Spectrum Prediction and Inverse Design for Plasmonic Waveguide System based on Artificial Neural Networks

Tian Zhang, Qi Liu, Jian Dai, Xu Han, Jianqiang Li, Yue Zhou and Kun Xu

Abstract—In this article, we propose a novel method using artificial neural networks (ANNs) to achieve spectrum prediction, inverse design and performance optimization for the metal-dielectric-metal waveguide coupled with cavities (MDMWCC) structure. Two relatively complex optical phenomena Fano resonance (FR) and plasmon induced transparency (PIT) effect originated from the MDMWCC structure have been selected as illustrations to verify the effectiveness of ANNs. When taking the near-field coupling and waveguide phase coupling into the designing of the MDMWCC structures, the FR and PIT effects can simultaneously emerge in transmission spectrum. Once ANNs are trained by using a small sampling of the training data generated by Monte Carlo method, it has been demonstrated that the transmission spectrum predicted by the ANNs is approximate to the simulated result with high precision. Moreover, for the expected transmission spectrum, the trained ANNs can be applied in the inverse design and performance optimization for the MDMWCC structure effectively. Compared with previous results, our proposed method can unearth the potential relationship between the structure parameters and simulated results for plasmonic devices, and it not only improves design efficiency but also has significant applications in defect detection, optical interconnects and so on.

Index Terms—Surface plasmons, Artificial neural networks, Integrated optics devices, Optical design and fabrication.

I. INTRODUCTION

Owing to the unique properties of near field enhancement effect including breaking the diffraction limit, the emergence of surface plasmon polaritons (SPPs) has attracted a great deal of research attentions [1]. Until now, diversified plasmonic structures have been proposed to excite and transmit the SPPs effectively, such as metamaterial [2, 3], dielectric and metallic grating [4, 5], metal-dielectric-metal (MDM) waveguide [6-8], graphene-based waveguide [9, 10], hybrid waveguide [11, 12] and so on. In these structures, the MDM waveguide coupled with cavities (MDMWCC) structure which can be easily integrated into the plasmonic circuits has been widely used because it is at subwavelength scale, supports long propagation length for SPPs and demands relatively simple fabrication by using electron beam lithography (EBL) and focused ion beam (FIB) etching [13, 14]. However, it has been demonstrated that the current fabrication etching precisions of the EBL and FIB technology can only reach 30 nm and 10 nm, respectively [15]. Therefore, the variation of the structure parameters of the fabricated plasmonic devices introduced by the manufacturing process with low fabrication precision not only leads to the degradation of plasmonic circuits but also affects the parameter determination, mechanism analysis and correction judgment because it’s difficult to ensure the performance of the fabricated device is as same as the designed one [15]. However, at present, lack of a simple, quick solution to predict and evaluate the electromagnetic response for different structure parameters except for the targeted simulations.

In this article, we propose a novel method using ANNs to achieve spectrum prediction, inverse design and performance optimization of the MDMWCC structure. Two relatively complex optical phenomena Fano resonance (FR) and plasmon induced transparency (PIT) effect originated from the MDMWCC structure have been selected as illustrations to verify the effectiveness of ANNs. When taking the near-field coupling and waveguide phase coupling into the designing of the MDMWCC structures, the FR and PIT effects can simultaneously emerge in transmission spectrum. Once ANNs are trained by using a small sampling of the training data generated by Monte Carlo method, it has been demonstrated that the transmission spectrum predicted by the ANNs is approximate to the simulated result with high precision. Moreover, for the expected transmission spectrum, the trained ANNs can be applied in the inverse design and performance optimization for the MDMWCC structure effectively. Compared with previous results, our proposed method can unearth the potential relationship between the structure parameters and simulated results for plasmonic devices, and it not only improves design efficiency but also has significant applications in defect detection, optical interconnects and so on.

In addition, several studies have been focused on the inverse design and performance optimization of the MDMWCC structure, which is crucial to the realization of subwavelength photonic integration. Recently, performance optimization and inverse design have been used to assist the design of photonic devices with relatively large size, such as mode (de)multiplexer [17], polarization beamsplitter [18], wavelength (de)multiplexer [19], polarization rotator [20], power splitter [21], power divider [22], reflector [23], photonic crystal [24] and so on. Generally speaking, inverse design is regarded as an optimization problem mathematically [17]. Several algorithms, such as evolution algorithm (genetic [20, 23], particle swarm [21], and ant colony [25]), topology optimization [17], adjoint method [19], convex optimization [19], nonlinear fast search method [18, 22], level set method [24] and so on, have been applied in solving this optimization problem. Among these algorithms, the genetic algorithms (searching the space step by step) is the most widely used in the inverse design due to its effectiveness, simplicity and intuitiveness [23]. However, it should not be ignored that the genetic algorithms (GAs) often converge to the local optimal solution [26]. In addition, a high computation cost will be taken when many structure parameters are solved by using GAs, and the cost grows exponentially as the number of parameters increases [26]. Thus, these limitations are evident the effective intelligence algorithms which can achieve reliable inverse design and optimization should be addressed in the design of photonic devices.
Recently, artificial neural networks (ANNs) has been applied to approximating many physics phenomenon with high degrees of precision [26-32]. For example, quantum states were represented by ANNs to solve the quantum many-body problem [27]. In addition, it had been demonstrated that the MC method which is a powerful method for studying many physics problems could be accelerated by using ANNs [28]. And the ANNs combined with MC method was used to solve the strongly correlated quantum systems [29]. More interestingly, Y. Shen et al. pointed out that ANNs could be used to simulate the light scattering of multilayer nanoparticles [26]. What’s more, it had been proved that the trained ANNs could solve the inverse design problem more quickly than numerical simulation method, such as finite difference time domain (FDTD) and finite element method (FEM) [30]. Moreover, a tandem network structure which composed of forward-modeling unit and inverse-design unit was proposed to avoid data inconsistency problem [31]. And efficient focusing lens and couplers with compact sizes were designed by using the reinforcement learning [32]. However, few studies are able to realize spectrum prediction, inverse design and performance optimization for plasmonic devices based on ANNs.

In this article, we propose a novel method using ANNs to achieve spectrum prediction, inverse design and performance optimization for the MDMWCC structures. In order to verify the effectiveness of ANNs, a relatively complex optical phenomenon Fano resonance (FR), especially the plasmon induced transparency (PIT) effect, originated from the mode interference in MDMWCC structures is taken into consideration. It is important to note that the spectrum prediction results generated by ANNs are approximate to the FDTD simulated results with high precision, and the ANN only requires a small sampling of simulation data compared with other algorithms. In addition, the ‘inverse’ ANN can be effectively applied in solving the inverse design and performance optimization problems for the MDMWCC structures. Obviously, compared with previous results, our proposed method can unearth the potential relationship between the structure parameters and simulated results, and it not only has significant applications in plasmonic devices but also improves the design efficiency of other photonics devices.

II. DEVICE DESIGN AND SIMULATION RESULTS

The physical mechanism of the FR and PIT effect both can be explained by using the bright-dark mode coupling theory, namely, they come from the coupling between the wideband bright modes and narrowband dark modes [2]. Compared with the FR, the PIT effect has a symmetric spectrum line shape around the transmission peak. As a result, the PIT effect is often regarded as a special case of the FR [2]. It has been demonstrated that the FR and PIT effect can be found in the transmission spectrum of the MDMWCC structure due to the mode coupling in cavities [6, 7]. And two different coupling methods are used to form the FR and PIT effect: one is based on the direct near-field coupling between bright modes and dark modes, the other is based on the indirect destructive interference through waveguide phase coupling [10]. Here, three MDMWCC structures which include different number of cavities are proposed to verify the effectiveness of ANNs. In all MDMWCC structures, we select the background metals which support the propagation of SPPs as silver (Ag) (the relative permittivity is described by the using Drude model with \(\varepsilon_s, \sigma_p, \gamma_p) = (3.7, 9.1 \text{ eV}, 0.018 \text{ eV}) [7])

It is important to note that the coupling distance between the rectangular cavities 4 and bus waveguide is \(l_1=480 \text{ nm}, l_2=520 \text{ nm}, l_3=560 \text{ nm} \) and \(w_1=w_2=w_3=100 \text{ nm} \), respectively. Moreover, to take the influence of near-field coupling and waveguide coupling into consideration simultaneously, two relatively complex MDMWCC structures which includes four or five cavities are proposed, and corresponding schematic diagrams are shown in Fig. 1(b) and (c), respectively. What should be paid attention to is that the structure parameters of the comb cavities 1, 2, and 3 are the same as those in Fig. 1(a). Compared with the three-resonators-coupled (THRC) system showed in Fig. 1(a), another rectangular cavity 4 is added in the up side of the cavities 1, 2, and 3 to construct a four-resonators-coupled (FORC) system in Fig. 1(b). It should be noted that the coupling distance between the rectangular cavities 4 and bus waveguide is \(L_4=l_1+g_4=580 \text{ nm} \). Therefore, the rectangular cavity 4 which is not connected to the MDM waveguide should be regarded as a dark mode due to the coupling strength between the cavity 4 and the plasmonic waveguide is negligible [7, 10]. Here, the length and width of the rectangular cavity 4 are set to be \(l_4=w_4=g_4=200 \text{ nm} \) and \(w_4=100 \text{ nm} \), respectively. What’s more, another rectangular cavity 5 is added in the FORC system to form a five-resonators-coupled (FIRC) system which includes two dark modes [Fig. 1(c)]. And the structure parameters of the rectangular cavity 5 are similar to those of the cavity 4, the coupling distance between the cavities 4 and 5 is \(g_5=20 \text{ nm} \).

When TM polarized SPPs are injected from the left port of the THRC structure, Fig. 2 reveals the FDTD calculated transmission spectrum when perfectly matched layer boundary conditions are used and the mesh sizes inside simulation area are kept as \(d_x=d_y=2 \text{ nm} \), which is enough to ensure convergence [33]. We can observe that two obvious transmission peaks which are indicated by B and D points exist in the transmission spectrum. It is noteworthy that three dips are located on the both sides of the peaks distinctively, which
indicates the double PIT effects emerge in the transmission spectrum [6]. In order to get insight into the physics mechanism of the double PIT effects, the normalized magnetic field distribution of the transmission peaks and dips indicated by B, D and A, C, E are exhibited in Fig. 2. We can find that it’s the waveguide phase coupling between the cavities that gives rise to the peaks in the double PIT effects, while the reason for the appearance of the dips is related to the resonance of the cavities [7, 10]. The coupled mode theory (CMT) theory can be used to explain the double PIT effects shown in Fig. 2(a) effectively [13-15]. It should be noted that the slight change of the waveguide distance between the cavities affects the coupling phase seriously, thus the optical characteristics of the PIT effects, especially for the central wavelength and transmittance, will be influenced by the variation of the structure parameters.

The physical mechanism of the double PIT effects in the THRC system is relatively simple, which only takes the waveguide phase coupling into consideration. By contrast, we propose two relatively complex MDMWCC structures which include the direct near-field coupling and indirect waveguide coupling simultaneously. From the schematic diagrams of the FORC [Fig. 1(b)] and FIRC [Fig. 1(c)], the rectangular cavities newly added in the structure can be regarded as dark modes because they are excited by the bright mode (comb cavities 3) indirectly rather than the bus waveguide directly [10]. The calculated transmission spectrums corresponding to the FORC and FIRC system are depicted in Fig. 3 and Fig. 4, respectively. Compared with the simulated transmission spectrum in Fig. 2, the optical characteristics around 1050 nm in Fig. 3(a) become sharp and asymmetric, indicating the appearance of the FR [33]. For the asymmetric spectrum, the transmittance of FR varies sharply from the peak to dip with a small wavelength shift of 12 nm. Obviously, the bandwidth of the FR is narrow, which is suitable for the application of switches, sensors, slow light and so on [33]. From the corresponding magnetic field distributions shown in the insets of Fig. 3, it can be observed that the plasmonic mode in the rectangular cavity 4 is excited for the transmission peak F and dip G collectively. And the occurrence of the transmission dip G is attributed to the excitation of the second order resonance in the cavity 4. It’s the destructive interference between the rectangular cavity 4 and the comb cavity 3 gives rise to the transmission peak F because the magnetic field in the comb cavity 3 is vanished by the dark mode (cavity 4). The reason for this phenomenon can be confirmed by changing the coupling distance $g_3$ between the cavity 4 and cavity 3. From Fig. 3, it can be observed that other peaks and dips are stable, while the FR becomes weak when $g_3$ increases from 20 nm to 30 nm. Moreover, when another rectangular cavity 5 is added in the up side of the cavity 4, the calculated transmission spectrums for different coupling distances $g_3=40$ nm, 60 nm are exhibited in Fig. 4. Interestingly, the double PIT effects and the double FRs appear in the transmission spectrum simultaneously, which is mentioned in the related papers rarely [13-15]. Notably, the phase of the double FRs is dramatically changed in the wavelength range from 1150 nm to 1200 nm, thus it’s very suitable for the application of slow light and switches [34]. From the magnetic field distributions F, G, H, I shown in Fig. 4, it can be observed that the physical mechanism of the double FRs is similar to the single FR shown in Fig. 3. However, due to the distinct suppression of magnetic field in cavities 4 (5), the difference is that the occurrences of the dips I and G relate to the resonance in cavity 5 and 4, respectively. And it’s the destructive interference between all the rectangular cavities and the comb cavity 3 forms the transmission peaks F and H, which is demonstrated by changing the coupling distance $g_3$. The optical characteristics of the FR become less steep when $g_3$ is increased from 40 nm to 60 nm.

Fig. 3. Simulated transmission spectrum of the FORC system. The insets are calculated magnetic field distributions for the incident light at wavelengths of 851 nm (A), 893 nm (B), 954 nm (C), 1010 nm (D), 1056 nm (E), and 1189 nm (F).

Fig. 4. Simulated transmission spectrum of the FIRC system. The insets are calculated magnetic field distributions for the incident light at wavelengths of 851 nm (A), 893 nm (B), 954 nm (C), 1010 nm (D), 1056 nm (E), 1151 nm (F), 1160 nm (G), 1178 nm (H) and 1189 nm (I).

III. OPTIMIZATION METHOD AND DISCUSSIONS

According to the above simulation results, a slight variation of the structure parameters of the waveguide and cavities can seriously affect the performance of the FR or PIT effect, such as transmittance, bandwidth, full width at half maximum (FWHM), and so on. To evaluate the variation introduced by the manufacturing process
quickly, the prediction of the transmission spectrum for arbitrary structure parameters of the MDMWCC structure are realized by using ANNs. The ANNs used here, as shown in Fig. 5(a), take the structure parameters (such as the geometrical parameters of the waveguide and cavities) as the input and effectively predict the electromagnetic responses of the MDMWCC structure (such as corresponding transmission spectrum and field distributions) [26]. It should be noted that the number of hidden layers in ANN and neurons per layer determine the performance, such as precision [35]. It is generally true that the ANNs with deep hidden layers, namely deep neural networks, are named as deep learning [36]. Despite simplified method, a high computation cost should be taken to train the deep neural networks due to the existence of a huge number of weights between the neurons in different layers.

For the THRC system shown in Fig. 1(a), the potential relationships between the structure parameters (the lengths and widths of the comb cavities 1, 2, 3 and the lengths of the gaps 1, 2 between the cavities) and the transmission spectrum are considered here. Repeated 2D FDTD simulations are employed to generate different 20,000 instances for 8 parameters considered here $(l_1, l_2, l_3, w_1, w_2, g_1, g_2)$ based on MC sampling [16]. It should be noticed that the variation ranges of the structure parameters for the MDMWCC structures are fixed to be ±20 nm. Specifically, it means that the smallest length of the resonator 1 is 460 nm, and the largest one is 500 nm. In the FDTD simulation, the length of the resonator 1 is randomly generated from 460 nm to 500 nm with the precision of 1 nm. It is noteworthy that the generation of the training and test instances including structure parameters and the discrete data points in simulated transmission spectrum based on MC method requires a significant amount of time. However, once the training process is completed, the weights and thresholds of ANNs are saved, thus the prediction process for new instance is rapid [37]. It only takes us near 30 hours to generate the training instances with NVIDIA Tesla P100 GPU accelerators [38]. When the training sets are generated, the ANN can be trained by using the 20,000 instances, while another 500 instances are left as the test sets to validate the training effect. Here, model training is done by minimizing a cost function which measures the distance between the predicted results generated by ANNs and the ground truth (2D FDTD simulations):

$$J = \frac{1}{\left(1-u/v\right)}$$

where $v$ relates to the total sum of squares $\left(\left(\left(y_{\text{true}}-y_{\text{true}}\right)^2\right)^{1/2}\right)$, and $u$ represents the residual sum of squares $\left(\left(\left(y_{\text{true}}-y_{\text{pred}}\right)^2\right)^{1/2}\right)$ [39]. The best and worst possible value of the cost function is 1.0 and arbitrary negative, respectively. In order to ensure good accuracy and reduce the training time effectively, a fully connected neural network with four or five hidden layers is constructed. Different network architecture with different depths and neurons per layer are analyzed, and the spectrum prediction architecture is finally set to have 6 layers with each layer having 8–50–200–500–100–200 neurons. Here, the network has an input layer of 8 neurons, which indicates that the number of structure parameters. The 200 neurons in the output layer match the discrete data points uniformly sampled from the transmission spectrum.

Due to the relatively simple network architecture, it takes a few minutes to train the ANNs by using multi-layer perception regressor in Scikit-learn library which is a famous machine learning toolbox for Python [40]. The training parameters, such as activation function, solver, L2 penalty, batch size, max_iter, and tolerance, are set to ‘relu’, ‘sgd’, $10^{-5}$, ‘auto’, 1000, and $10^{-5}$, respectively. For the training sets, after hundreds of iterative training steps, the score of cost function is finally stabilized at 0.9356 by using the ANNs with above-mentioned network architecture. The score of cost function for the test sets is about 0.9269, which means that no matter training or test sets, the predicted transmission spectrums generated from the ANNs are very close to the simulated results calculated by FDTD method. To illustrate the effectiveness of spectrum prediction based on ANNs, two arbitrary structure parameters are randomly selected from the training and test sets to make a comparative analysis between the predicted results and the FDTD simulated results. Fig. 5(b) shows the comparison results corresponding to the geometrical parameters $(l_1=486\,\text{nm}, l_2=555\,\text{nm}, l_3=585\,\text{nm}, w_1=93\,\text{nm}, w_2=91\,\text{nm}, w_3=115\,\text{nm}, g_1=294\,\text{nm}, g_2=320\,\text{nm})$ randomly selected from the training sets. In Fig. 5(b), the red line relates to the original transmission spectrum, while the blue dots represent the predicted transmission spectrum generated by ANNs. It can be found that the predicted results originated
from the trained ANNs match quite well with the original transmission spectrum which only contains a peak located at 890 nm. We also select an arbitrary set of structure parameters from the test sets \( l_1=466 \text{ nm}, l_2=524 \text{ nm}, l_3=589 \text{ nm}, w_1=115 \text{ nm}, w_2=93 \text{ nm}, w_3=90 \text{ nm}, g_1=280 \text{ nm}, g_2=335 \text{ nm} \), the simulated (red line) and predicted (blue dots) double PIT effects are exhibited in Fig. 5(c). It can be observed that the predicted results are very close to the simulated results even outside of the training sets. Undoubtedly, the results in Fig. 5(c) confirm that the trained ANNs not only fit to the training data, but also learn some potential relationship between the structure parameters and transmission spectrum for the THRC system, and can effectively predict correct transmission spectrum which has not been trained. Thus, the trained ANN can solve problems that it has not encountered, and generalize the mechanism of the complex physics system to some extent.

For the THRC system shown in Fig. 1(a), the inverse design and performance optimization based on ANNs are also considered here. For this purpose, we should design arbitrary transmission spectrum within reasonable limits, and the trained ANNs could predict the structure parameters that would most closely produce the artificial transmission spectrum. Compared with the ‘forward’ ANNs which is applied in the spectrum prediction (from structure parameters to electromagnetic response), an ‘inverse’ network architecture which can reproduce the structure parameters of the THRC system is constructed specially. Thus, the inputs and outputs of the ‘inverse’ network architecture are the discrete points uniformly sampled from the transmission spectrum and the structure parameters for the MDMWCC structures, respectively. After plenty of validation, the network architecture of the ‘inverse’ ANNs is set to 6 layers with each layer having 200-100-200-500-100-8 neurons. After a few iterative training steps, the ‘inverse’ ANN can predict the structure parameters which reproduce the similar transmission spectrum effectively. The effectiveness of the inverse design for the THRC system is validated quantitatively by calculating the prediction accuracy with the cost function. Finally, the values of cost function for the training sets and test sets are stabilized around 0.9169 and 0.9029, respectively. In order to provide a vivid visualization of the inverse design effect based on the ANNs, the original transmission spectrum randomly selected from the test sets is inputted in the ‘inverse’ ANNs. The red circles in Fig. 5(d) show the original structure parameters, while the blue circles relate to the predicted structure parameters generated by the ‘inverse’ ANNs. For the sake of convenience, the structure parameters are normalized to a range from 0 to 1. Interestingly, it can be observed that most of the predicted structure parameters agree with the original structure parameters accurately. Fig. 5(e) depicts the simulated transmission spectrum corresponding to the original structure parameters and predicted structure parameters \( l_1=492 \text{ nm}, l_2=529 \text{ nm}, l_3=615 \text{ nm}, w_1=84.8 \text{ nm}, w_2=106 \text{ nm}, w_3=82.8 \text{ nm}, g_1=264 \text{ nm}, g_2=342 \text{ nm} \), respectively. Compared with the original transmission spectrum, we discover that the predicted structure parameters generated by the ANNs can reproduce very similar transmission spectrum. Certainly, it no doubt provides a new way to train ANNs for the inverse design of complex MDMWCC structure.

Similar to the inverse design, the ‘inverse’ ANNs can be used in optimizing for a specific property of the MDMWCC structure, such as bandwidth, FWHM, transmittance and so on. In order to validate the performance optimization of the transmittance for an arbitrary wavelength, the transmission spectrum randomly selected from the test sets is shifted manually. The red and blue solid lines in Fig. 5(f) are the original and red-shifted transmission spectrum, respectively. It can be found that the transmittance at 900 nm increases from 0.05 to 0.68, which indicates the optimization of the transmittance for 900 nm by manually shifting the transmission spectrum. The shifted transmission spectrum is inputted in the ‘inverse’ ANNs, and the most probable structure parameters are predicted by the ANNs. The transmission spectrum is represented by the red dashed line in Fig. 5(f), which is the FDTD simulation result corresponding to the predicted structure parameters generated by the ‘inverse’ ANN \( l_1=486 \text{ nm}, l_2=550 \text{ nm}, l_3=608 \text{ nm}, w_1=89.7 \text{ nm}, w_2=96 \text{ nm}, w_3=94 \text{ nm}, g_1=290 \text{ nm}, g_2=341 \text{ nm} \). The optimization of the transmittance for an arbitrary wavelength can be achieved by using ANNs due to the similarity between the predicted transmission spectrum and red-shifted transmission spectrum. Moreover, we try to optimize the bandwidth of optical channel in the double PIT effects based on the ANNs. In order to obtain desired FWHM, the transmittance and bandwidth of the left channel in the double PIT effects is reduced appropriately, and the optimized transmission spectrum represented by the orange line in Fig. 5(g). By contrast, the red line in Fig. 5(g) represent the original transmission spectrum. Analogously, the discrete points in the optimized transmission spectrum are inputted in the ‘inverse’ ANNs, then the predicted structure parameters are \( l_1=493 \text{ nm}, l_2=554 \text{ nm}, l_3=605 \text{ nm}, w_1=93 \text{ nm}, w_2=104 \text{ nm}, w_3=93 \text{ nm}, g_1=284 \text{ nm}, g_2=341 \text{ nm} \). The FDTD simulated transmission spectrum for these predicted structure parameters generated by the ANNs is exhibited by the blue dots in Fig. 5(g). It can be discovered that the predicted transmission spectrum agrees well with the optimized transmission spectrum, which means the performance optimization of the bandwidth can be achieved by using the ANNs.

Finally, we use the ANNs to solve the spectrum prediction, inverse design and performance optimization problems for relatively complex MDMWCC structures (the FORC and FIRC systems). Since the complex MDMWCC structures have more cavities than the THCR system, we should take more structure parameters into consideration. Thus, the ‘forward’ ANNs which are applied in spectrum prediction for the FORC and FIRC system are designed as 12-50-200-500-100-200 and 15-100-200-500-200-100-200, respectively. After many iterative rounds of model training, the values of cost function gradually raise to 0.9123 (FORC) and 0.9086 (FIRC) for the test sets, which indicates that the ‘forward’ ANNs can effectively predict the transmission spectrum for complex MDMWCC structures. Fig. 6(a) and (b) show the original and predicted transmission spectra generated by the ‘forward’ ANNs for the FORC and FIRC system, respectively. We observe that the original and predicted transmission spectrums are broadly similar even though the similarity for the complicated optical characteristics (such as the FR) is imperfect. The reason for this is attributed to the insufficiency of training data and simple network architecture. Actually, we can improve the precision in spectrum prediction by adding training data and designing complex network architecture. However, it is at the cost of computational time and power, and the over-fitting problem should be noticed [41, 42]. In addition, we also validate the effectiveness of the inverse design for the FORC and FIRC system. Compared with the THRC system, the inverse design for the complex MDMWCC structures requires more sophisticated network architecture because there are more structure parameters should be...
predicted. After a series of experiments, the network architectures of the ‘inverse’ ANNs designed for the FORC and FIRC system are 200-200-500-200-50-12 and 200-200-500-500-200-100-15, respectively. And the values of the cost function are stabilized at 0.9012 (FORC) and 0.8921 (FIRC) when the ‘inverse’ ANNs are trained successfully. Fig. 6(c) and (d) exhibits the original (red) and predicted (blue) structure parameters for the FORC and FIRC system, respectively. It should be noticed that those structure parameters correspond to the transmission spectrums which are randomly selected from the test sets. In order to vividly exhibit the inverse design effect, the insets in Fig. 6(c) and (d) relate to the original (blue dots) and simulated (red line) transmission spectrums calculated for the predicted structure parameters \( l_1=490 \text{ nm}, l_2=521 \text{ nm}, l_3=581 \text{ nm}, l_4=896 \text{ nm}, w_1=101 \text{ nm}, w_2=107 \text{ nm}, w_3=115 \text{ nm}, w_4=114 \text{ nm}, g_1=267 \text{ nm}, g_2=320 \text{ nm}, g_3=18.6 \text{ nm}, s_1=1.2 \text{ nm} \) and \( l_1=466 \text{ nm}, l_2=548 \text{ nm}, l_3=581 \text{ nm}, l_4=923 \text{ nm}, l_5=922 \text{ nm}, w_1=101 \text{ nm}, w_2=112 \text{ nm}, w_3=89.3 \text{ nm}, w_4=120 \text{ nm}, w_5=94.6 \text{ nm}, g_1=259 \text{ nm}, g_2=319 \text{ nm}, g_3=15 \text{ nm}, g_4=60 \text{ nm}, s_1=8.2 \text{ nm}, s_2=12.1 \text{ nm} \), respectively. It can be found that the structure parameters generated by the ‘inverse’ ANNs are very close to the original structure parameters although the similarity is worse for the steep characteristics due to the insufficiency of training data, which indicates the inverse design for the FORC and FIRC is effective. Moreover, we also attempt to prove the feasibility of the ANNs applied in the transmittance and bandwidth optimization for the complex MDMWCC structures. It has been demonstrated that the FR originated from the FORC system has steeply optical characteristics and narrow bandwidth. So we expect to further reduce the bandwidth of the FR to achieve more pronounced slow light effect [34]. For this purpose, especially for the bandwidth of the FR, the transmission spectrum is designed optimally (blue line in Fig. 6(e)). After the spectrum optimization, the bandwidth between the peak and dip of the FR is reduced from 12 nm to 8 nm. The optimized transmission spectrum is inputted into the ‘inverse’ ANNs, and the predicted structure parameters are \( l_1=482 \text{ nm}, l_2=539 \text{ nm}, l_3=601 \text{ nm}, l_4=903 \text{ nm}, w_1=101 \text{ nm}, w_2=100 \text{ nm}, w_3=102 \text{ nm}, w_4=101 \text{ nm}, g_1=276 \text{ nm}, g_2=331 \text{ nm}, g_3=20 \text{ nm} \) and \( s_1=1 \text{ nm} \). Here, the blue dots in Fig. 6(e) represents the FDTD simulation results calculated for the predicted structure parameters. Surprisingly, we observe that the simulation results are close to the optimized transmission spectrum, which confirms the effectiveness of the bandwidth optimization by using the ANNs. What’s more, in order to optimize the transmittance for a given wavelength, the original transmission spectrum (red line in Fig. 6(f)) of the FIRC system is randomly selected from the test sets and moved to the short wavelength direction manually. The blue line in Fig. 6(f) is the blue-shifted transmission spectrum. Here, we take this blue-shifted transmission spectrum for example to prove the performance optimization of the transmittance at a specific wavelength for the FIRC system. Obviously, the transmission spectrum in the all wavelength range (700 nm-1300 nm) can be adjusted to achieve steeply optical characteristics or high transmittance by shifting the transmission spectrum. When the shifted transmission spectrum is inputted in the ‘inverse’ ANNs, the predicted structure parameters \( l_1=443 \text{ nm}, l_2=526 \text{ nm}, l_3=609 \text{ nm}, l_4=896 \text{ nm}, l_5=908 \text{ nm}, w_1=104 \text{ nm}, w_2=101 \text{ nm}, w_3=109 \text{ nm}, w_4=96 \text{ nm}, w_5=111 \text{ nm}, g_1=266 \text{ nm}, g_2=327 \text{ nm}, g_3=15 \text{ nm}, g_4=60 \text{ nm}, g_5=60 \text{ nm}, s_1=5.4 \text{ nm}, s_2=7.4 \text{ nm} \) are outputted rapidly. Apparently, it is concluded that the optimization of transmittance is feasible by utilizing ANNs because of the similarity between the blue-shifted transmission spectrum and the simulated transmission spectrum (blue dots line) calculated for the predicted structure parameters

**Fig.6** (a) The original and predicted transmission spectrums generated by the ANN for the FORC system. (b) The original and predicted transmission spectrums generated by the ANN for the FIRC system. The original (red) and predicted structure parameters (blue) corresponding to the transmission spectrums which is randomly selected from the test sets for the FORC (c) and FIRC (d) system. (e) The optimization of the transmittance for the FORC system. (f) The optimization of the bandwidth for the FIRC system.

IV. CONCLUSION

In this article, we propose a novel method using ANNs to achieve spectrum prediction, inverse design and performance optimization for the MDMWCC structures. Two optical phenomena FR and PIT effect originated from the mode coupling in MDMWCC structure have been selected as illustrations to verify the effectiveness of ANNs. It has been demonstrated that the transmission spectrums predicted by the ANNs are approximate to the simulated results with high precision when the ANNs are trained by using a small sampling of simulation data generated by the MC method. In addition, the trained ANNs can be applied in the inverse design and performance optimization for the MDMWCC structure effectively. Compared with previous results, our proposed method is more concise and effective to implement spectrum prediction, inverse design and performance optimization for plasmonic devices, and it not only improves design efficiency but also has significant applications in defect detection, optical interconnects and so on.
