot{F}_n$ and $\dot{\Phi}_n$ are equal to the voltages on the $n$-th nodes of the pump and the signal transmission-lines, respectively. The phase difference on the $n$-th SQUID is expressed in terms of magnetic fluxes on the corresponding nodes, i.e., $\varphi_n = (\Phi_{n+1} - \Phi_n)/\varphi_0$. The dimensionless coefficient $\kappa = M/L'$ determines the strength of coupling of the pump and the signal lines.

2. Pump transmission line

In the case of small coupling, $\kappa \ll 1$, compensated by sufficiently large input pump-power,

$$P_{p}^{\text{in}} \approx P_{p}^{\text{out}} \gg P_{s}^{\text{out}} + P_{i}^{\text{out}}, \quad (A7)$$

where $P_{s,i}^{\text{out}}$ is the output signal (idler) power, the backaction of the signal line on the pump line can be neglected. Then, the decoupled equation of motion for fluxes $F_n$ can be obtained from the Euler-Lagrange equation

$$\frac{d}{dt} \frac{\partial L}{\partial F_n} - \frac{\partial L}{\partial F_n} \approx \frac{d}{dt} \frac{\partial L_p}{\partial F_n} - \frac{\partial L_p}{\partial F_n} = 0. \quad (A8)$$

Using Eq. (A5) this equation reads

$$\ddot{F}_n + \omega_0^2 (F_{n-1} - 2F_n - F_{n+1}) = 0, \quad (A9)$$

where $\omega_0 = 1/\sqrt{LC}$ is the cutoff frequency of the pump transmission line. Here, the index range is $n = 1, 2, ..., N - 1$, and the boundary values are $F_0 = F_\text{in}$ and $F_N = F_\text{out}$.

The set of coupled differential equations given by (A9) is the discrete analog of the partial differential equation describing plane waves. It is easy to verify by substitution that, for a sufficiently small frequency $\omega_p \ll \omega_0$, i.e.,
when the wavelength is larger than the size of the elementary cell, \( a_p \gg a \), the solution describing the wave traveling, for example, in the right direction has the shape:

\[
F_n \propto e^{i(k_p n - \omega_p t + \chi_p)}.
\]

(A10)

Here, \( k_p \) is the wave number normalized on the reverse size of the cell \( a^{-1} \) and \( \chi_p \) is an initial phase. Incorporating Eq. (A10) into Eq. (A9) yields

\[
- \left[ \omega_p^2 - \omega_0^2 (- e^{-i k_p} + 2 - e^{i k_p}) \right] F_n = 0,
\]

or, equivalently,

\[
\left[ \omega_p^2 - 4 \omega_0^2 \sin^2(k_p/2) \right] F_n = 0.
\]

(A11)

This equation determines the dispersion relation of the transmission line (see, for example, Ref. [3]),

\[
k_p(\omega_p) = \pm 2 \arcsin (\omega_p / 2 \omega_0) ,
\]

(A12)

which, in our case, of positive small \( k_p \) yields the relation

\[
k_p = \frac{\omega_p}{\omega_0} \left( 1 + \frac{\omega_p^2}{2 \omega_0^2} \right).
\]

(A13)

This formula describes the standard positive dispersion, \( d^2 k_p / d \omega_p^2 > 0 \).

Without the loss of generality, we set the pump phase \( \chi_p \) in Eq. (A10) in such a way that the pump wave has the form

\[
F_n = \varphi_0 A_{p0} \cos[k_p(n - 0.5) - \omega_p t],
\]

(A14)

where dimensionless amplitude \( A_{p0} \) is real and positive. In this case, current \( I_p^{(n)} \) flowing through inductance \( L' \) in the \( n \)-th cell equals

\[
I_p^{(n)} = -(F_{n+1} - F_n) / L',
\]

(A15)

and the flux induced in the \( n \)-th cell of the signal transmission line is

\[
M I_p^{(n)} = -\kappa (F_{n+1} - F_n)
\]

\[
= 2 \varphi_0 \kappa A_{p0} \sin \frac{k_p^2}{2} \sin(k_p n - \omega_p t)
\]

\[
\approx \kappa \varphi_0 A_{p0} k_p \sin(k_p n - \omega_p t).
\]

(A16)

This formula describes the wave of magnetic flux that ensures the necessary time variation of the SQUID inductance.

3. Signal transmission line

Incorporating expression (A17) into Eq. (A10), we obtain in the adiabatic approximation the equations of motion for the fluxes \( \Phi_n \),

\[
\frac{d}{dt} \frac{\partial L}{\partial \dot{\Phi}_n} - \frac{\partial L}{\partial \Phi_n} = \frac{d}{dt} \frac{\partial L_s}{\partial \dot{\Phi}_n} - \frac{\partial L_s}{\partial \Phi_n} = 0,
\]

(A18)

\[
C \dot{\Phi}_n + C_f (-\dot{\Phi}_{n-1} + 2 \dot{\Phi}_n - \dot{\Phi}_{n+1})
\]

\[
+ I_c^{(n)}(t) \sin[(\Phi_n - \Phi_{n-1}) / \varphi_0]
\]

\[
- I_c^{(n+1)}(t) \sin[(\Phi_{n+1} - \Phi_n) / \varphi_0] = 0.
\]

(A19)

Here, the time-dependent critical current of the \( n \)-th SQUID is

\[
I_c^{(n)}(t) = I_{c0} [1 + m \sin(k_p n - \omega_p t)],
\]

(A20)

where magnitude \( I_{c0} \) is determined by the constant flux \( \Phi_{dc} \), i.e.,

\[
I_{c0} = 2 I_{c0} | \cos(\Phi_{dc} / 2 \varphi_0)|.
\]

(A21)

The small, positive value of \( m \ll 1 \) is found by linearizing Eq. (A1) in vicinity of the optimal working point \( \Phi_{dc} = \pi \varphi_0 / 3 \) (see Fig. 2),

\[
m = \frac{\kappa}{2} k_p A_{p0} \tan(\Phi_{dc} / 2 \varphi_0) \approx \frac{\sqrt{3}}{2} \kappa k_p A_{p0}.
\]

(A22)

Assuming that the phases on the SQUIDs are small, i.e., \( |\varphi_n| \ll 1 \), we make the approximation

\[
\sin \varphi_n \approx \varphi_n - \varphi_n^3 / 6,
\]

(A23)

and neglect high-order cross terms \( \propto m \varphi_n^3 \). We thus replace the \( n \)-th SQUID with the time-dependent (in general case, slightly nonlinear) inverse inductance \( 1 / L_{jn}^{(n)}(t, \varphi_n) \), i.e.,

\[
\frac{L_{j0}}{L_{jn}^{(n)}} = 1 + m \sin(k_p n - \omega_p t) - \frac{1}{2 \varphi_0^2} (\Phi_{n+1} - \Phi_n)^2,
\]

(A24)

where \( L_{j0} = \varphi_0 / I_0 \). Incorporating Eq. (A20) into Eq. (A19) and using approximation (A23), we obtain

\[
\omega_0^2 \Phi_n - \omega_0^2 (-\Phi_{n-1} + 2 \Phi_n - \Phi_{n+1}) + [1 + m \sin(k_p n - \omega_p t)] (\Phi_n - \Phi_{n-1})
\]

\[
- \{1 + m \sin(k_p (n + 1) - \omega_p t)] (\Phi_{n+1} - \Phi_n)
\]

\[
- \frac{1}{2 \varphi_0^2} [(\Phi_n - \Phi_{n-1})^3 - (\Phi_{n+1} - \Phi_n)^3] = 0.
\]

(A25)

Here, the cutoff frequency of the bare transmission line is \( \omega_0 = 1 / \sqrt{L_{j0} C_J} \) and the Josephson plasma frequency is \( \omega_J = 1 / \sqrt{L_{j0} C_J} \).

For sufficiently small amplitude, \( |\varphi_n| \ll 1 \), small frequency, \( \omega \ll \omega_0, \omega_J \), and the absence of a pump \( (m = 0) \), a solution of Eq. (A25) has the form of the plane wave,

\[
\Phi_n \propto e^{i(k n - \omega t + \chi)},
\]

(A26)

where \( k \) is the wave number and \( \chi \) is the phase. Incorporating this expression into Eq. (A25) yields

\[
- \left[ \omega^2 + \omega_0^2 \left( \frac{\omega^2}{\omega_J^2} - 1 \right) (- e^{-i k} + 2 - e^{i k}) \right] \Phi_n = 0.
\]

(A27)
The corresponding dispersion equation reads
\[ \omega^2 - 4\omega_0^2 \left( 1 - \frac{\omega^2}{\omega_0^2} \right) \sin^2(k/2) = 0 \] (A28)
and has the solution
\[ k(\omega) = \pm 2 \arcsin \left( \frac{\omega/2\omega_0}{\sqrt{1 - \omega^2/\omega_0^2}} \right), \] (A29)
which for the wave propagating in the right direction \( k \) in the form of a continuum wave equation, plasma resonance in the SQUIDs.

including the wave-like variation of the distributed linear inductance of the transmission line,
\[ L_j^{(n)}(t) \rightarrow L_j(x, t) = \frac{L_{j0}}{1 + m \sin(k_p x - \omega_p t)}. \] (A36)

The fourth term on the right-hand-side of Eq. (A25) describes nonlinear effects and it becomes essential only in the cells, where the amplitude of the signal/idler is not sufficiently small.

**Appendix B: Effect of parameter variations**

Sufficiently small variations of the line parameters is the basic requirements for proper operation of the Josephson parametric amplifiers based on traveling microwaves (for example, see in Ref. 13 the evaluation of fabrication tolerances in the LC cells enabling the resonant phase matching in the four-wave mixing TWIPA). As long as in our circuit the pump and the signal (idler) waves travel along two different lines, the appreciable parameter variations in either line may cause significant phase mismatch. The signal line including the Josephson junctions and thereby having more complex design is, therefore, more prone to such variations.

\[
\Phi_n(t) \rightarrow \Phi(x, t).
\] (A31)

Thus, variable \( x \) is a dimensionless coordinate, whereas the genuine coordinate variable is \( X = ax \), where \( a \) is the cell size.12 The parameter-modulation function \( f_n(t) = [1 + m \sin(k_p n - \omega_p t)] \) entered into Eq. (A25) is now replaced by the continuous function, i.e.,
\[ f_n(t) \rightarrow f(x, t) = [1 + m \sin(k_p x - \omega_p t)]. \] (A32)

Following the method derived by Yaakobi et al.13 the finite differences can be expressed via partial derivatives of a continuous function \( F(x) \) according to the following rules:
\[
F_{n+1} - F_n = \frac{\partial F}{\partial x},
\] (A33)
\[
F_{n+1} - 2F_n + F_{n-1} = \frac{\partial^2 F}{\partial x^2}.
\] (A34)

Then, the set of the finite-difference equations (A19) takes the form of a continuum wave equation,
\[
\frac{\partial^2 \Phi}{\partial x^2} - \omega_0^{-2} \frac{\partial^2 \Phi}{\partial t^2} + \omega_j^2 \frac{\partial^4 \Phi}{\partial t^2 \partial x^2} - \frac{1}{6\omega_0^2} \frac{\partial}{\partial x} \left( \frac{\partial^3 \Phi}{\partial x^3} \right) + \frac{\partial}{\partial t} \left( m \sin(k_p x - \omega_p t) \frac{\partial \Phi}{\partial x} \right) = 0. \] (A35)

The condition of zero phase mismatch for the small detuning, \( |\delta| < 1 \), is given by Eqs. (25), (29), and (30), i.e.,
\[
\delta k = k_p - k_i - k_s = \nu - \eta/3 = \frac{\omega_p^2}{\omega_0^2} - \frac{\omega_p^2}{\omega_0^2} \left[ 1 + \frac{\omega_p^2}{2\omega_0^2} \right] = 0. \] (B1)

Because the cutoff frequency of the bare transmission line, \( \omega_0 \), and the plasma frequency, \( \omega_j \), are both proportional to \( I_0^{1/2}(\Phi_{dc}) \), this condition can be fulfilled by applying the optimal DC flux bias, \( \Phi_{dc} = \Phi_{dc}^{opt} \). In the case of inaccurate flux setting or instability of the flux bias in time, \( \Phi_{dc} = \Phi_{dc}^{opt} + \delta \Phi_{dc} \), the corresponding deviation of the Josephson critical current from the optimal value \( I_0 \) is
\[
\delta I_0 = \frac{\partial I_c}{\partial \Phi_{dc}} \delta \Phi_{dc} = \epsilon I_0. \] (B2)

Here we used the notation \( \epsilon = -\sqrt{3} \delta \Phi_{dc}/\varphi_0 \) and applied formula (A21) in the point \( \Phi_{dc}/2\varphi_0 = \pi/3 \). The nonzero value \( \delta I_0 \) causes deviation of the cutoff and the plasma frequencies, \( \omega_0, J \rightarrow \omega_0, J + \delta \omega_0, J \), where
\[
\frac{\delta \omega_0, J}{\omega_0, J} = \frac{1}{\omega_0, J} \frac{\partial \omega_0, J}{\partial I_0} \delta I_0 = 0.5 \epsilon. \] (B3)
The corresponding phase mismatch is
\[
\Delta k = \frac{\omega_p}{\omega_0} - \frac{\omega_p}{\omega_0(1 + 0.5\epsilon)} \left[ 1 + \frac{\omega_p^2}{8\omega_j^2(1 + 0.5\epsilon)^2} \right]
\approx 0.5\epsilon \omega_p/\omega_0,
\]
where a small term \(\omega_p^2/\omega_j^2\) had been omitted.

Then, taking the target frequency \(\omega_p = 0.2\omega_0\) (yielding \(\Delta k = 0.1\epsilon\)), the values of modulation coefficient \(m = 0.06\), the exponential gain coefficient \(g_0 = 0.255\omega_p/\omega_0 = 0.003\), and the line length \(N = 1000\) (yielding the nominal gain of 20 dB), we obtain the corresponding suppression of the gain (see Eq. (B5)),
\[
G/G_{\text{max}} = 1 - \left( \frac{\Delta k}{2g_0} \right)^2 \tanh^2(g_0N) \approx 1 - 275 \epsilon^2.
\]
This formula yields the 1 dB reduction of the gain for reasonably small value of \(|\epsilon| \approx 0.02\) or, equivalently, reasonably small inaccuracy in the magnetic flux setting of \(|\delta\Phi_{\text{dc}}| = \epsilon\Phi_0/\sqrt{3} \approx 0.01\Phi_0.

2. Signal line inhomogeneity

In practical circuits, the electrical parameters can have a somewhat irregular distribution over the length of the line. This primarily concerns the Josephson inductance \(L_{J0}(x)\), whose local value depends on the critical current \(I_0\) of corresponding SQUID. This critical current depends on the area of the Josephson junction, the local critical current density \(j_c\) and the offset magnetic flux \(\Phi_{\text{dc}}\), whose value, under assumption of homogeneous magnetic field, depends on the size and shape of the SQUID loop. In fabrication, however, variations of these parameters can only be controlled within certain limits.

In our circuit, which comprises Josephson junctions with an area of about 1 \(\mu\text{m}^2\), the parameter which is most prone to random variations is the critical current. To roughly model small variations of the critical current \(\delta I_0(x)\) around its mean value \((I_0)\) (leading to small variations of the reverse Josephson inductance \(\delta L_{J0}^{-1}\) around the mean value \((L_{J0}^{-1})\)), we should add a corresponding small random term to the linear part of equation of motion (B5), i.e.,
\[
\frac{\partial^2 \Phi}{\partial x^2} - \omega_0^{-2} \frac{\partial^2 \Phi}{\partial t^2} + \omega_j^{-2} \frac{\partial^2 \Phi}{\partial t^2 \partial x^2} + \frac{\partial}{\partial x} \left\{ m \sin(k_p x - \omega_p t) + \zeta(x) \right\} \frac{\partial \Phi}{\partial x} = 0.
\]
where
\[
\zeta(x) = \delta I_0(x)/(I_0) = \delta L_{J0}^{-1}(x)/(L_{J0}^{-1})
\]
is a random dimensionless function.

This function is defined on the nodes, \(x = n\), and has, presumably, a small rms value, \(\sqrt{\zeta^2(x)} = \sigma \ll 1\) and a short correlation length \((\ell_\epsilon \sim 1)\). Here, the sign \(\langle \cdot \rangle\) denotes averaging over the statistical ensemble. The cutoff and plasma frequencies are now defined as
\[
\omega_0 = 1/\sqrt{(L_{J0})C} \quad \text{and} \quad \omega_J = 1/\sqrt{(L_{J0})C_J},
\]
respectively, whereas the random values \(\zeta(x)\) cause local variations of these frequencies and, therefore, of the wave number that leads to a phase mismatch. The small higher-order term \(\sim m\zeta(x)\) describing variation of the parametric coupling is here omitted.

In order to roughly evaluate the random drift of the phase and, therefore, the resulting phase mismatch we put in Eq. (B6) the zero pump, \(m = 0\), and find the solution in the simple wave form,
\[
\Phi(x,t) = \frac{\Phi_0}{2} A e^{i[kx-\omega t+\Theta(x)]} + \text{c.c.}
\]
Here, the complex phase \(\Theta(x) = \psi(x) - i\rho(x)\) includes the random phase as such, \(\psi(x)\), and the logarithm of the random amplitude, \(\rho(x) = \ln[A(x)/A_0]\). Both these variables are induced by small perturbation \(|\zeta(x)| \ll k\) and slowly vary in space, i.e., \([\partial_\zeta x] 1/\epsilon x \ll k\). Keeping only essential terms in Eq. (B9), we then obtain two decoupled equations for \(\psi(x)\) and \(\rho(x)\), i.e.,
\[
\frac{dp}{dx} = \frac{1}{2} \frac{d\zeta}{dx} \quad \text{and} \quad \frac{d\psi}{dx} = -k/2 \zeta(x).
\]
Equation (B10) yields the solution for the wave amplitude, \(A(x) = A_0(1 + 0.5\zeta(x))\), which space variation mimics the local fluctuation of the transmission line admittance,
\[
Y(x) = \sqrt{C/L_{J0}(x)} = \sqrt{1 + 0.5\zeta(x)} Y_0
\]
around its average value \(Y_0 = 1/Z_0\).

The solution of equation (B11) for the wave phase \(\psi\) has the form
\[
\psi(x) = -0.5k \int_0^x \zeta(x') dx'.
\]
This formula describes the diffusion of phase \(\psi(x)\) (the Brownian motion process) and, therefore, yields the statistical average values \(\langle \psi(x) \rangle = 0\) and \(\langle \psi^2(x) \rangle = 0.25k^2\sigma x\). The corresponding drift of the phase on the length \(x = N\) can be estimated as \(\Psi = \sqrt{\langle \psi^2(N) \rangle} = 0.5k\sqrt{\sigma N}\). For the critical current variations \(\sigma\) of the order of 0.05 (see, for example, Ref. 22), the dimensionless wave-number value \(k = 0.1\) and the line length \(N = 1000\) this formula yields \(\Psi \approx 0.35\) rad and, therefore, still negligibly small suppression of the power gain due to such phase mismatch, i.e.,
\[
G/G_{\text{max}} = 1 - \left( \frac{\Psi}{2g_0N} \right)^2 \tanh^2(g_0N) \approx 0.997.
\]
Another problem that may arise in fabrication is a notable gradient of the local critical current density $V_{j_c}(r)$ of the Nb trilayer, which may account for a drop of up to 30% in $j_c$ over the 3 inch wafer. In this case, inhomogeneity of the distributed inductance in the straight signal line takes the form $L_{j0}(x) = L_{j0}^{(0)}/(1 + \mu x)$. For example, for the total length of the line $\ell = aN \sim 5 \text{ cm}$, the product $\mu N$ can be on the order of 0.1. Then, the corresponding maximum phase drift $\Psi = 0.25k\mu N^2$ can approach the excessively large value of 2.5 rad. This unwanted effect resulting from linear variation of $j_c$ can possibly be mitigated by applying the offset magnetic field with a small gradient in the direction of the transmission line. This field should compensate the regular change in the critical currents of the junctions via a corresponding change of offset flux in the SQUIDs. Although this method leads to complication of experiment, it may seemingly also work in the case when the SQUID array has a meander shape.

Finally, it should be noted that appreciable inhomogeneities of the circuit parameters with correlation length comparable with characteristic wavelengths (in our case, about 30-60 elementary cells) may cause partial reflections of traveling waves inside the transmission lines and, hence, deteriorate the TWJPA performance. Analysis of such case which may also take place in the conventional TWJPs based on the Josephson nonlinearity is, however, beyond the scope of this manuscript.
