Abstract—Large-scale machine learning and data mining applications require computer systems to perform massive computations that need to be parallelized across multiple nodes, for example, massive matrix-vector and matrix-matrix multiplication. The presence of straggling nodes – computing nodes that unpredictably slow down or fail – is a major bottleneck in such distributed computations. We propose a rateless fountain coding strategy to alleviate the problem of stragglers in distributed matrix-vector multiplication. Our algorithm creates a stream of linear combinations of the $m$ rows of the matrix, and assigns them to different worker nodes, which then perform row-vector products with the encoded rows. The original matrix-vector product can be decoded as soon as slightly more than $m$ row-vector products are collectively finished by the nodes. This strategy enables fast nodes to steal work from slow nodes, without requiring the master to perform any dynamic load-balancing. Compared to recently proposed fixed-rate erasure coding strategies which ignore partial work done by straggling nodes, rateless coding achieves significantly lower overall delay, as well as small computational and decoding overhead.

I. INTRODUCTION

A. Motivation for Coded Matrix-vector multiplication

Matrix vector multiplications form the core of a plethora of scientific computing and machine learning applications that include solving partial differential equations [1], forward and back propagation in neural networks [2], computing the PageRank of graphs [3] etc. In the present age of Big Data, most of these applications involve multiplying extremely large matrices and vectors and the computations cannot be performed efficiently on a single machine. This has motivated the development of several algorithms [4], [5] that seek to speed up matrix vector multiplication by computing it in a distributed fashion across multiple computation nodes. These algorithms achieve speedup by distributing the computation equally among all the nodes in the system. The individual nodes (the workers) perform their respective tasks in parallel while a central node (the master) aggregates the output of all the processors to complete the computation. Unfortunately, such approaches are usually bottlenecked by the presence of a few slow workers, called stragglers [6], that cause the entire computation to be delayed since the master needs to wait for all workers to complete the tasks assigned to them.

A natural approach to countering stragglers involves replicating individual tasks at multiple worker nodes [7]–[10], and waiting for any one copy to finish. Replication is a special case of the more general erasure coding framework wherein stragglers are modeled as erasures and codes are employed to add redundancy so that only a subset of processors are required to complete the tasks assigned to them. This is analogous to erasure codes for communication channels which can be used to reconstruct the original message from a subset of the transmitted bits.

The usage of codes to provide error-resilience in computation has its origins in works on algorithmic fault tolerance [11]. Recent works such as [12]–[14] have employed Maximum Distance Separable (MDS) codes to speed up the computation of matrix vector products in a distributed setting. To illustrate the key idea of MDS coding, consider the example of multiplying a matrix $A$ with vector $x$ using 3 worker nodes and a $(3, 2)$ MDS code. Suppose we split $A$ along rows into two matrices $A_1$ and $A_2$ such that $A = [A_1^T A_2^T]^T$. The worker nodes store matrices $A_1$, $A_2$ and $A_1 + A_2$ respectively, and each node multiplies its matrix with $x$. Results from any two worker nodes are sufficient to obtain $Ax$, and thus the system is tolerant to 1 straggling node. These codes reduce the overall latency, but they discard the partial work done by straggling nodes, possibly resulting in a large amount of redundant computation.

B. Benefits of using Rateless Codes

We propose the use of rateless fountain codes [15]–[18] for distributed matrix-vector multiplication of a $m \times n$ matrix $A$ with a $n \times 1$ vector $x$. The rateless coded matrix-vector multiplication algorithm generates coded linear combinations of the $m$ rows of matrix $A$ and distributes them across $p$ worker nodes. Each node also receives a copy of the vector $x$. The master node needs to wait for any $m_d = m(1 + \epsilon)$ row-vector products to be completed in total by the nodes, where $\epsilon$ is a small decoding overhead such that $\epsilon \to 0$ as $m \to \infty$. Rateless codes offer the following key benefits over previously proposed coding techniques based on MDS codes.

1) Near-perfect Load Balancing: In order to adjust to varying speeds of worker nodes and minimize the overall time to complete the multiplication $Ax$, one can use a perfect load-balancing scheme that dynamically assigns one row-vector product computation task to each worker node, as soon as
the node finishes its current task. Thus, faster nodes complete more tasks than slower nodes, and the $p$ nodes collectively finish $m$ row-vector products. Our rateless coding strategy achieves nearly the same load balancing benefit without the communication overhead of dynamically allocating the tasks, one row-vector product at a time. In our strategy, the nodes need to collectively finish $m_d = m(1 + \epsilon)$ row-vector products, for small $\epsilon$. In contrast, MDS coding strategies do not adjust to different degrees of node slowdown; they use the results from $k$ nodes, and ignore the remaining $p - k$ nodes. As a result rateless code achieve a much lower delay than MDS coding strategies.

2) **Negligible Redundant Computation:** A major drawback of MDS coding is that if there is no straggling, the worker nodes collectively perform $mp/k$ row-vector products, instead of $m$. Our strategy performs a maximum of $m_d = m(1 + \epsilon)$, where, the overhead $\epsilon$ goes to zero as $m$, the number of rows in the matrix $A$ increases.

3) **Maximum straggler tolerance:** A $(p,k)$ MDS coded distributed computation is robust to $p-k$ straggling nodes, for $k \in [1, 2, \ldots, p]$. Reducing $k$ increases straggler tolerance but also adds more redundant computation. Rateless coding can tolerate up to $p - 1$ stragglers, with negligible redundant computation overhead.

4) **Low Decoding Complexity:** Another benefit of using rateless codes is the extremely fast decoding of $\mathcal{O}(m \ln m)$ which allows our approach to scale efficiently even for very large $m$.

Rateless fountain codes have demonstrated superior performance over MDS codes in providing robustness against erasures in communication channels which has led to their adoption in a variety of communication standards [17]. Due to the aforementioned benefits we believe that they can enjoy similar success in the realm of coded distributed computation as well. In the sequel we describe the details of the rateless coded algorithm for distributed matrix vector multiplication and validate its effectiveness in mitigating stragglers through theoretical analysis and numerical simulations.

C. **Organization**

The rest of the paper is organized as follows. In Section II we review previous works on coded distributed computing. Section III formally presents the system model, performance criterion and comparison benchmarks. In Section IV we describe the proposed rateless fountain coding strategy for distributed matrix vector multiplication. Section V shows theoretical analysis and simulation results comparing rateless codes with other strategies in terms of delay and number of redundant computations. Finally, Section VI presents ongoing and future research directions.

II. **BACKGROUND AND RELATED WORK**

A. **The Problem of Stragglers**

Stragglers are slow computing nodes that slow down any distributed computation that depends on all nodes completing the task assigned to them. Straggling of nodes is widely observed in cloud infrastructure [6] and existing systems like MapReduce [19] and Spark [20] generally deal with this problem by launching replicas of straggling tasks, which are referred to as back-up tasks. This strategy of task replication has many variants such as [7], [8], and has been theoretically analyzed in [9] and [10] where schemes for adding redundant copies based on the tail of the runtime distribution at the workers are proposed.

Erasure codes were first employed to overcome the issue of straggling nodes in the context of content download from distributed storage [21], [22]. A content file that is divided into $k$ chunks and coded using a $(p,k)$ maximum-distance-separable code, can be recovered by downloading any $k$ out of $p$ encoded chunks. Queueing models to analyze the latency of coded content download jobs were proposed and analyzed in [23]-[27]. However, unlike distributed storage, erasure coding of computing jobs is not straightforward. A job with $n$ parallel tasks needs to be designed such that the execution of any $k$ out of $n$ tasks is sufficient to complete the job.

B. **Distributed Coded Computation**

The idea that error-correcting codes can be used for fault-tolerance in computing tasks has its roots in works on algorithmic fault tolerance [4], [5]. Recently, this approach has spurred a rich body of research that uses erasure codes in modern distributed computing tasks including matrix-vector multiplication, matrix-matrix multiplication, and distributed gradient descent.

Matrix-vector multiplication: Two major approaches to computing distributed matrix vector products are the uncoded and MDS coded approaches. In the uncoded case the $m \times n$ matrix $A$ is divided into $p$ submatrices along the rows, and each worker multiplies one sub-matrix with the vector $x$. The MDS coded approach of [12] provides straggler tolerance since the matrix-vector product can be decoded from the results of computations at any $k$ out of $p$ nodes.

Subsequent works like [13], [28] build upon the MDS coded approach by designing a sparse encoded matrix thus reducing the amount of computation at each node. Applications of coded matrix vector multiplication that have been proposed include computing the Fourier Transform of a signal [29] and the Page Rank of a graph [30].

In this work we introduce a scheme for coded distributed matrix vector multiplication that makes use of rateless erasure codes, specifically LT codes [15]. While the use of LT codes for matrix-vector multiplication has been recently proposed in [31], it does not utilize partial work done by straggling nodes, which is the key novel contribution of our work. Due to this our approach achieves near optimal straggler tolerance as well as negligible overhead of redundant computation.

Matrix-matrix multiplication: A natural generalization of matrix vector multiplication is matrix-matrix multiplication. In the distributed setting this involves splitting the 2 matrices to be multiplied into submatrices that are distributed and multiplied across the worker nodes of the system with the results being aggregated at the master. The authors of [32]...
propose a coding scheme called Polynomial Codes in which each node stores a linear combination of submatrices and the final product can be recovered using polynomial interpolation on the encoded products of submatrices obtained from the non-straggling nodes. Works that build upon this approach show that the minimum number of workers that need to complete their task for the decoding to succeed can be reduced further at the cost of increasing communication between the master and worker nodes [33], and also construct codes that can preserve the sparsity of input matrices by ensuring that the each encoded submatrix is a linear combination of a small number of submatrices of the original matrix [34].

While these are the major coded distributed computing tasks that have been studied, there are also works dealing with coded gradient descent [35–37], coded convolution [38], and coded distributed optimization [39]. In this work we address the original problem of coded distributed matrix vector multiplication and propose a new encoding scheme that uses the work done by each node in the system (including the stragglers) and can approach perfect load balancing in an asymptotic sense. In the future we plan to extend this approach to other applications like computing matrix-matrix products and coded gradient descent using the same underlying principles as in the present work.

III. PROBLEM FORMULATION

A. System Model

Consider the problem of multiplying a \( m \times n \) matrix \( A \) with a \( n \times 1 \) vector \( x \) using \( p \) worker nodes. A central fusion node, referred to as the master node collects the results of computing tasks assigned to the worker nodes. The task allocation is shown in Fig. 1. The worker nodes can only communicate with the master, and cannot directly communicate with other workers. The goal is to compute the result \( b = Ax \) in a distributed fashion and mitigate the effect of unpredictable node slowdown or straggling.

Straggler mitigation is achieved through coding wherein the \( m \times n \) matrix \( A \) is encoded using an error correcting code which operates on the rows of the matrix as source symbols to give the \( m_c \times n \) encoded matrix \( A_e \). The workers compute the product \( A_e x \) in a distributed fashion. Every coding scheme adds some amount of redundant computations due to which \( m_c > m \). This added redundancy mitigates the effect of stragglers because we only need a subset of the elements of \( A_e x \) to recover the desired matrix-vector product \( Ax \). We quantify the amount of redundancy added by the parameter \( \alpha = m_c/m \).

Matrix \( A_e \) is split along its rows to give submatrices \( A_{e,1}, \ldots, A_{e,p} \) with the task of computing the product \( A_{e,i} x \) assigned to worker \( i \). We assume that the submatrix \( A_{e,i} \) is stored in memory at worker \( i \) to enable fast access which is the case in real world distributed computing systems like Spark [20]. The vector \( x \) is provided as input to the system and is communicated by the master to all the workers when the computation of the product \( Ax \) is required.

Each worker needs to compute a sequence of row vector products of the form \( a_{e,i} x \) where \( a_{e,i} \) is the \( j \)th row of \( A_e \). The time taken by a worker node to finish computing one or more row-vector products may be random due to variability in the node speed, or variability in the complexity of the computation task itself. Nodes that run on a shared computing infrastructure may slow down significantly and unpredictably due to several factors such as outages, virtualization, congestion etc., as observed in the systems literature [6], [8]. We theoretically analyze the effect of such slow-down on various distributed computing schemes in Section V where we model the time taken by a worker node to finish computing as a random variable, and study how its probability distribution affects the performance of different coding strategies.

The master node aggregates the computations of all, or a subset of, the workers into the vector \( b_e \), which is then decoded to give the final result \( b = Ax \). If \( b_e \) is not decodable, the master waits until more row-vector products are completed by the workers.

B. Performance Criterion

We use the following metrics to compare different coding schemes for distributed matrix vector multiplication.

Definition 1 (Latency (T)). We define latency \( T \) as the time required by the system to complete enough number of computations so that the result \( b \) can be successfully decoded from the worker computations aggregated in \( b_e \).

Definition 2 (Computations (C)). be number of computations \( C \) is defined as the total number of row-vector products \( a_{e,i} x \) performed collectively by the worker nodes until the vector \( b = Ax \) is decoded.

The matrix in question can be the original matrix \( A \) in the uncoded case, or the encoded matrix \( A_e \) in the coded case. The cost of a single computation in terms of number of symbol operations remains the same in both cases since encoding does not change the size of the matrix rows. Thus the overall computation cost is proportional to the total number of computations (C) performed by the system. The minimum
number of computations that must be performed by the system is \( m \) since we wish to compute an \( m \)-dimensional matrix-vector product.

In Section \( \textbf{V} \) we analyze the trade-off between latency and computations by modeling the delay at each worker node as a random variable that depends on the number of row-vector product tasks performed by that worker. Our coded computing scheme achieves a win-win in the latency-computation trade-off by giving significantly lower expected latency than existing schemes for the same amount of redundant computation. We also present simulation results to validate the theoretical findings.

C. Benchmarks for Comparison

We compare the performance of the proposed rateless coded strategy with two benchmarks: the replication, and the MDS-coded strategies, which are described formally below. Fig. 2 illustrates the differences in the way row-vector product tasks are assigned to and collected from workers in each strategy.

The \( r \)-Replication Strategy. A simple distributed multiplication strategy is to split \( \bm{A} \) along its rows into \( p/r \) submatrices \( \bm{A}_{1}, \ldots, \bm{A}_{p/r} \), with \( r \times n/p \) rows each (assume that \( p/r \) divides \( m \)) and multiply each submatrix with \( \bm{x} \) in parallel on \( r \) nodes. The master collects the results from the fastest of the \( r \) nodes that have been assigned the task of computing the product \( \bm{A}_i \bm{x} \) for all \( i \). The computed products are aggregated into the \( m \times 1 \) vector \( \bm{b} \). Setting \( r = 1 \) corresponds to the naive or uncoded strategy where each submatrix-vector product is computed at a single worker node. While this approach performs the least number of computations it is susceptible to straggling nodes or node failures. Increasing the number of replicas provides greater straggler tolerance at the cost of redundant computations. Real distributed computing frameworks like Mapreduce and Spark often use \( r = 2 \) i.e. each computation is assigned to \( 2 \) different worker nodes for added reliability and straggler tolerance.

The \( (p,k) \) MDS-Coded Strategy. Recent works like [12], [13] have applied MDS coding to overcome the problem of stragglers in the uncoded strategy. The strategy involves multiplying \( \bm{A} \) at the central node with a suitable encoding matrix \( \bm{F} \) denoting the MDS codes. If a matrix is encoded using a \( (p,k) \) MDS code, the matrix \( \bm{A} \) is split along its rows into \( k \) matrices \( \bm{A}_1, \ldots, \bm{A}_k \), each having \( m/k \) rows. The MDS code adds \( p-k \) redundant matrices \( \bm{A}_{k+1}, \ldots, \bm{A}_{p} \) which are independent linear combinations of the matrices \( \bm{A}_1, \ldots, \bm{A}_k \). Worker \( i \) computes the product of matrix \( \bm{A}_i \) with vector \( \bm{x} \). Thus the system is robust to \( p-k \) stragglers. However this strategy adds a significant computation overhead. When none of the nodes are slow, the system performs \( mp/k \) row-vector products, whereas in the uncoded case it only performs \( m \) row-vector products.

IV. PROPOSED RATELESS CODING STRATEGY

In this section we propose the use of rateless codes to mitigate the effect of stragglers in computing the matrix-vector product \( \bm{b} = \bm{A} \bm{x} \). Our algorithm achieves near-perfect load balancing and low latency, with negligible computation overhead. We describe our algorithm in two parts - first, we describe how LT codes [15], one of the first practically realizable rateless codes, can be applied to perform coded matrix multiplication, and then we describe a distributed implementation of this scheme using the master-worker framework described in Section \( \textbf{III.A} \).

A. LT-Coded Matrix-vector Multiplication

LT codes, described by Luby in [15] are a class of rateless erasure codes that can be used to generate a potentially limitless number of encoded symbols from a set of \( m \) source symbols. The original source symbols can be recovered with a high probability from any \( M' \) encoded symbols using an iterative decoding algorithm based on belief propagation that is commonly called the peeling decoder [15]–[17]. Here \( M' \) is a random variable. In our analysis we deal with \( m_d = \mathbb{E}[M'] \) which we formally define as the decoding threshold of our algorithm.

Definition 3 (Decoding Threshold (\( m_d \)). We define decoding threshold \( m_d \) as the expected number of encoded symbols required to decode a set of \( m \) source symbols under the proposed rateless coding strategy.

To apply LT codes to the task of encoding the matrix-vector product \( \bm{b} = \bm{A} \bm{x} \), we treat the rows of the matrix \( \bm{A} \) as source symbols. Each encoded symbol is the sum of a randomly chosen subset of source symbols. Thus rows of the encoded matrix are given by \( \bm{a}_{e,i} = \sum_{j \in S} a_i \), where \( S \) is a random subset of rows of \( \bm{A} \).

To choose \( S \), we first choose the degree of the encoded symbol according to a degree distribution. The degree \( d \) of an encoded symbol is defined as the number of source symbols that contribute to the encoded symbol and is chosen according to the Robust Soliton degree distribution, the details of which are described in Appendix \( \textbf{A} \) and in Luby’s original work [15].

Once the degree \( d \) is chosen, encoding is performed by choosing \( d \) source symbols uniformly at random (this determines \( S \)) and adding them to generate an encoded symbol. The encoding process is illustrated in Fig. 3.

Once the rows of the encoded matrix \( \bm{A}_e \) are generated, we can compute the encoded matrix vector product \( \bm{b}_e = \bm{A}_e \bm{x} \). To decode the desired matrix vector product \( \bm{b} = \bm{A} \bm{x} \) from a subset of \( m_d \) symbols of \( \bm{b}_e \) we use the iterative peeling decoder described in [15]–[17]. If \( \bm{b} = [b_1, b_2, \ldots, b_m] \), the decoder may receive symbols \( b_1 + b_2 + b_3, b_2 + b_4, b_3, b_4, \ldots \), and so on. Decoding is performed in an iterative fashion. In each iteration, the decoder finds a degree one encoded symbol, covers the corresponding source symbol, and subtracts the symbol from all other encoded symbols connected to that source symbol. This decoding process is illustrated in Fig. 3.

The Robust Soliton degree distribution [11] used for encoding the rows of \( \bm{A} \) ensures that with high probability there are degree one symbols at each iteration, thus leading to fast and low-complexity decoding.
**Task replicated at 2 workers**

- Select fastest worker from each group

**m/k tasks at each worker**

- Select fastest k workers overall

**αm tasks in total**

- Wait for m(1+𝜖) tasks across all workers

---

**(a) Replication Strategy**

- m/k tasks at each worker

**(b) MDS-Coding Strategy**

- ⍺m tasks in total

**(c) Rateless Coded Strategy**

- Wait for m(1+𝜖) tasks across all workers

---

Fig. 2: Each square represents one row-vector product task out of a total of m tasks to be completed by the p workers. In the replication scheme, the master waits for the fastest worker for each submatrix. With MDS-coding, the master needs to wait for k across all p workers, but each worker has to complete m/k tasks. The rateless coded strategy requires waiting for only m(1+𝜖) tasks across all workers.

---

Fig. 3: Bipartite graph representation of the encoding of the rows a₁, a₂, ..., aₘ of matrix A. Each encoded row is the sum of d rows of A chosen uniformly at random, where d is drawn from the Robust Soliton degree distribution [11].

Since the encoding uses a random bipartite graph, the number of symbols required to decode the m source symbols successfully is a random variable M'. For the Robust Soliton distribution, [15] gives a high probability bound on M'.

**Lemma 1** (Theorems 12 and 17 in [15]). *The original set of m source symbols can be recovered from a set of any M' = m + O(√m ln²(m/δ)) with probability at least 1 − δ.*

In our analysis we denote m_d = E[M']. Using the theoretical guarantees for LT codes (see Appendix A of [?] we can show that m_d = m(1 + 𝜖), where 𝜖 → 0 as m → ∞. In practice one can choose a small enough value of δ and compute the corresponding value of M' such that decoding is successful with a high probability.

---

**B. Distributed Implementation**

We now describe the implementation of LT-Coded matrix vector multiplication in a distributed master-worker frame-
work. The encoding and decoding tasks are performed at the master while the workers multiply rows of the encoded matrix with the vector \( x \) i.e. they compute products of the form \( a_{e,j} x \) and communicate the result to the master.

The encoding step can be treated as a pre-processing step in that it is only performed initially. Thus the \( m \times n \) matrix \( A \) is encoded by treating the rows \( a_1, a_2, \ldots, a_m \) of the matrix as source symbols to generate \( m_e = o m \) rows of the encoded matrix \( A_e \) as described in Section IV-A. Since the general motivation for performing distributed matrix vector multiplication is that \( A \) is too large to be stored in memory at a single machine, the encoding step can be performed by accessing rows of \( A \) stored in a distributed file system \([40]–[42]\) and computing their sum to generate a row of \( A_e \). While the cost of communicating matrix rows over a distributed file system may be high, we note that this is a one-time cost since the matrix is encoded only once.

The rows of the encoded matrix are then distributed among the worker nodes. Each worker node is assigned an equal number of rows of \( A_e \) as illustrated in Fig. 1. The \( o m/p \) rows assigned to each node are stored in its local memory. This can be accomplished using distributed memory abstractions like Resilient Distributed Datasets \([20]\). Subsequently, whenever we wish to multiply \( A \) with a vector \( x \), the master communicates \( x \) to the workers. Each worker multiplies \( x \) with each row of \( A_e \) stored in its memory and returns the product (a scalar) to the master. Alternately, to minimize communication, the worker may only send progress updates to the master node indicating the number of row-product computation tasks it has completed, and send the products only upon request by the master.

The master node receives coded row-vector products from the worker nodes. Since the master is aware of the mapping, such as in Fig. 3 from source symbols to encoded symbols, it can use this knowledge to recover the desired matrix vector product \( b = Ax \) from a subset of the elements of \( b_e = A_e x \) using the iterative peeling decoder. For a matrix with \( m \) rows, the decoding process will require \( m_d = m(1 + \epsilon) \) row-vector products, in expectation, where \( \epsilon \) is a small overhead, such that \( \epsilon \to 0 \) as \( m \to \infty \), that depends on the parameters of the Robust Soliton distribution defined in \([11]\).

Once the master decodes all the elements in the product vector \( b = Ax \), it sends a done signal to all workers nodes to stop their local computation. The workers will continue sending row-vector products to the master, until the master sends the done signal. A worker node may complete all the \( o m/p \) row-vector products assigned to it before receiving the done signal. This worker will then remain idle, while the master collects more row-vector products from other workers until it is able to decode \( b \).

While we have used LT Codes \([15]\) for our analysis and simulations due to their ease of implementation and fast decoding, we note that any rateless random linear network code which generates \( o m (\alpha > 1) \) encoded symbols that are linear independent with high probability can be used for encoding the \( m \) rows of matrix \( A \). A larger value of \( \alpha \) implies higher redundancy, and more tolerance to straggling nodes. In particular one can consider more advanced rateless codes such as Raptor Codes \([16], [17]\) and Online Codes \([43]\). Raptor Codes have better encoding and decoding properties than LT codes and we are exploring using them instead of LT codes in our ongoing systems implementation.

V. THEORETICAL ANALYSIS

In this section we discuss our main theoretical results, which are summarized in Table 1. We first describe our model for computation delays at each worker node, and then compare the latency and computations of the proposed rateless LT coding strategy with the benchmarks described in Section III. The proofs of the theoretical results presented here are given in Appendix B.

A. Delay Model

We assume that worker \( i \) requires time \( Y_i \) to perform \( C_i \) computations where

\[
Y_i = X_i + \tau C_i,
\]

for all \( i = 1, \ldots, p \) (1)

and \( X_i \sim \text{exp}(\mu) \), is an exponential random variable with rate \( \mu \). Thus, the delay involves the sum of two components – an exponential random variable \( X_i \) that models the network latency, initial setup time, and other random components, and a constant shift that is linear in the number of computations. If a worker completes \( C_i \) row-vector products this shift is \( C_i \tau \), where \( \tau \) is the time taken to perform each computation. The distribution of the per-worker runtime can be shown to be

\[
\mathbb{P}(Y_i \leq t) = 1 - \exp(-\mu(t - \tau C))
\]

(2)

While this follows the shifted exponential delay models used in \([12], [14] \) and \([38]\), the key difference is that the shift is parameterized by the number of computations at each worker. We believe this is a more realistic model since it clearly captures the effect of increasing the amount of computations on the delay - if a worker is assigned more computations, there is larger delay, and unlike previous works, the decay rate \( \mu \) of the exponential part of the delay does not change with the number of computations performed by that worker. Fig. 5 illustrates the latency of the LT coded strategy, \( T_{LT} \) under this delay model.
B. Latency Analysis

In what follows we give expressions for the expected latency of each of the coded computing schemes studied so far. We use $T_{\text{rep}}$, $T_{\text{MDS}}$, $T_{\text{LT}}$, to represent the latency of the replication, MDS-coded, and LT-coded schemes respectively.

**Theorem 1** (Latency of the Rateless Coded Strategy). For large $m_e$, i.e. $\alpha = m_e/m \to \infty$, the expected latency for the LT-coded case with $p$ workers and $X_i \sim \exp(\mu)$ for all workers $i = 1, \ldots, p$, is bounded as

$$
\mathbb{E}[T_{\text{LT}}] \leq \frac{\tau m_d}{p} + \frac{1}{\mu} + \tau, \\
\mathbb{E}[T_{\text{LT}}] \geq \frac{\tau m_d}{p} + \frac{1}{\mu} + \frac{1}{p\mu},
$$

where $m_d = m(1 + \epsilon)$ is the expected number of symbols necessary for successful decoding.

**Remark 1.** For finite values of $m_e$, if each worker is assigned $m_e/p$ computations, it is possible that not all values of $C_i$ that satisfy $\sum_{i=1}^{p} C_i = m_d$ are permissible since we also need to enforce the constraint $C_i \leq m_e/p$. Hence we need large redundancy ($\alpha = m_e/m \to \infty$) for the results of Theorem 1 to be strictly true. However in Fig. 6 we see that even for fairly small amounts of redundancy ($\alpha = m_e/m = 2$) the latency distribution for the LT and DBL schemes is almost identical.

**Theorem 2** (Latency of Replication and MDS Coding). The expected latency for the $r$--Replication and the $(p, k)$ MDS-coded strategies with $X_i \sim \exp(\mu)$ for all workers $i = 1, \ldots, p$ is

$$
\mathbb{E}[T_{\text{rep}}] = \frac{\tau mr}{p} + \frac{1}{\mu} H_{p/r} \approx \frac{\tau mr}{p} + \frac{1}{\mu} \log \frac{p}{r},
$$

$$
\mathbb{E}[T_{\text{MDS}}] = \frac{\tau m}{k} + \frac{1}{\mu} (H_p - H_{p-k}) \approx \frac{\tau m}{k} + \frac{1}{\mu} \log \frac{p}{p-k},
$$

where $H_j = \sum_{v=1}^{j} 1/v$, the $j^{th}$ Harmonic number.

**Remark 2.** Observe that in (5) and (6) above, adding redundancy (increasing $r$ and reducing $k$ respectively) leads to an increase in the first term (more computation at each node) and decrease in the second term (less delay due to stragglers). Thus, straggler mitigation comes at the cost of additional computation at the workers which might even lead to an increase in latency. This is seen in Fig. 6 where the latency actually increases on adding redundancy for the MDS-coded case.

C. Computations and Decoding Complexity

Table I shows a comparison of the different strategies in terms of the total number of row-vector product computations performed by the workers until all can be decoded. One of the main advantages of the rateless coded strategy is that the number of computations performed by all the workers asymptotically (as $m \to \infty$) approaches the minimum number of computations ($m$) required to recover a $m$--dimensional matrix-vector product (lemma). On the other hand, the following theorems show that the total computations performed by all workers (fast and slow) in the replication and MDS-coded schemes is much larger than $m$.

**Theorem 3** (Tail of Computations for MDS Coding). The tail of the number of computations of the MDS coded strategy, $C_{\text{MDS}}$, with $p$ workers and $X_i \sim \exp(\mu)$ is bounded as

$$
\Pr(C_{\text{MDS}} \geq mp/k - C_0) \geq 1 - \exp(-\mu\theta_{\text{MDS}}) \quad (7)
$$

where $\theta_{\text{MDS}} = \frac{\tau C_0}{(p-k)^2} - \frac{\tau}{p-k} \quad (8)$

**Theorem 4** (Tail of Computations for Replication). The tail of the number of computations of the replication strategy, $C_{\text{rep}}$, with $p$ workers and $X_i \sim \exp(\mu)$ is bounded as

$$
\Pr(C_{\text{rep}} \geq mnr - C_0) \geq 1 - \sum_{i=0}^{p/r-1} \frac{1}{i!} \exp(-\mu\theta_{\text{rep}}) (\mu\theta_{\text{rep}})^i \quad (9)
$$

where $\theta_{\text{rep}} = \frac{\tau C_0}{(r-1)^2} - \frac{\tau p}{r(r-1)} \quad (10)$

Let us also compare the decoding complexity of the strategies (given in Table I). The replication strategy has an optimal decoding complexity $O(m)$, with $O(1)$ operations per symbol. For MDS codes, the decoding involves inverting a $k \times k$ matrix which takes $O(k^3)$ operations naively, and multiplying it with an $m \times 1$ vector which takes $O(mk)$ operations, resulting in an overall decoding complexity $O(mk + k^3)$. Rateless LT codes create each encoded row with $O(\log m)$ rows of $A$ and use an iterative decoding process which needs $O(\log m)$ operations per symbol, which results in a decoding complexity $O(m \log m)$.

To conclude our analysis in this section we present simulations (Fig. 6) for the replication, MDS, and LT-coded schemes under our delay model for a distributed matrix-vector multiplication task with number of matrix rows $m = 10000$, number of worker nodes $p = 10$ and delay model parameters $\mu = 0.2$, $\tau = 0.005$. The key observation from the simulations is that for the same amount of redundancy in each of the three schemes ($\alpha = 2.0$ for LT Codes, $r = 2$ for replication and $k = 5$ for MDS codes), the LT coded strategy has the lowest latency and performs fewest computations.

VI. CONCLUDING REMARKS

Due to the massive size of matrices arising in modern data-driven applications, computations such as matrix-vector multiplication need to be parallelized across multiple nodes. In this
paper we propose an erasure coding strategy based on rateless fountain codes to overcome bottlenecks caused by slow or straggling nodes. For a matrix with \( m \) rows, our strategy requires the nodes to collectively finish slightly more than \( m \) row-vector products, and thus it can seamlessly adapt to varying node speeds and achieve near-perfect load balancing. Moreover, it has a small overhead of redundant computations (asymptotically zero), and low decoding complexity. Thus, it strikes a better latency-computation trade-off than the un-coded and fixed-rate erasure coding strategies.

We are currently working on implementing the proposed rateless coding scheme in a real distributed computing cluster and will evaluate its performance for large-scale data processing applications such as neural network inference and PageRank. We also plan to investigate the theory behind LT codes and other improved versions of fountain codes such as Raptor-Q codes [17] and systematic fountain codes. More broadly, this work demonstrates that rateless codes are superior to fixed-rate coding strategies for the purpose of adapting to variability and heterogeneity in node speeds, as well as node failures. While we have only considered matrix-vector multiplication so far, we believe that the core rateless coding idea is applicable to a wide range of linear computations such as matrix-matrix multiplication, convolution and Fourier Transforms.

Author Joshi also sincerely thanks Emina Soljanin, Alyson Fox, Fiona Knoll and Nadia Kazemi for fruitful initial discussions during the Women in Data Science and Mathematics (WiSDM) Research Collaboration Workshop held at Brown University in July 2017.

REFERENCES

A. Properties of LT Codes

The number of original rows in each encoded row, or the degree \( d \), is chosen according to the Robust Soliton degree distribution wherein the probability of choosing \( d \) is proportional to

\[
\rho(d) = \begin{cases} 
\frac{R d}{m} & \text{for } d = 1 \\
\frac{R}{m} + \frac{1}{m(m-1)} & \text{for } d = 2, \ldots, m/R - 1 \\
\frac{R}{m} + \frac{1}{m(m-1)} & \text{for } d = m/R \\
\frac{1}{m(m-1)} & \text{for } d = m/R + 1, \ldots, m 
\end{cases}
\]

where \( R = c \log(m/\delta) \sqrt{m} \) for some \( c > 0 \) and \( \delta \in [0, 1] \), with \( c \) and \( \delta \) being design parameters. Some guidelines for choosing \( c \) and \( \delta \) can be found in [44]. The probability of choosing \( d = d_0 \) is equal to \( \rho(d_0)/\sum_{i=1}^{m} \rho(i) \). Once the degree \( d \) is chosen, encoding is performed by choosing \( d \) source symbols uniformly at random (this determines \( S_d \)) and adding them to generate an encoded symbol. The encoding process is illustrated in Fig. 3.

Fig. 7 shows simulation results for the number of symbols decoded successfully for each encoded symbol received. For this we perform LT-Coded multiplication of a randomly generated \( 10,000 \times 10,000 \) matrix with a \( 10,000 \times 1 \) vector. The matrix \( A \) is encoded using an LT code with parameters \( c \) and \( \delta \) chosen according to the guidelines of [44]. We generate a single row of the encoded matrix \( A_\epsilon \) at a time which is then multiplied with the \( 10,000 \times 1 \) size vector \( x \) to give a single element of the encoded matrix vector product \( b_\epsilon \). The process is repeated until we have enough symbols for successfully decoding the entire \( 10,000 \times 1 \) size vector \( b \) using the peeling decoder. The plots of Fig. 7 correspond to different choices of \( c \) and \( \delta \). Each case we observe an avalanche behavior wherein very few symbols are decoded up to a point (approximately up to 10,000 encoded symbols received) after which the decoding proceeds very rapidly to completion. This effectively illustrates the fact that the computation overhead of the proposed LT coded matrix vector multiplication strategy is very small \( (m_d = m(1 + \epsilon)) \).

The theoretical encoding and decoding properties of LT codes are summarized in the following lemmas:

Lemma 2 (Theorem 13 in [15]). For any constant \( \delta > 0 \), the average degree of an encoded symbol is \( O(\log(m/\delta)) \) where \( m \) is the number of source symbols.

Corollary 1. Each encoding symbol can be generated using \( O(\log m) \) symbol operations on average.

Lemma 3 (Theorem 17 in [15]). For any constant \( \delta > 0 \) and for a source block with \( m \) source symbols, the LT decoder can recover all the source symbols from a set of \( m' = m + O(\sqrt{m} \log^3(m/\delta)) \) with probability at least \( 1 - \delta \).

Corollary 2. The decoding threshold \( m_d \) as defined in Definition 3 is given by \( m_d = m(1 + \epsilon) \) where \( \epsilon \to 0 \) as \( m \to \infty \).

Corollary 3. Since the average degree of an encoded symbol is \( O(\log(m/\delta)) \) the decoding requires \( O(m \log m) \) symbol operations on average.

---

Fig. 7: The number of decoded symbols is almost constant until \( m = 10,000 \) encoded symbols are received after which it increases rapidly.
Fig. 8: Worker $i$ has a random exponential initial delay $X_i$, after which it completes row-vector product tasks (denoted by the small rectangles), taking time $\tau$ per task. The latency $T_{LT}$ is the time to complete $m_d$ tasks in total.

B. Proof of Theoretical Results

1) Delay Model and Order Statistics Primer: We first state some standard results \cite{45} on order statistics of exponential random variables to aid the understanding of the latency analysis presented subsequently. If $X_1, X_2, \ldots, X_p$ are exponential random variables with rate $\mu$, their $k$th order statistic is denoted by $X_{k:p}$. Thus, $X_{1:p} = \min(X_1, X_2, \ldots, X_p)$, and $X_{p:p} = \max(X_1, X_2, \ldots, X_p)$. The expected value of $X_{k:p}$ is given by

$$E[X_{k:p}] = \frac{1}{\mu} \left( \frac{1}{p} + \frac{1}{p-k+1} \right),$$

(12)

and

$$H_p - H_{p-k} = \frac{1}{\mu},$$

(13)

where $H_p$ is the $p$th Harmonic number

$$H_p \triangleq \sum_{i=1}^{p} \frac{1}{i} \quad \text{for} \quad p = 1, 2, \ldots$$

(14)

For large $p$, $H_p = \log p + \gamma$, where $\gamma$ is the Euler-Mascheroni constant and thus we can use the approximation $H_p \simeq \log p$ for large $p$.

Also the difference of consecutive order statistics of i.i.d exponential random variables is also exponentially distributed as,

$$(X_{l+1:p} - X_{l:p}) \overset{\triangle}{=} U_{p-l}$$

(15)

where $U_{p-l} \sim \exp((p-l)\mu)$.

2) Proof of Theorem \cite{7} As per our model, the time taken by worker $i$ to perform $B_i$ computations is given by

$$Y_i = X_i + \tau B_i, \quad \text{for} \quad i = 1, \ldots, p.$$  

(16)

The latency $T_{LT}$ is the earliest time when $\sum_{i=1}^{p} B_i = m_d$, as illustrated in Fig. 5. We note that, in this case it is not necessary that each worker has completed at least 1 computation. Specifically, if $T_{LT} - X_i \leq \tau$ for any $i$ then it means that worker $i$ has not performed even a single computation in the time that the system as a whole has completed $m_d$ computations (owing to the large initial delay $X_i$). Therefore we define

$$W_{LT} := \{ i : T_{LT} - X_i \geq \tau \}$$

(17)

Here $W_{LT}$ is the set of workers for which $B_i > 0$. Thus

$$T_{LT} = \max_{i \in W_{LT}} Y_i,$$

(18)

$$= \max_{i \in W_{LT}} (X_i + \tau B_i),$$

(19)

$$\geq \min_{i \in \{1, \ldots, p\}} X_i + \tau \max_{i \in W_{LT}} B_i,$$

(20)

$$\geq \min_{i \in \{1, \ldots, p\}} X_i + \tau \frac{m'}{p},$$

(21)
where to obtain (20), we replace each $X_i$ in (19) by $\min_{i \in [1,\ldots,p]} X_i$ and then we can bring it outside the maximum. To obtain (21), we observe that in order for the $p$ workers to collectively finish $m'$ computations, the maximum number of computations completed by a worker has to be at least $m/p$. Taking expectation on both sides we get

$$\mathbb{E}[T_{LT}] \geq \mathbb{E}[\min (X_1, X_2, \ldots, X_p)] + \frac{\tau m'}{p},$$

(22)

$$= \frac{1}{\mu p} + \frac{\tau m'}{p},$$

(23)

where the lower bound in (23) follows from the result (13) on order statistics of exponential random variables. To derive the upper bound, we note that

$$T_{LT} \leq X_i + \tau (B_i + 1) \quad \text{for all } i = 1, \ldots, p$$

(24)

This is because at time $T_{LT}$ each of the workers $1, \ldots, p$, have completed $B_1, \ldots, B_p$ row-vector product tasks respectively, but they may have partially completed the next task. The 1 added to each $B_i$ accounts for this edge effect, which is also illustrated in Fig. 8. Summing over all $i$ on both sides, we get

$$\sum_{i=1}^{p} T_{LT} \leq \sum_{i=1}^{p} X_i + \sum_{i=1}^{p} \tau (B_i + 1)$$

(25)

$$pT_{LT} \leq \sum_{i=1}^{p} X_i + \tau (m_d + p)$$

(26)

Taking expectation on both sides and rearranging we obtain the upper bound,

$$p\mathbb{E}[T_{LT}] \leq \frac{p}{\mu} + \tau (m_d + p),$$

(27)

$$\mathbb{E}[T_{LT}] \leq \frac{\tau m_d}{p} + \frac{1}{\mu} + \tau.$$

(28)

3) Proof of Theorem 2
In the $r$-replication strategy each submatrix $A_i$ is replicated at $r$ workers and we wait for the fastest of these $r$ workers. Without loss of generality, we assume that submatrix $A_1$ is stored at workers $1, 2, \ldots, r$, submatrix $A_2$ is stored at workers $r+1, r+2, \ldots, 2r+r$ and so on. More generally submatrix $A_i$ is stored at workers $(i-1)r+1, \ldots, ir$. Thus the time taken to compute the product $A_i \cdot x$ is given by

$$Z_i = \min \{ Y_{(i-1)r+1}, Y_{(i-1)r+2}, \ldots, Y_{ir} \}$$

(29)

$$= \min \{ X_{(i-1)r+1} + \tau B_{(i-1)r+1}, \ldots, X_{ir} + \tau B_{ir} \}$$

(30)

$$= \min \{ X_{(i-1)r+1}, \ldots, X_{ir} \} + \frac{\tau m_r}{p}$$

(31)

$$= W_i + \frac{\tau m_r}{p}$$

(32)

where $W_i = \min(X_{(i-1)r+1}, \ldots, X_{ir})$ is an $\exp(r\mu)$ random variable since it is the minimum of $r \exp(\mu)$ random variables. This is because the fastest of the $r$ workers that store $A_i$ is the one corresponding to $\min(X_{(i-1)r+1}, \ldots, X_{ir})$ and this worker must perform $\frac{\tau m_r}{p}$ computations to compute the product $A_i \cdot x$.

The latency $T_{rep}$ is the time at which the product $A_i \cdot x$ is computed for all $i = 1, \ldots, p/r$ since $A$ is split into $p/r$ submatrices. Thus

$$T_{rep} = \max \{ Z_1, Z_2, \ldots, Z_{p/r} \},$$

(33)

$$= \max \{ W_1, W_2, \ldots, W_{p/r} \} + \frac{\tau m_r}{p},$$

(34)

Taking expectation on both sides

$$\mathbb{E}[T_{rep}] = \frac{\tau m_r}{p} + \mathbb{E}[\max \{ W_1, W_2, \ldots, W_{p/r} \}],$$

(35)

$$= \frac{\tau m_r}{p} + \frac{1}{r\mu} H_{p/r},$$

(36)

$$\simeq \frac{\tau m_r}{p} + \frac{1}{r\mu} \log \frac{p}{r},$$

(37)

where (36) and (37) follow from (13) and (14). This proves the result for the expected latency of the replication strategy.
The latency in the MDS-coded case is $T_{\text{MDS}} = Y_{k:p}$, where $Y_{k:p}$ is the $k$th order statistic of the individual worker latencies $Y_1, Y_2, \ldots, Y_p$ since we only wait for the fastest $k$ workers to finish the task assigned to them. In this case, each of the fastest $k$ workers performs $\frac{m}{k}$ computations and thus the expected overall latency is given by

$$
E[T_{\text{MDS}}] = E[X_{k:p}] + \frac{\tau m}{k},
$$

(38)

$$
= \frac{\tau m}{k} + \frac{1}{\mu} (H_p - H_{p-k}),
$$

(39)

$$
\simeq \frac{\tau m}{k} + \frac{1}{\mu} \log \frac{p}{p-k},
$$

(40)

where (39) and (40) follow from the exponential order statistics results in (13) and (14).

4) Proof of Theorem 3: As per our model, we represent the number of computations at worker $i$ by the random variable $B_i$. We also use the random variable $C_{\text{MDS}}$ to denote the total number of computations performed by all $p$ workers until $T_{\text{MDS}}$, which is the time when the master collects enough computations to be able to recover the matrix-vector product $b = Ax$. Thus

$$
C_{\text{MDS}} = B_1 + B_2 + \ldots + B_p
$$

(41)

$$
= B_{1:p} + B_{2:p} + \ldots + B_{p:p},
$$

(42)

where the second expression is simply the right-hand side of the first expression written in terms of the corresponding order statistics. We note that under our model the time spent by worker $i$ in performing $B_i$ computations is $Y_i = X_i + \tau B_i$ where $X_i$ denotes setup/initial delay and $\tau$ is a constant denoting the time taken to perform a single computation. Thus $B_{1:p}$ corresponds to the worker that performs the least number of computations which is also the worker with the largest value of setup time i.e $X_{p:p}$ since all workers stop computing at the same time ($T_{\text{MDS}}$). Thus for a given $C_0$, the tail of the total number of computations performed in the MDS Coded strategy is given by

$$
\Pr \left( C_{\text{MDS}} \leq \frac{mp}{k} - C_0 \right) = \Pr \left( \sum_{i=1}^{p} B_{i:p} \leq \frac{mp}{k} - C_0 \right)
$$

(43)

$$
= \Pr \left( \sum_{i=1}^{p-k} B_{i:p} + \frac{m}{k} \times k \leq \frac{mp}{k} - C_0 \right)
$$

(44)

$$
= \Pr \left( \sum_{i=1}^{p-k} B_{i:p} \leq \frac{m(p-k)}{k} - C_0 \right)
$$

(45)

$$
\leq \Pr \left( (p-k) B_{1:p} \leq \frac{m(p-k)}{k} - C_0 \right)
$$

(46)

$$
= \Pr \left( B_{1:p} \leq \frac{m}{k} - \frac{C_0}{p-k} \right)
$$

(47)

where (44) follows from the fact that the fastest $k$ workers which correspond to $B_{p-k+1:p}, B_{p-k+2:p}, \ldots, B_{p:p}$ must perform all the tasks assigned to them i.e $m/k$ computations each, while (46) follows from the fact that $B_{2:p}, \ldots, B_{p:p}$ are always larger than $B_{1:p}$ by definition.

At this point we note that the worker which performs $B_{1:p}$ computations has setup time $X_{p:p}$. There can be two possibilities – either $T_{\text{MDS}} > X_{p:p}$, or $T_{\text{MDS}} \leq X_{p:p}$. If $T_{\text{MDS}} > X_{p:p}$ then

$$
T_{\text{MDS}} \leq X_{p:p} + \tau (B_{1:p} + 1)
$$

(48)

where the added 1 accounts for the edge effect of partial computations at the nodes. If $T_{\text{MDS}} \leq X_{p:p}$ then also the upper bound (48) holds. Thus overall (by rearranging terms in (48)) we obtain,

$$
B_{1:p} \geq \frac{T_{\text{MDS}} - X_{p:p}}{\tau} - 1
$$

(49)
Thus we can write

\[
\Pr \left( \text{MDS} \leq \frac{mp}{k} - C_0 \right) \leq \Pr \left( \frac{T_{\text{MDS}} - X_{FPP}}{\tau} - 1 \leq \frac{m}{k} - \frac{C_0}{p - k} \right) \leq \Pr \left( \frac{T_{\text{MDS}} - X_{FPP}}{\tau} - 1 \leq \frac{m}{k} - \frac{C_0}{p - k} \right)
\]  

(50)

\[
= \Pr \left( X_{FPP} - X_{k:p} \geq \frac{\tau C_0}{p - k} - \tau \right) = \Pr \left( \sum_{l=k}^{p-1} (X_{l+1:p} - X_{l:p}) \geq \frac{\tau C_0}{p - k} - \tau \right)
\]  

(51)

(52)

where (51) follows from the fact that \( T_{\text{MDS}} = X_{FPP} + \tau m/k \).

If \( X_i \sim \exp(\mu) \) we can use the result from (15) to simplify the above expression further,

\[
\Pr \left( \text{MDS} \leq \frac{mp}{k} - C_0 \right) \leq \Pr \left( \sum_{i=1}^{p-k} U_i \geq \frac{\tau C_0}{p - k} - \tau \right)
\]  

(53)

\[
\leq \Pr \left( (p-k) U_1 \geq \frac{\tau C_0}{p - k} - \tau \right)
\]  

(54)

\[
= \Pr \left( U_1 \geq \frac{\tau C_0}{(p-k)^2} - \frac{\tau}{p - k} \right)
\]  

(55)

\[
= \exp \left( -\mu \left( \frac{\tau C_0}{(p-k)^2} - \frac{\tau}{p - k} \right) \right)
\]  

(56)

where (54) is obtained from the fact that \( \Pr(U_1 \geq u) \geq \Pr(U_l \geq u) \) for \( l = 2, \ldots, p-k \) for any \( u \) since \( U_l \sim \exp(\mu) \). Lastly (56) is obtained from the expression for the tail distribution of an exponential random variable.

5) **Proof of Theorem 4**

As per our model, we represent the number of computations at worker \( i \) by the random variable \( B_i \). We also use the random variable \( C_{\text{rep}} \) to denote the total number of computations performed by all \( p \) workers until \( \tau \), which is the time when the master collects enough computations to be able to recover the matrix-vector product \( \mathbf{b} = \mathbf{A} \mathbf{x} \). Thus

\[
C_{\text{rep}} = B_1 + B_2 + \ldots + B_p = \sum_{i=1}^{p/k} \sum_{j=1}^{r} B_{i(-1)r+j},
\]  

(57)

(58)

where the term inside the summation in the second expression represents the number of computations performed by each worker that store a copy of the submatrix \( A_i \) (for a given \( i \)). In what follows, we use the shorthand notation \( D_{i,j}^r = B_{ij(-1)r+j} \) and use \( D_{i,j}^r \) to denote the order statistics of \( D_{i,1}^r, \ldots, D_{i,r}^r \). Rewriting the above expression in terms of the order statistics we get,

\[
C_{\text{rep}} = \sum_{i=1}^{p/k} \sum_{j=1}^{r} D_{i,j}^r,
\]  

(59)

and the tail bound,

\[
\Pr(C_{\text{rep}} \leq mp - C_0) = \Pr \left( \sum_{i=1}^{p/k} \sum_{j=1}^{r} D_{i,j}^r \leq mp - C_0 \right)
\]  

(60)

\[
= \Pr \left( \sum_{i=1}^{p/k} \sum_{j=1}^{r-1} D_{i,j}^r \leq m(r-1) - C_0 \right)
\]  

(61)

\[
\leq \Pr \left( (r-1) \sum_{i=1}^{p/k} D_{i,1}^r \leq m(r-1) - C_0 \right)
\]  

(62)

\[
= \Pr \left( \sum_{i=1}^{p/k} D_{i,1}^r \leq m - \frac{C_0}{r-1} \right)
\]  

(63)
where (61) follows from the fact that for any given submatrix $A_i, i = 1, \ldots, p/r$, the fastest worker that stores a copy of that submatrix, which corresponds to $D_{i,r}^j$ (fastest worker performs the most computations) must perform all the tasks assigned to it i.e. $mr/p$ computations each, while (62) follows from the fact that $D_{2,r}, \ldots, D_{r,r}$ are always larger than $D_{1,r}^j$ by definition.

At this point we introduce the shorthand notation $V_{i,r}^j = X_{(i-1)r+j}$ for the setup time of the worker that stores the $j^{th}$ copy of submatrix $A_i$ and note that the worker which performs $D_{1,r}^j$ computations has setup time $V_{r,r}^j$ ($V_{r,r}^j$ are the order statistics of $V_{1,r}^j, \ldots, V_{r,r}^j$). There can be two possibilities – either $T_{\text{rep}} \geq V_{r,r}^j$, or $T_{\text{rep}} \leq V_{r,r}^j$. If $T_{\text{rep}} > V_{r,r}^j$ then

$$T_{\text{rep}} \leq V_{r,r}^j + \tau(D_{1,r}^j + 1)$$

(64)

where the added 1 accounts for the edge effect of partial computations at the nodes. If $T_{\text{rep}} \leq V_{r,r}^j$ then also the upper bound (64) holds. Thus overall (by rearranging terms in (64)) we obtain,

$$D_{1,r}^j \geq \frac{T_{\text{rep}} - V_{r,r}^j}{\tau} - 1$$

(65)

Thus we can write

$$\Pr(C_{\text{rep}} \leq mr - C_0) \leq \Pr \left( \frac{T_{\text{rep}} - V_{r,r}^j}{\tau} - 1 \right) \leq \frac{m - C_0}{r - 1}$$

(66)

$$= \Pr \left( \frac{T_{\text{rep}} - \sum_{i=1}^{r} V_{r,r}^j}{\tau} \right) \geq \frac{\tau C_0}{r - 1} - \frac{\tau p}{r}$$

(67)

where $W_{\text{rep}} = \max_i V_{1,r}^j = \max_{1 \leq i \leq p/r} \min_{1 \leq j \leq r} X_{(i-1)r+j}$ and (67) follows from the fact that

$$T_{\text{rep}} = \max_{1 \leq i \leq p/r} \min_{1 \leq j \leq r} X_{(i-1)r+j} + \tau mr/p$$

From our definition of $W_{\text{rep}}$ we see that,

$$V_{r,r}^j - W_{\text{rep}} \leq V_{r,r}^j - V_{1,r}^j$$

(68)

and the consequent stochastic dominance can be used to get an upper bound on (67) as,

$$\Pr(C_{\text{rep}} \leq mr - C_0) \leq \Pr \left( \frac{T_{\text{rep}} - \sum_{i=1}^{r} V_{r,r}^j}{\tau} \right) \geq \frac{\tau C_0}{r - 1} - \frac{\tau p}{r}$$

(69)

$$= \Pr \left( \frac{T_{\text{rep}} - \sum_{i=1}^{r-1} \sum_{j=1}^{r} (V_{r,r}^j - V_{1,r}^j)}{\tau} \right) \geq \frac{\tau C_0}{r - 1} - \frac{\tau p}{r}$$

(70)

If $X_i \sim \exp(\mu)$ we can use the result from (15) to simplify the above expression further (since $V_{r,r}^j = X_{(i-1)r+j}$ are also exponentially distributed and thus $(V_{r,r}^j - V_{1,r}^j) \sim U_{r,r}^j, U_{r,r}^j \sim \exp((r-j)\mu)$),

$$\Pr(C_{\text{rep}} \leq mr - C_0) \leq \Pr \left( \sum_{i=1}^{p/r} \sum_{j=1}^{r-1} U_{r-r}^j \geq \frac{\tau C_0}{r - 1} - \frac{\tau p}{r} \right)$$

(71)

$$\leq \Pr \left( \sum_{i=1}^{p/r} U_{1}^i \geq \frac{\tau C_0}{r - 1} - \frac{\tau p}{r} \right)$$

(72)

$$= \Pr \left( \sum_{i=1}^{p/r} U_{1}^i \geq \frac{\tau C_0}{(r-1)^2} - \frac{\tau p}{r(r-1)} \right)$$

(73)

$$= \sum_{i=0}^{p/r-1} \frac{1}{i!} \exp(-\mu\theta)(\mu\theta)^i$$

(74)

where (72) is obtained from the fact that $\Pr(U_{1}^i \geq u) \geq \Pr(U_{r-r}^j \geq u)$ for $j = 1, \ldots, r-2$ for any $u$ since $U_{r-r} \sim \exp((r-j)\mu)$. Lastly (73) is obtained from the expression for the tail distribution of an Erlang random variable which is the sum of $p/r$ exponential random variables with rate $\mu$ and

$$\theta = \frac{\tau C_0}{(r-1)^2} - \frac{\tau p}{r(r-1)}$$

(75)
