Abstract
We study dynamic changes of agents’ observational power in logics of knowledge and time. We consider $\text{CTL}^*\text{K}$, the extension of $\text{CTL}^*$ with knowledge operators, and enrich it with a new operator that models a change in an agent’s way of observing the system. We extend the classic semantics of knowledge for perfect-recall agents to account for changes of observation, and we show that this new operator strictly increases the expressivity of $\text{CTL}^*\text{K}$. We reduce the model-checking problem for our logic to that for $\text{CTL}^*\text{K}$, which is known to be decidable. This provides a solution to the model-checking problem for our logic, but its complexity is not optimal. Indeed we provide a direct decision procedure with better complexity.

Keywords and phrases Epistemic logic, Temporal logic, Model checking

1 Introduction

In multi-agent systems, agents usually have only partial information about the state of the system [23]. This has led to the development of epistemic logics, often combined with temporal logics, for describing and reasoning about how distributed systems and agents’ knowledge evolve over time. Such formalisms have been applied to the modelling and analysis of, e.g., distributed protocols [13] [12], information flow and cryptographic protocols [20] [13] and knowledge-based programs [27].

In these frameworks, an agent’s view of a particular state of the system is given by an observation of that state. In all the cited settings, an agent’s observation of a given state does not change over time. In other words, these frameworks have no primitive for reasoning about agents whose observation power can change. Because this phenomenon occurs in real scenarios, for instance when a user of a system is granted access to previously hidden data, we propose here to tackle this problem. Precisely, we extend classic epistemic

temporal logics with a new unary operator, $\Delta^o$, that represents changes of observation power, and is read “the agent changes her observation power to $o'$. For instance, the formula $\Delta^{o_1}AF(\Delta^{o_2}(Kp \lor K\neg p))$ expresses that “For an agent with initial observation power $o_1$, in all possible futures there exists a point where, if the agent updates her observation power to $o_2$, she learns whether or not the proposition $p$ holds”. If in this example $o_1$ and $o_2$ represent different “security levels” and $p$ is sensitive information, then the formula expresses a possible avenue for attack. The logics and model-checking procedures that we present in this paper allow the expression and evaluation of such properties. Another motivation for studying such logics comes from the recently introduced Strategy Logic with Imperfect Information [6], an extension of Strategy Logic [19] in which agents can dynamically change observation power when changing strategies.

There is a rich history of epistemic logic in AI, including the static and temporal settings [12], the dynamic setting [28] as well as the strategic setting [23]. The most common logics of knowledge and time are $CTLK$, $LTLK$ and $CTL^*K$, which extend the classic temporal logics $CTL$, $LTL$ and $CTL^*$ with epistemic operators. These logics have been studied for two main recall abilities: no memory or perfect recall. For memoryless agents, adapting the semantics of these logics to include the observation-change operator is straightforward. Model-checking algorithms also can be easily adapted by keeping updated in the procedure each agent’s current observation, and this information is of linear size. The resulting logics thus have a PSPACE-complete model-checking problem, as $LTLK$, $CTLK$ and $CTL^*K$ do [21, 16].

The case of agents with perfect recall, which we study in this work, is more delicate. The model-checking problem for $LTLK$ and $CTL^*K$ is nonelementary decidable [25, 8, 1], with $k$-EXPTIME upper-bound for formulas with at most $k$ nested knowledge operators. The same upper-bounds are known for $CTLK$ [10]. In this work we show that, as for the memoryless semantics, the introduction of observation changes in epistemic temporal logics with perfect recall does not increase the complexity of the model-checking problem.

We extend $CTL^*K$ (which subsumes $CTLK$ and $LTLK$) with observation-change operators $\Delta^o$, starting with the single-agent case, and we solve its model-checking problem. To do so we define an alternative semantics which, unlike the natural one, is based on a bounded amount of information. Once the two semantics proven to be equivalent, designing a model-checking algorithm is almost straightforward. We then extend the logic to the multi-agent case, introducing operators $\Delta^o_a$ for each agent $a$, and we extend our approach to solve its model-checking problem. Next, we study the expressivity of our logic, showing that the observation-change operator increases expressivity. We finally provide a reduction to $CTL^*K$ which shows how to remove observation-change operators, at the cost of a blow-up in the size of the model. Our direct model-checking procedure is shown to have a better complexity than going through this reduction and using known model-checking algorithms for $CTL^*K$.

## 2 $CTL^*K\Delta$

In this section we define the logic $CTL^*K\Delta$, which extends $CTL^*K$. We first study the case where there is only one agent (and thus only one knowledge operator). We will extend to the multi-agent setting in Section 5.

### 2.1 Notation

A finite (resp. infinite) word over some alphabet $\Sigma$ is an element of $\Sigma^*$ (resp. $\Sigma^\omega$). The length of a finite word $w = w_0 \ldots w_n$ is $|w| = n + 1$, and we let last($w$) = $w_n$. Given a finite (resp. infinite) word $w$ and $0 \leq i \leq |w|$ (resp. $i \in \mathbb{N}$), we let $w_i$ be the letter at position $i$ in
$w$, $w_{\leq i}$ is the prefix of $w$ that ends at position $i$, and $w_{\geq i}$ is the suffix that starts at position $i$. We write $w \preceq w'$ if $w$ is a prefix of $w'$.

2.2 Syntax

We fix a countably infinite set of atomic propositions, $AP$. We also let $O$ be a finite set of observations, that represent possible observational powers of the agent. Note that in this work, “observation” does not refer to a punctual observation of a system’s state, but rather a way of observing the system, or “observational power” of an agent.

As for state and path formulas in $CTL^*$, we distinguish between history formulas and path formulas. We say history formulas instead of state formulas because, considering agents with perfect recall of the past, the truth of epistemic formulas depends not only on the current state, but also on the history before reaching this state.

Definition 1 (Syntax). The sets of history formulas $\varphi$ and path formulas $\psi$ are defined by the following grammar:

$$
\begin{align*}
\varphi &::= p \mid \neg \varphi \mid \varphi \land \varphi \mid A\psi \mid K\varphi \mid \Delta o \varphi \\
\psi &::= \varphi \mid \neg \psi \mid \psi \land \psi \mid X\psi \mid \psi U \psi,
\end{align*}
$$

where $p \in AP$ and $o \in O$.

We call $CTL^* K \Delta$ formulas all history formulas so defined. Operators $X$ and $U$ are the classic next and until operators of temporal logics, and $A$ is the universal path quantifier from branching-time temporal logics. $K$ is the knowledge operator from epistemic logics, and $K\varphi$ reads as “the agent knows that $\varphi$ is true”. Our new observation change operator, $\Delta o$, reads as “the agent now observes the system with observation $o$”.

As usual, we define $\top = p \lor \neg p$, $\varphi \lor \varphi' = \neg (\varphi \land \neg \varphi)$, $\varphi \rightarrow \varphi' = \neg \varphi \lor \varphi'$, as well as the temporal operators finally ($F$) and always ($G$): $F\varphi = \top U \varphi$, and $G\varphi = \neg F \neg \varphi$.

2.3 Semantics

The models of $CTL^* K \Delta$ are Kripke structures equipped with one observation relation $\sim_o$ on states for each observation $o$.

Definition 2 (Models). A Kripke structure with observations is given as a structure $M = (AP, S, T, V, \{\sim_o\}_{o \in O}, s^\iota, o^\iota)$, where

- $AP \subset AP$ is a finite subset of atomic propositions,
- $S$ is a set of states,
- $T \subseteq S \times S$ is a left-total transition relation,
- $V : S \rightarrow 2^{AP}$ is a valuation function,
- $\sim_o \subseteq S \times S$ is an equivalence relation, for each $o \in O$,
- $s^\iota \subseteq S$ is an initial state, and
- $o^\iota \in O$ is the initial observation.

A path is an infinite sequence of states $\pi = s_0 s_1 \ldots$ such that for all $i \geq 0$, $s_i T s_{i+1}$, and a history $h$ is a finite prefix of a path. For $I \subseteq S$, we write $T(I) = \{ s' \mid \exists s \in I \text{ st. } s T s' \}$ for the set of successors of states in $I$. Finally, for $o \in O$ and $s \in S$, we let $[s]_o = \{ s' \mid s \sim_o s' \}$ be the equivalence class of $s$ for relation $\sim_o$.

\footnote{i.e., for every $s \in S$ there exists $s' \in S$ such that $s T s'$. This cosmetic restriction is made to avoid having to deal with finite runs ending in deadlocks.}
Remark. We model agents’ information via indistinguishability relations \( \sim_o \), where \( s \sim_o s' \) means that \( s \) and \( s' \) are indistinguishable for an agent who has observation power \( o \). Other approaches exist. One is via observation functions (see, e.g., [25]), that map states to atomic observations, and where two states are indistinguishable for an observation function if they have the same image. Another consists in seeing states as tuples of local states, one for each agent, two global states being indistinguishable for an agent if her local state is the same in both (see, e.g., [16]). All these formalisms are essentially equivalent with respect to epistemic temporal logics [20]. In these alternative formalisms, observation change would correspond to, respectively, changing observation function, and changing local states in global states. Note that the formalism via local states, because indistinguishability is hard-coded in states of the system, is less adapted to the modelling of observation change.

Observation records. To define which histories the agent cannot distinguish, we need to keep track of how she observed the system at each point in time. To do so, we record each observation change as a pair \((o, n)\), where \( o \) is the new observation and \( n \) is the time when this change occurs.

Definition 3. An observation record is a finite word over \( \mathcal{O} \times \mathbb{N} \).

Note that observation records are meant to represent changes of observational ability, and thus they do not contain the initial observation (which is given in the model). We write \( \emptyset \) for the empty observation record.

Example 4. Consider a model \( M \) with initial observation \( o' \), a history \( h = s_0 \ldots s_4 \) and an observation record \( r = (o_1, 0) \cdot (o_2, 3) \cdot (o_3, 3) \). The agent first observes state \( s_0 \) with observation \( o' \). The observation record shows that at time 0, thus before the first transition, the agent changed for observation \( o_1 \). She then observed state \( s_0 \) again, but this time with observation \( o_1 \). Then the system goes through states \( s_1 \) and \( s_2 \) and reaches \( s_3 \), all of which she observes with observation \( o_1 \). At time 3, the agent changes to observation \( o_2 \), and thus observes state \( s_3 \) again, but this time with observation \( o_2 \), and finally she switches to observation \( o_3 \) and thus observes \( s_3 \) once more, with observation \( o_3 \). Finally, the system goes to state \( s_4 \), which the agent observes with observation \( o_3 \).

We write \( r \cdot (o, n) \) for the observation record obtained by appending \((o, n)\) to the observation record \( r \), and \( r[m] \) for the record consisting of all pairs \((o, m)\) in \( r \) such that \( m = n \). We say that an observation record \( r \) stops at \( n \) if \( r[m] \) is empty for all \( m > n \), and \( r \) stops at history \( h \) if it stops at \(|h| - 1 \). Unless otherwise specified, when we consider an observation record \( r \) together with a history \( h \), it is understood that \( r \) stops at \( h \).

Observations at time \( n \). We let \( ol(r, n) \) be the list of observations used by the agent at time \( n \). It consists of the observation that the agent has when the \( n \)-th transition is taken, plus those of observation changes that occur before the next transition. It is defined by induction on \( n \):

\[
ol(r, 0) = o' \cdot o_1 \cdot \ldots \cdot o_k, \quad \text{if } r[0] = (o_1, 0) \cdot \ldots \cdot (o_k, 0), \text{ and}
\]

\[
ol(r, n + 1) = \text{last}(ol(r, n)) \cdot o_1 \cdot \ldots \cdot o_k, \quad \text{if } r[n + 1] = (o_1, n + 1) \cdot \ldots \cdot (o_k, n + 1).
\]

Observe that \( ol(r, n) \) is never empty: if no observation change occurs at time \( n \), \( ol(r, n) \) only contains the last observation taken by the agent. If \( r \) is empty, the latter is the initial observation \( o_0 \) defined by the model.
Example 5. Consider record \( r = (o_1,0) \cdot (o_2,3) \cdot (o_3,3) \). We have that \( ol(r,0) = o' \cdot o_1 \), \( ol(r,1) = ol(r,2) = o_1 \), \( ol(r,3) = o_1 \cdot o_2 \cdot o_3 \), and \( ol(r,4) = o_3 \).

Synchronous perfect recall. The usual definition of synchronous perfect recall states that for an agent with observation \( o \), histories \( h \) and \( h' \) are indistinguishable if they have the same length and are point-wise indistinguishable, i.e., \(|h| = |h'|\) and for each \( i < |h| \), \( h_i \sim_o h_i' \).

We adapt this definition to changing observations: two histories are indistinguishable if, at each point in time, the states are indistinguishable for all observations used at that time.

Definition 6 (Dynamic synchronous perfect recall). Given an observation record \( r \), two histories \( h \) and \( h' \) are equivalent, written \( h \approx^r h' \), if

\[
|h| = |h'| \text{ and } \forall i < |h|, \forall o \in ol(r,i), \ h_i \sim_o h_i'.
\]

We now define the natural semantics of CTL*KD.

Definition 7 (Natural semantics). Fix a model \( M \). A history formula \( \varphi \) is evaluated in a history \( h \) and an observation record \( r \). A path formula \( \psi \) is interpreted on a run \( \pi \), a point in time \( n \in \mathbb{N} \) and an observation record. The semantics is defined by induction on formulas:

\[
\begin{align*}
    h,r \models p & \quad \text{if } \ p \in V(\text{last}(h)) \\
    h,r \models \neg \varphi & \quad \text{if } \ h,r \not\models \varphi \\
    h,r \models \varphi_1 \land \varphi_2 & \quad \text{if } \ h,r \models \varphi_1 \text{ and } h,r \models \varphi_2 \\
    h,r \models A\psi & \quad \text{if } \ \forall \pi \text{ s.t. } h \leq \pi, \pi,|h| - 1, r \models \psi \\
    h,r \models K\varphi & \quad \text{if } \ \forall h' \text{ s.t. } h \approx^r h', h', r \models \varphi \\
    h,r \models \Delta^o\varphi & \quad \text{if } \ h,r \cdot (o,|h| - 1) \models \varphi \\
    \pi,n,r \models \varphi & \quad \text{if } \ \pi,s.t., r\models \varphi \\
    \pi,n,r \models \neg \psi & \quad \text{if } \ \pi,n, r \not\models \psi \\
    \pi,n,r \models \psi_1 \land \psi_2 & \quad \text{if } \ \pi,n,r \models \psi_1 \text{ and } \pi,n,r \models \psi_2 \\
    \pi,n,r \models X\psi & \quad \text{if } \ \pi,(n + 1), r \models \psi \\
    \pi,n,r \models \psi_1 U\psi_2 & \quad \text{if } \exists m \geq n \text{ s.t. } \pi,m, r \models \psi_2 \text{ and } \\
    & \quad \forall k \text{ s.t. } n \leq k < m, \pi,k, r \models \psi_1
\end{align*}
\]

We say that a model \( M \) with initial state \( s^i \) satisfies a CTL*KD formula \( \varphi \), written \( M \models \varphi \), if \( s^i,0 \models \varphi \).

We first discuss a subtlety of our semantics, which is that an agent can observe the same state consecutively with several observations.

Remark. Consider the formula \( \Delta^o \varphi \) and history \( h \). By definition, \( h,r \models \Delta^o \varphi \) iff \( h,r \cdot (o',|h| - 1) \models \varphi \). Note that although the history did not change (it is still \( h \)), the observation record is extended by the observation \( o' \) at time \(|h| - 1\), with the following consequence. Suppose that \( ol(r, |h| - 1) = o \). After switching to \( o' \), the agent considers possible all histories \( h' \) such that \( h \sim_o h' \) (they were considered possible before the change of observation) and ii) \( last(h) \sim_o last(h') \) (they are still considered possible after the change of observation). Informally this means that by changing observation from \( o \) to \( o' \), the agent’s information is further refined by \( o' \), and it is as though the agent at time \(|h| - 1\) observed the system with observation \( o \cap o' \). At later times, her observation is simply \( o' \), until another change of observation occurs.

2.4 Examples of observation change

Example 8. A logic of accumulative knowledge (and resource bounds) is introduced in [15]. It studies agents that can perform successive observations to improve their knowledge of
the situation, each observation refining their current view of the world. In their framework, an observation models a yes/no question about the current situation; if the answer is ‘yes’, the agent can eliminate all possible worlds for which the answer is ‘no’, and vice versa. Formally, an observation is a binary partition of the possible states, and the agent learns in which partition is the current state. Such observations are particular cases of our models’ indistinguishability relations, and the semantics of an agent performing an observation $o$ is exactly captured by the semantics of our operator $\Delta^o$. Similarly, performing sequence of observations $o_1 \ldots o_n$ corresponds to the successive application of operators $\Delta^{o_1} \ldots \Delta^{o_n}$. As an example, [15] shows how to model a medical diagnosis in which the disease is narrowed down by performing a series of successive tests.

Our logic is incomparable with the one discussed in the previous example, in which observations have a cost, but no temporal aspect is considered. In this work we do not consider costs, but we study the evolution of knowledge through time in addition to dynamic observation change. We now illustrate with an example how both interact.

► Example 9 (Security scenario). Consider a system with two possible levels of security clearance, which define what information users have access to, and are modelled by observations $o_1$ and $o_2$. In this scenario, we want to hide a secret $p$ from the users. A desirable property is thus expressed by the formula $(\Delta^{o_1}AG\neg KP) \land (\Delta^{o_2}AG\neg KP)$, which means that a user using either $o_1$ or $o_2$ will never know that $p$ holds. Model $M$ from Figure [1] satisfies this formula.

Now consider the formula $\varphi = \Delta^{o_1}EF\Delta^{o_2}KP$, which means that if the user starts with observation $o_1$, there exists a moment where she might discover the secret by changing her observation. We show that $M$ satisfies $\varphi$ and thus that it should forbid users to change their security level. Consider the history $h = s_0s_2s_5$ in model $M$ with initial observation $o_1$. At time 0 the user knows that the system is in state $s_0$. After going to $s_2$, she does not know if the current state is $s_2$ or $s_1$, as they are indistinguishable using $o_1$. At time 2, at first the user does not know whether the system is in $s_4$ or $s_5$. Even though $s_6$ and $s_5$ are indistinguishable with $o_1$, she does not consider $s_6$ possible, as she remembers that the system was not in $s_3$ before. Now, if she changes to observation $o_2$, she sees that the system is either in state $s_5$ or $s_6$. Refining her previous knowledge that the system is either in state $s_4$ or $s_5$, she deduces that the current state is $s_5$, and that $p$ holds.

► Example 10 (Fault-Tolerant Diagnosability). Diagnosability is a property of systems in which the occurrence of a failure is always eventually detected [22]. In the setting considered in [7], a diagnosability condition is a pair $(c_1, c_2)$ of nonempty disjoint sets of states that the
system should always be able to tell apart. The system is monitored through a set of sensors, and they study the problem of finding minimal sets of sensors that ensure diagnosability. That is, find a minimal sensor configuration \( sc \) such that \( \Delta^{o_{sc}}AG(Kc_1 \lor Kc_2) \) holds, where \( o_{sc} \) is the observation corresponding to sensor configuration \( sc \).

In CTL\(^*\)\(K\Delta\) one can express and model-check a stronger notion of diagnosability that we call fault-tolerant diagnosability, where the system must remain diagnosable even after the loss of a sensor. For a given diagnosability condition \((c_1, c_2)\) and sensor configuration \( sc \), we write \( o_{sc} \) the original observation (with every sensor in \( sc \)), \( o_i \) the observation where sensor \( i \) failed, and \( p_i \) is a proposition indicating the failure of sensor \( i \). The following formula expresses that sensor configuration \( sc \) ensures fault-tolerant diagnosability of the system:

\[
\Phi_{\text{diag}} = \Delta^{o_{sc}}AG((Kc_1 \lor Kc_2) \land (p_i \rightarrow \Delta^{o_i}AG(Kc_1 \lor Kc_2))).
\]

Observe that it is possible for a system to satisfy \( \Phi_{\text{diag}} \) but not \( \Delta^{o_i}AG(Kc_1 \lor Kc_2) \) if sensor \( i \), before failing, brings some piece of information that is crucial for diagnosis.

### 2.5 Model-checking problem

We are interested in the model checking problem for CTL\(^*\)\(K\Delta\) which consists in, given a model \( M \) and a formula \( \varphi \), deciding whether \( M \models \varphi \).

**Model-checking approach.** Perfect-recall semantics refers to histories of unbounded length, but it is well known that in many situations it is possible to maintain a bounded amount of information that is sufficient to deal with perfect recall. We show that it is also the case for our logic, by generalising the classic approach to take into account observation change. Intuitively, it is enough to know the current state, the current observation and the set of states that the agent believes the system might be in. The latter is usually called information set in epistemic temporal logics and games with imperfect information. We define an alternative semantics based on information sets instead of histories and records, and we prove that this semantics is equivalent to the natural one presented in this section. Because information sets are of bounded size, it is then easy to build from this alternative semantics a model checking algorithm for CTL\(^*\)\(K\Delta\).

### 3 Alternative semantics

We define an alternative semantics for CTL\(^*\)\(K\Delta\). It is based on information sets, a classic notion in games with imperfect information [29], whose definition we now adapt to our setting.

**Definition 11 (Information sets).** Given a model \( M \), the information set \( I(h,r) \) after a history \( h \) and an observation record \( r \) is defined as follows:

\[
I(h,r) = \{ s \in S \mid \exists h', h' \approx^r h \text{ and } \text{last}(h') = s \}.
\]

This information is sufficient to evaluate epistemic formulas for one agent when we consider the S5 semantics of knowledge, i.e., when indistinguishability relations are equivalence relations as is the case here. We now describe how this information can be maintained along the evaluation of a formula. To do so, we define two update functions for information sets. One is used when the agent changes of observational power, and the other when a transition is taken in the model.
Definition 12 (Information set updates). Fix a model $M = (AP, S, T, V, \{\sim_o\}_{o \in O}, s', o')$. Functions $U_T$ and $U_\Delta$ are defined as follows, for all $I \subseteq S$, all $s, s' \in S$ and $o, o' \in O$.

\[
U_T(I, s', o) = T(I) \cap [s']_o \\
U_\Delta(I, s, o') = I \cap [s]_{o'}
\]

These updates read as follows. When the agent has observational power $o$ and information set $I$, and the model takes a transition to a state $s'$, the new information set is $U_T(I, s', o)$, which consists of all successors of her previous information set $I$ that are $\sim_o$-indistinguishable with the new state $s'$. The agent is in state $s$ with information set $I$, and she changes for observational power $o'$, her new information set is $U_\Delta(I, s, o')$, i.e., all states that she considered possible before and that she still considers possible after switching to $o'$.

We let $O(h, r)$ be the last observation taken by the agent after history $h$, according to $r$. Formally, $O(h, r) = o_n$ if $ol(r, |h| - 1) = o_1 \ldots o_n$. The following result establishes that the functions $U_\Delta$ and $U_T$ correctly update information sets. It is proved by simple application of the definitions.

Proposition 13. For every history $h \cdot s$, every observation record $r$ that stops at $h$, and every observation $o$, it holds that

\[
I(h \cdot s, r) = U_T(I(h, r), s, O(h, r)), \quad \text{and} \quad I(h \cdot r \cdot (o, |h| - 1)) = U_\Delta(I(h, r), \text{last}(h), o).
\]

Using these update functions we can now define our alternative semantics for $\text{CTL}^*\text{KA}$.

Definition 14 (Alternative semantics). Fix a model $M$. A history formula $\varphi$ is evaluated in a state $s$, an information set $I$ and an observation $o$. A path formula $\psi$ is interpreted on a run $\pi$, an information set $I$ and an observation $o$. The semantic relation $\models_I$ is defined by induction on formulas:

\[
\begin{align*}
& s, I, o \models_I p \quad \text{if} \quad p \in V(s) \\
& s, I, o \models_I \neg \varphi \quad \text{if} \quad s, I, o \not\models_I \varphi \\
& s, I, o \models_I \varphi_1 \land \varphi_2 \quad \text{if} \quad s, I, o \models_I \varphi_1 \quad \text{and} \quad s, I, o \models_I \varphi_2 \\
& s, I, o \models_I A\varphi \quad \text{if} \quad \forall \pi \text{ s.t. } \pi_0 = s, \quad \pi, I, o \models_I \varphi \\
& s, I, o \models_I K\varphi \quad \text{if} \quad \forall s' \in I, \quad s', I, o \models_I \varphi \\
& s, I, o \models_I \Diamond' \varphi \quad \text{if} \quad s, U_\Delta(I, s, o'), o' \models_I \varphi \\
& \pi, I, o \models_I \varphi \quad \text{if} \quad \pi_0, I, o \models_I \varphi \\
& \pi, I, o \models_I \neg \psi \quad \text{if} \quad \pi, I, o \not\models_I \psi \\
& \pi, I, o \models_I \psi_1 \land \psi_2 \quad \text{if} \quad \pi, I, o \models_I \psi_1 \quad \text{and} \quad \pi, I, o \models_I \psi_2 \\
& \pi, I, o \models_I X\psi \quad \text{if} \quad \pi_{\geq 1}, U_T(I, \pi_1, o), o \models_I \psi \\
& \pi, I, o \models_I \psi_1 U\psi_2 \quad \text{if} \quad \exists n \geq 0 \text{ such that } \pi_{\geq n}, U^n_T(I, \pi, o), o \models_I \psi_2 \quad \text{and} \\
& \forall m \text{ such that } 0 \leq m < n, \quad \pi_{\geq m}, U^m_T(I, \pi, o), o \models_I \psi_1,
\end{align*}
\]

where $U^n_T(I, \pi, o)$ is the iteration of the temporal update, defined inductively as follows:

\[
\begin{align*}
& U^0_T(I, \pi, o) = I, \quad \text{and} \\
& U^{n+1}_T(I, \pi, o) = U_T(U^n_T(I, \pi, o), \pi_{n+1}, o).
\end{align*}
\]

Using Proposition 13 one can prove that the natural semantics $\models$ and the information semantics $\models_I$ are equivalent (the proof is in Appendix A).

Theorem 15. For every history formula $\varphi$, model $M$, history $h$ and observation record $r$ that stops at $h$,

\[
h, r \models \varphi \quad \text{iff} \quad \text{last}(h), I(h, r), o(h, r) \models_I \varphi.
\]
4 Model checking $\text{CTL}^*\mathbf{K}\Delta$

In this section we devise a model-checking procedure based on the equivalence between the natural and alternative semantics (Theorem 15), and we prove the following result.

**Theorem 16.** Model checking $\text{CTL}^*\mathbf{K}\Delta$ is in Exptime.

**Augmented model.** Given a model $M$, we define an augmented model $\hat{M}$ in which the states are tuples $(s, I, o)$ consisting of a state $s$ of the original model, an information set $I$ and an observation $o$. According to Theorem 15, history formulas can be viewed on this model as state formulas, and a model checking procedure can be devised by merely following the definition of the alternative semantics.

Let $M = (\text{AP}, S, T, V, \{\sim_o\}_{o \in O}, s^1, o^1)$. We define the Kripke structure $\hat{M} = (S', T', V', s'^1)$, where:

- $S' = S \times 2^S \times O$,
- $(s, I, o) T' (s', I', o)$ if $s T s'$ and $I' = U_T(I, s', o)$,
- $V'(s, I, o) = V(s)$, and
- $s'' = (s', [s']_o, o')$.

We call $\hat{M}$ the augmented model, and we write $\hat{M}_o$ the Kripke structure obtained by restricting $\hat{M}$ to states of the form $(s, I, o')$ where $o' = o$. Note that the different $\hat{M}_o$ are disjoint with regards to $T'$.

**Model-checking procedure.** We now define the function $\text{Check}\text{CTL}^*\mathbf{K}\Delta$ which evaluates a history formula in a state of the augmented model $\hat{M}$:

Function $\text{Check}\text{CTL}^*\mathbf{K}\Delta (\hat{M}, (s, I, o), \Phi)$ returns true if $M, s, I, o \models \varphi$ and false otherwise, and is defined as follows: if $\Phi$ is a $\text{CTL}^*$ formula, we evaluate it using a classic model-checking procedure for $\text{CTL}^*$. Otherwise, $\Phi$ contains a subformula of the form $\varphi = K\varphi_1$ or $\varphi = \Delta'\varphi_1$ where $\varphi_1 \in \text{CTL}^*$. We evaluate $\varphi_1$ in every state of $\hat{M}$, and mark those that satisfy $\varphi_1$ with a fresh atomic proposition $p_{\varphi_1}$. Then, if $\varphi = K\varphi_1$, we mark with a fresh atomic proposition $p_{\varphi_1}$ every state $(s, I, o)$ of $\hat{M}$ such that for every $s' \in I$, $(s', I, o)$ is marked with $p_{\varphi_1}$. Else, $\varphi = \Delta'\varphi_1$ and we mark with a fresh proposition $p_{\varphi}$ every state $(s, I, o)$ such that $(s, U_{\Delta}(I, s', o'), o')$ is marked with $p_{\varphi}$. Finally, we recursively call function $\text{Check}\text{CTL}^*\mathbf{K}\Delta$ on the marked model and formula $\Phi'$ obtained by replacing $\varphi$ with $p_{\varphi}$ in $\Phi$.

To model check a formula $\varphi$ in a model $M$, we first build $\hat{M}$, and call function $\text{Check}\text{CTL}^*\mathbf{K}\Delta (\hat{M}, (s, [s]_o, o_1), \varphi)$.

**Example 17.** Let $M$ be the model depicted in Fig. 2, where $o_1$ is the blind observation ($\sim_{o_1} = S \times S$), $o_2$ is the perfect observation ($s \sim_{o_2} s'$ iff $s = s'$), $s_1$ is the initial state and the agent is initially blind (the initial observation is $o_1$). Note that we did not represent indistinguishability relations $o_1$ and $o_2$. The augmented model $\hat{M}$ is depicted in Fig. 3 where we only drew relevant states, i.e. those that are reachable from the initial state via transitions and observation changes.

Consider formula $\varphi = \Delta^{o_2}(Kq \lor \Delta^{o_1}KAq)$ which means that if the agent changes to the perfect observation, then either the agent knows that $q$ holds, or even after switching back to the blind observation she knows that in every possible next step, $q$ holds. After running the algorithm, we get the following valuation for $\hat{M}$:

- $V'(s_1, \{s_1, s_2\}, o_1) = \{q, p_{\varphi}\}$
- $V'(s_2, \{s_1, s_2\}, o_1) = \{p_{\varphi}\}$
We now extend The correctness of the algorithm follows from the following when

\[ \Delta^o \]

In the following, we let false beliefs about what agent \( o \) is that if agent \( a \) changes observation without agent \( b \) knowing it, agent \( b \) may entertain false beliefs about what agent \( a \) knows. This would not be consistent with the S5 semantics

\[ V'(s_1, \{s_1\}, o_1) = \{ q, p(Kq), p(Kq \lor \Delta^1KA\bot q), p_\varphi \} \]
\[ V'(s_2, \{s_2\}, o_1) = \{ p(\Delta^1KA\bot q), p(Kq \lor \Delta^1KA\bot q), p_\varphi \} \]
\[ V'(s_1, \{s_1\}, o_2) = \{ q, p(Kq), p(Kq \lor \Delta^1KA\bot q), p_\varphi \} \]
\[ V'(s_2, \{s_2\}, o_2) = \{ p(\Delta^1KA\bot q), p(Kq \lor \Delta^1KA\bot q), p_\varphi \} \]

Let us explain why \( p_\varphi \) is eventually marked in the initial state \( (s_1, \{s_1, s_2\}, o_1) \) of \( \hat{M} \). First look at state \( (s_1, \{s_1\}, o_2) \). Since \( q \) is in \( V(s_1) \), \( q \) is also in \( V'(s_1, \{s_1\}, o_2) \). Next, because for all \( s' \) in \( \{s_1\} \), \( q \) is in \( V'(s', \{s_1\}, o_2) \), the fresh atom \( p(Kq) \) is added in \( V'(s_1, \{s_1\}, o_2) \) and thus the fresh atom \( p(Kq \lor \Delta^1KA\bot q) \) is later also added in \( V'(s_1, \{s_1\}, o_2) \). Finally, when \( \Delta^o(Kq \lor \Delta^1KA\bot q) \) is evaluated on \( (s_1, \{s_1, s_2\}, o_1) \), since \( U_\Delta(\{s_1, s_2\}, s_1, o_2) = \{s_1\} \) and \( p(Kq \lor \Delta^1KA\bot q) \) is in \( V'(s_1, \{s_1\}, o_2) \), the fresh atom \( p_\varphi \) is eventually added in \( V'(s_1, \{s_1, s_2\}, o_1) \).

The algorithm thus returns, as expected, that \( M \models \varphi \).

![Figure 2 Model \( M \)](image)

![Figure 3 The augmented model \( \hat{M} \)](image)

**Algorithm correctness.** The correctness of the algorithm follows from the following properties:

- For each formula \( K\varphi_1 \) chosen by the algorithm,
  \[ p_\varphi \in V'(s, I, o) \iff M, s, I, o \models K\varphi_1 \]
- For each formula \( \Delta^o\varphi_1 \) chosen by the algorithm,
  \[ p_\varphi \in V'(s, I, o) \iff M, s, I, o \models \Delta^o\varphi_1 \]

**Complexity analysis.** In the following, we let \( |M| \) be the number of states in model \( M \). Model checking a \( CTL^* \) formula \( \varphi \) on a model \( M \) with state-set \( S \) can be done in time \( 2^{O(|\varphi|)}O(|S|) \) \[11, 17\]. Our procedure, for a \( CTL^*\Delta \) formula \( \varphi \) and a model \( M \), calls the \( CTL^* \) model-checking procedure for at most \( |\varphi| \) formulas of size at most \( |\varphi| \), on each state of the augmented model \( \hat{M} \). The latter is of size \( 2^{O(|M|)} \times |O| \), but each call to the \( CTL^* \) model-checking procedure is performed on a disjoint component \( \hat{M}_a \) of size \( 2^{O(|M|)} \). Our overall procedure thus runs in time \( |O| \times 2^{O(|\varphi|+|M|)} \).

5 Multi-agent setting

We now extend \( CTL^*\Delta \) to the multi-agent setting. We fix \( Ag = \{ a_1, \ldots, a_m \} \) a finite set of agents and define the logic \( CTL^*\Delta_m \). This logic contains, for each agent \( a \) and observation \( o \), an operator \( \Delta^o_a \) which reads as "agent \( a \) changes observation \( o \). We consider that these observation changes are public in the sense that all agents are aware of them. The reason is that if agent \( a \) changes observation without agent \( b \) knowing it, agent \( b \) may entertain false beliefs about what agent \( a \) knows. This would not be consistent with the S5 semantics.
5.1 Syntax and natural semantics

We first extend the syntax, with knowledge operators $K_a$ and observation change operators $\Delta^o_a$ for each agent.

- **Definition 18 (Syntax).** The sets of history formulas $\varphi$ and path formulas $\psi$ are defined by the following grammar:

$$\varphi ::= p \mid \neg \varphi \mid \varphi \land \varphi \mid A\varphi \mid K_a\varphi \mid \Delta^o_a\varphi$$

$$\psi ::= \varphi \mid \neg \psi \mid \psi \land \psi \mid X\psi \mid \psi U\psi,$$

where $p \in AP$, $a \in Ag$ and $o \in O$.

Formulas of $CTL^*K\Delta_m$ are all history formulas.

The models of $CTL^*K\Delta_m$ are as for the one-agent case, except that we assign one initial observation to each agent. In the following we shall write $o$ for a tuple $\{o_a\}_{a \in Ag}$, $o_a$ for $o_a$, and $o'[a \leftarrow o]$ for the tuple $o$ where $o_a$ is replaced with $o$. Finally, for $i \in \{1, \ldots, m\}$, $o_i$ refers to $o_{a_i}$.

- **Definition 19 (Multiagent models).** A multiagent Kripke structure with observations is given by a structure $M = (AP, S, T, V, \{\sim_o\}_{o \in O}, s^i, o')$, where

- $AP \subseteq AP$ is a finite subset of atomic propositions,
- $S$ is a set of states,
- $T \subseteq S \times S$ is a left-total transition relation between states,
- $V : S \rightarrow 2^{AP}$ is a valuation function,
- $\sim_o \subseteq S \times S$ is an equivalence relation, for each $o \in O$,
- $s^i \subseteq S$ is an initial state, and
- $o'$ is the initial observation for each agent.

We now adapt some definitions to the multi-agent setting.

**Records tuples.** We now need one observation record for each agent. We shall write $r$ for a tuple $\{r_a\}_{a \in Ag}$. Given a tuple $r = \{r_a\}_{a \in Ag}$ and $a \in Ag$ we write $r_a$ for $r_a$, and for an observation $o$ and time $n$ we let $r \cdot (o, n)_a$ be the record tuple $r$ where $r_a$ is replaced with $r_a \cdot (o, n)$. Finally, for $i \in \{1, \ldots, m\}$, $r_i$ refers to $r_{a_i}$.

**Observations at time $n$.** We let $ol_a(r, n)$ be the list of observations used by agent $a$ at time $n$:

$$ol_a(r, 0) = o^i_a \cdot o_1 \cdots o_k,$$

if $r_a[0] = (o_1, 0) \cdots (o_k, 0)$, and

$$ol_a(r, n + 1) = \text{last}(ol_a(r, n)) \cdot o_1 \cdots o_k,$$

if $r_a[n + 1] = (o_1, n + 1) \cdots (o_k, n + 1)$.

- **Definition 20 (Dynamic synchronous perfect recall).** Given a record tuple $r$, two histories $h$ and $h'$ are equivalent for agent $a$, written $h \approx^a h'$, if

$$|h| = |h'| \text{ and } \forall i < |h|, \forall o \in ol_a(r, i), h_i \sim_o h'_i.$$
As in the one-agent case, we define an alternative semantics that we prove equivalent to the
A model when a transition is taken. We now define the second update function $U^k$ (Definition 21). Let $M$ be a model, $h$ a history in $M$ and $r$ a record tuple. We only define the semantics for the following inductive cases, the remaining ones are straightforwardly adapted from the one-agent case (Definition 7).

\[ h, r \models K_a \varphi \quad \text{if} \quad \forall h' \text{ s.t. } h' \approx_{\kappa}^n h, \ h', r \models \varphi \]

\[ h, r \models \Delta^a \varphi \quad \text{if} \quad h, r \cdot (o, |h| - 1) \models \varphi \]

A model $M$ with initial state $s'$ satisfies a $\text{CTL}^* \text{K}\Delta_m$ formula $\varphi$, written $M \models \varphi$, if $s', \emptyset \models \varphi$, where $\emptyset$ is the tuple where each agent has empty observation record.

### 5.2 Alternative semantics

As in the one-agent case, we define an alternative semantics that we prove equivalent to the natural one and upon which we build our model-checking algorithm. The main difference here is that we need richer structures than information sets to represent an epistemic situation of a system with multiple agents. For instance, to evaluate formula $K_a K_b K_c \varphi$, we need to know what agent $a$ knows about agent $b$'s knowledge of agent $c$'s knowledge of the system's state.

#### $k$-trees

Fix a model $M = (\text{AP}, S, T, V, \{\sim_o\}_{o \in O}, s', o')$. Intuitively, a $k$-tree over $M$ is a structure of the form $\langle s, I_1, \ldots, I_m \rangle$, where $s \in S$ is the current state of the system, and for each $i \in \{1, \ldots, m\}$, $I_i$ is a set of $(k - 1)$-trees that represents the state of knowledge (of depth $k - 1$) of agent $a_i$. Formally, for every history $h$ and record tuple $r$ we define by induction on $k$ the $k$-tree $I^k(h, r)$ as follows:

\[
I^0(h, r) = \langle \text{last}(h), \emptyset, \ldots, \emptyset \rangle \\
I^{k+1}(h, r) = \langle \text{last}(h), I_1, \ldots, I_m \rangle,
\]

where for each $i$, $I_i = \{I^k(h', r) \mid h' \approx_{\kappa}^m r \}$. For a $k$-tree $I^k = \langle s, I_1, \ldots, I_m \rangle$, we call $s$ the root of $I^k$, and write it $r(I^k)$. We also write $I^k(a)$ for $I_i$, where $a = a_i$, and we let $T^k$ be the set of $k$-trees for $M$.

Observe that for one agent (i.e. $m = 1$), a 1-tree is an information set together with the current state.

#### Updating $k$-trees

We now generalise our update functions $U^\Delta_a$ and $U^T$ (Definition 12) to update $k$-trees. We first define, by induction on $k$, the function $U^k_T$ that updates $k$-trees when a transition is taken.

\[
U^0_T(h, o) = \langle s', \emptyset, \ldots, \emptyset \rangle \\
U^{k+1}_T(h, o) = \langle s', I_1', \ldots, I_m' \rangle,
\]

where for each $i$,

\[
I_i' = \{U^k_T(I^k, s''_i, o) \mid I^k \in I_i, s''_i \approx_{\kappa} s'_i \text{ and } r(I^k)T s''_i \}.
\]

$U^k_T$ takes the current $k$-tree $\langle s, I_1, \ldots, I_m \rangle$, the new state $s'$ and the current observation $o$ for each agent, and returns the new $k$-tree after the transition.

We now define the second update function $U^k_\Delta_a$, which is used when an agent $a_i$ changes observation for some $o'$.

\[
U^0_\Delta(h, o) = \langle s, \emptyset, \ldots, \emptyset \rangle \\
U^{k+1}_\Delta(h, o, a_i) = \langle s, I_1', \ldots, I_m' \rangle,
\]

where for each $i$,
where for each \( j \neq i \),
\[
I_j^k = \{ U^k_I(I^k, o', a_i) \mid I^k \in I_j \}, \quad \text{and}
\]
\[
I_i^k = \{ U^k_I(I^k, o', a_i) \mid I^k \in I_i \text{ and } r(I^k) \sim_{o'} s \}. 
\]

The intuition is that when agent \( a_i \) changes observation for \( o' \), in every place of the \( k \)-tree that refers to agent \( a_i \)’s knowledge, we remove possible states (and corresponding subtrees) that are no longer equivalent to the current possible state for \( a_i \)’s new observation \( o' \).

We let \( O(h, r) \) be the tuple of last observations taken by each agent after history \( h \), according to \( r \). For each \( a \in Ag \), \( O(h, r)_a = o_a \) if \( o_a(r, |h| - 1) = o_1 \ldots o_n \). The following proposition establishes that functions \( U^k_I \) and \( U^k_{\Delta} \) correctly update \( k \)-trees.

**Proposition 22.** For every history \( h \cdot s \), record tuple \( r \) that stops at \( h \), observation tuple \( o \) and integer \( k \), it holds that
\[
I^k(h \cdot s, r) = U^k_I(I^k(h, r), s, o(h, r)), \quad \text{and}
\]
\[
I^k(h, r \cdot (o, |h| - 1)_a) = U^k_{\Delta}(I^k(h, r), o, a).
\]

The proof can be found in Appendix [3].

We now define the alternative semantics for \( \text{CTL}^* \mathcal{K} \Delta_m \).

**Definition 23** (Alternative semantics). The semantics of a history formula \( \varphi \) of knowledge depth \( k \) is defined inductively on a \( k \)-tree \( I^k \) and a tuple of current observations \( o \) (note that the current state is the root of the \( k \)-tree).

\[
I^k, o \models I p \quad \text{if } p \in V(r(I^k))
\]
\[
I^k, o \models I \neg \varphi \quad \text{if } I^k, o \not\models I \varphi
\]
\[
I^k, o \models I \varphi_1 \land \varphi_2 \quad \text{if } I^k, o \models I \varphi_1 \text{ and } I^k, o \models I \varphi_2
\]
\[
I^k, o \models I A \psi \quad \text{if } \forall \pi \text{ s.t. } \pi_0 = r(I^k), \pi, I^k, o \models I \psi
\]
\[
I^k, o \models I K_a \varphi \quad \text{if } \forall I^{k-1} \in I^k(a), I^{k-1}, o \models I \varphi
\]
\[
I^k, o \models I \Delta^k \varphi \quad \text{if } U^k_{\Delta}(I^k, o', a), o[a \leftarrow o'] \models I \varphi
\]

where \( o[a \leftarrow o'] \) is \( o \) where \( o_a \) is replaced with \( o' \)

\[
\pi, I^k, o \models I \varphi \quad \text{if } I^k, o \models I \varphi
\]
\[
\pi, I^k, o \models I \neg \psi \quad \text{if } \pi, I^k, o \not\models I \psi
\]
\[
\pi, I^k, o \models I \psi_1 \land \psi_2 \quad \text{if } \pi, I^k, o \models I \psi_1 \text{ and } \pi, I^k, o \models I \psi_2
\]
\[
\pi, I^k, o \models I X \psi \quad \text{if } \pi_{\geq 1}, U^k_I(I^k, \pi_1, o), o \models I \psi
\]
\[
\pi, I^k, o \models I \psi_1 U \psi_2 \quad \text{if } \exists n \geq 0 \text{ such that } I^{k_n}(I^k, \pi, o), o \models I \psi_2 \text{ and } \forall m \text{ such that } 0 \leq m < n, I^{k_m}(I^k, \pi, o), o \models I \psi_1,
\]

where \( U^k_{\Delta} \) is the iteration of \( U^k_I \), defined similarly to the mono-agent case.

The following theorem can be proved similarly to Theorem [15] using Proposition [22] instead of Proposition [13].

**Theorem 24.** For every history formula \( \varphi \) of knowledge depth \( k \), each model \( M \), history \( h \) and tuple of records \( r \),

\[
h, r \models \varphi \iff I^k(h, r), o(h, r) \models I \varphi.
\]
6 Model checking $\text{CTL}^*\Delta_m$

Like in the mono-agent case, it is rather easy to devise from this alternative semantics a model-checking algorithm for $\text{CTL}^*\Delta_m$, the main difference being that the states of the augmented model are now $k$-trees. In this section we adapt the model-checking procedure for $\text{CTL}^*\Delta$ to the multi-agent setting, once again relying on the equivalence between the natural and alternative semantics (Theorem 24), and we prove the following result.

$\textbf{Theorem 25.}$ The model-checking problem for $\text{CTL}^*\Delta_m$ is in $k$-EXPTIME for formulas of knowledge depth at most $k$.

Augmented model. Given a model $M$, we define an augmented model $\hat{M}$ in which the states are pairs $(I^k, o)$ consisting of a $k$-tree $I^k$ and an observation for each agent, $o$.

Let $M = (\mathcal{AP}, S, T, V, \{\sim_o\}_{o \in \mathcal{O}}, s', o')$. We define the Kripke structure $\hat{M} = (S', T', V', s')$, where:

- $S' = T^k \times O^k$
- $(I^k, o) T' (I^k', o)$ if $s T s'$ and $I^k = U^k(I^k, s', o)$, where $s = r(I^k)$ and $s' = r(I^k')$
- $V'(I^k, o) = V(r(I^k))$, and
- $s' = (I^k(s'), \emptyset, o')$

We call $\hat{M}$ the augmented model, and we write $\hat{M}_o$ the Kripke structure obtained by restricting $\hat{M}$ to states of the form $(I^k, o')$ where $o' = o$. Note that the different $\hat{M}_o$ are disjoint with regards to $T'$.

Model-checking procedure. We now define the function $\text{CHECK}\text{CTL}^*\Delta_m$, which evaluates a history formula in a state of the augmented model $\hat{M}$.

Function $\text{CHECK}\text{CTL}^*\Delta_m(\hat{M}, (I^k, o_c, \Phi))$ returns true if $M, I^k, o_c \models_1 \varphi$ and false otherwise, and is defined as follows: if $\Phi$ is a $\text{CTL}^*$ formula, we evaluate it using a classic model-checking procedure for $\text{CTL}^*$. Otherwise, $\Phi$ contains a subformula of the form $\varphi = K_a \varphi'$ or $\varphi = \Delta a \varphi'$ where $\varphi' \in \text{CTL}^*$. We evaluate $\varphi'$ in every state of $\hat{M}$, and mark those that satisfy $\varphi'$ with a fresh atomic proposition $p_{\varphi'}$. Then, if $\varphi = K_a \varphi'$, we mark with a fresh atomic proposition $p_a$ every state $(I^k, o)$ of $\hat{M}$ such that for every $I^{k-1} \in I^k(a)$, $(I^{k-1}, o)$ is marked with $p_{\varphi'}$. Else, $\varphi = \Delta a \varphi'$ and we mark with a fresh proposition $p_{\varphi'}$ every state $(I^k, o)$ such that $(U^k(I^k, o', a), o[a \leftarrow o'])$ is marked with $p_{\varphi'}$. Finally, we recursively call function $\text{CHECK}\text{CTL}^*\Delta_m$ on the marked model and formula $\Phi'$ obtained by replacing $\varphi$ with $p_{\varphi'}$ in $\Phi$.

To model check a formula $\varphi$ in a model $M$, we build $\hat{M}$ and call $\text{CHECK}\text{CTL}^*\Delta_m(\hat{M}, (I^k(s'), \emptyset, o'), \varphi)$.

Algorithm correctness. The correctness of the algorithm follows from the following properties:

- For each formula $K_a \varphi$ chosen by the algorithm, $p_{\varphi} \in V'(I^k, o)$ iff $M, I^k, o \models_1 K_a \varphi$
- For each formula $\Delta a \varphi$ chosen by the algorithm, $p_{\varphi} \in V'(I^k, o)$ iff $M, I^k, o \models_1 \Delta a \varphi$

Complexity analysis. The number of different $k$-trees for $m$ agents and a model with $l$ states is no greater than $C_k = \exp(m \times l, k)/m$, where $\exp(a, b)$ is defined as $\exp(a, 0) = a$ and $\exp(a, b + 1) = 2^{\exp(a, b)}$ [25]. The size of the augmented model $\hat{M}$ is thus bounded by $\exp(m \times l, k)/m \times |O|^{|A|}$, and it can be computed in time $\exp(O(m \times l, k) \times |O|^{|A|})$. Model checking a $\text{CTL}^*$ formula $\varphi$ on a model $M$ with state-set $S$ can be done in time $2^{O(|S|)} \times O(|S|)$ [11] [17]. For a $\text{CTL}^*\Delta_m$ formula $\varphi$ of knowledge depth at most $k$ and
a model $M$ with $l$ states, our procedure calls the \textit{CTL}^* model-checking procedure for at most $|\varphi|$ formulas of size at most $|\varphi|$, on each state of the augmented model $M$ which has size $\exp(m \times l, k)/m \times |O|^m$. Each recursive call (for each subformula and state of $M$) is performed on a disjoint component $\tilde{M}_o$ of size at most $\exp(m \times l, k)/m$, and thus takes time $2^{O(|\varphi|)} \times \exp(m \times l, k)/m$, and there are at most $|\varphi| \times \exp(m \times l, k)/m \times |O|^m$ of them. Our overall procedure thus runs in time $|O|^m \times 2^{O(|\varphi|)} \times \exp(O(m \times l, k)$, i.e. $|O|^{|Ag|} \times 2^{O(|\varphi|)} \times \exp(O(|Am| \times |M|), k)$.

7 Expressivity

In this section we prove that the observation-change operator adds expressiveness to epistemic temporal logics. Formally, we compare the expressiveness of \textit{CTL}^* \textit{K}\textit{K}\textit{D}_m with that of \textit{CTL}^* \textit{K}\textit{m} \textit{K}\textit{m} \textit{K}\textit{m}, which is the syntactic fragment of \textit{CTL}^* \textit{K}\textit{D}_m obtained by removing the observation-change operator. Our semantics for \textit{CTL}^* \textit{K}\textit{D}_m generalises that of \textit{CTL}^* \textit{K}\textit{m}, with which it coincides on \textit{CTL}^* \textit{K}\textit{m} formulas. Note that our multi-agent models (Definition 19) are more general than usual models for \textit{CTL}^* \textit{K}\textit{m}, as they may contain observation relations that are not initially assigned to any agent, but such relations are mute in the evaluation of \textit{CTL}^* \textit{K}\textit{m} formulas.

For two logics $\mathcal{L}$ and $\mathcal{L}'$ over the same class of models, we say that $\mathcal{L}'$ is at least as expressive as $\mathcal{L}$, written $\mathcal{L} \preceq \mathcal{L}'$, if for every formula $\varphi \in \mathcal{L}$ there exists a formula $\varphi' \in \mathcal{L}'$ such that $\varphi \equiv \varphi'$. \textit{L'} is strictly more expressive than $\mathcal{L}$, written $\mathcal{L} \prec \mathcal{L}'$, if $\mathcal{L} \preceq \mathcal{L}'$ and $\mathcal{L}' \not\preceq \mathcal{L}$. Finally, $\mathcal{L}$ and $\mathcal{L}'$ are equiexpressive, written $\mathcal{L} \equiv \mathcal{L}'$, if $\mathcal{L} \preceq \mathcal{L}'$ and $\mathcal{L}' \preceq \mathcal{L}$.

- Proposition 26. For all $m \geq 1$, \textit{CTL}^* \textit{K}\textit{m} \preceq \textit{CTL}^* \textit{K}\textit{D}_m.

\textbf{Proof.} This simply follows from the fact that \textit{CTL}^* \textit{K}\textit{D}_m extends \textit{CTL}^* \textit{K}\textit{m}. $\blacksquare$

We first point out that when there is only one observation, i.e., $|O| = 1$, the observation-change operator has no effect, and thus \textit{CTL}^* \textit{K}\textit{D}_m is no more expressive than \textit{CTL}^* \textit{K}\textit{m}.

- Proposition 27. For $|O| = 1$, \textit{CTL}^* \textit{K}\textit{m} \equiv \textit{CTL}^* \textit{K}\textit{D}_m.

\textbf{Proof.} We show that for $|O| = 1$, \textit{CTL}^* \textit{K}\textit{D}_m \preceq \textit{CTL}^* \textit{K}\textit{m}$, which together with Proposition 26 provides the result. Observe that when $|O| = 1$, observation change has no effect, and in fact observation records can be omitted in the natural semantics. For every \textit{CTL}^* \textit{K}\textit{D}_m formula $\varphi$, define the \textit{CTL}^* \textit{K}\textit{m} formula $\varphi'$ by removing all observation-change operators $\Delta_a^n$ from $\varphi$. It is easy to see that $\varphi \equiv \varphi'$.

We now show that as soon as we have at least two observations, the observation-change operator adds expressiveness. We first consider the mono-agent case.

- Proposition 28. If $|O| > 1$ then \textit{CTL}^* \textit{K}\textit{D} \not\preceq \textit{CTL}^* \textit{K}.

\textbf{Proof.} Assume that $O$ contains $o_1$ and $o_2$. Consider the model $M$ from Example 9 (Figure 1), and define the model $M'$ which is the same as $M$ except that $s_4$ and $s_5$ are indistinguishable for both $o_1$ and $o_2$, while in $M$ they are only indistinguishable for $o_1$ (see Figure 1). In both models, agent $a$ is initially assigned observation $o_1$. We exhibit a formula of \textit{CTL}^* \textit{K}\textit{D} that can distinguish between $M$ and $M'$, and thus that no formula of \textit{CTL}^* \textit{K} can, which shows that \textit{CTL}^* \textit{K}\textit{D} \not\preceq \textit{CTL}^* \textit{K}.

Consider formula $\varphi = EF\Delta_a^nK_ap$. With a reasoning similar to that detailed in Example 9 we can show that $M \models \varphi$. We now show that $M' \not\models \varphi$: The only history in which agent $a$ may get to know that $p$ holds is the path $s_0s_2s_5$, since in other histories $p$ does not hold. After observing this path with observation $o_1$, agent $a$ considers that both $s_4$ and $s_5$ are
possible. She still does after switching to observation \( o_2 \), as \( s_4 \) and \( s_5 \) are \( o_2 \)-indistinguishable.

Now to see that no formula of \( \text{CTL}^*K \) can distinguish between these two models, it is enough to see that in both models the only agent \( a \) is assigned observation \( o_1 \), and thus on these models no operator of \( \text{CTL}^*K \) can refer to observation \( o_2 \), which is the only difference between \( M \) and \( M' \).

This proof for the mono-agent case relies on the fact that \( \text{CTL}^*K \Delta \) can refer to observations that are not initially assigned to any agent, and thus cannot be referred to within \( \text{CTL}^*K \). The same proof can be easily adapted to the multi-agent case, by considering the same models \( M \) and \( M' \) and assigning the same initial observation \( o_1 \) to all agents. We show that in fact, when we have at least two agents, \( \text{CTL}^*K \Delta m \) is strictly more expressive than \( \text{CTL}^*K m \) even when we only consider models in which all observations are initially assigned to some agent.

\[\blacktriangleright\text{Proposition 29.}\] If \( |O| > 1 \) and \( m \geq 2 \), it holds that \( \text{CTL}^*K \Delta m \nless \text{CTL}^*K m \) even when restricted to models where all observations are initially assigned.

\[\text{Proof.}\] Assume that \( O \) contains \( o_1 \) and \( o_2 \). We consider the case of two agents \( a \) and \( b \) \((m = 2)\); the proof can easily be generalised to more agents. Consider again the models \( M \) and \( M' \) used in the proof of Proposition 28. This time, in both models, agent \( a \) is initially assigned observation \( o_1 \) and agent \( b \) observation \( o_2 \). For the same reasons as before, formula \( \varphi = EF\Delta o_2 K_a p \) distinguishes between \( M \) and \( M' \).

Now to see that no formula of \( \text{CTL}^*K_m \) can distinguish these two models, recall that the only difference between \( M \) and \( M' \) concerns observation \( o_2 \), and that agents \( a \) and \( b \) are bound to observations \( o_1 \) and \( o_2 \) respectively. Since in \( \text{CTL}^*K_m \) agents cannot change observation, the modification of \( o_2 \) between \( M \) and \( M' \) can only affect the knowledge of agent \( b \), by letting her consider in \( M' \) that history \( s_0 s_1 s_4 \) is indistinguishable to history \( s_0 s_2 s_5 \). However this is not the case: indeed, \( s_4 \) and \( s_5 \) are not \( o_2 \)-indistinguishable, and because we consider perfect recall, \( s_0 s_1 s_4 \) and \( s_0 s_2 s_5 \) are not \( o_2 \)-indistinguishable neither, even though \( s_4 \) and \( s_5 \) are.

More formally, define the perfect-recall unfolding of a model \( M \) as the infinite tree consisting of all possible histories starting in the initial state, in which two nodes \( h \) and \( h' \) are related for \( o_i \) if \( |h| = |h'| \) and for all \( i < |h|, h_i \sim_o h'_i \). By its semantics it is clear that \( \text{CTL}^*K_m \) is invariant under perfect-recall unfolding. Now it suffices to notice that the
perfect-recall unfoldings of \( M \) and \( M' \) are the same, and thus cannot be distinguished by any \( \text{CTL}^* K \) formula.

\[ \blacksquare \]

**Remark.** Unlike \( \text{CTL}^* K \), \( \text{CTL}^* K \Delta \) is not invariant under the perfect-recall unfoldings considered in the proof of Proposition 29. The reason is that in these unfoldings, observation relations on histories are defined for fixed observations, and therefore cannot account for observation changes induced by operators \( \Delta^o \).

Putting together Propositions 26, 28 and 29, we obtain:

**Theorem 30.** If \( |O| > 1 \) then \( \text{CTL}^* K < \text{CTL}^* K \Delta \).

### 8 Eliminating observation change

In this section we show how to reduce the model-checking problem for \( \text{CTL}^* K \Delta \) to that of \( \text{CTL}^* K \). The approach can be easily generalised to the multi-agent case.

Fix an instance \((M, \Phi)\) of the model-checking problem for \( \text{CTL}^* K \Delta \), where \( M \) is a (non-agent) model and \( \Phi \) is a \( \text{CTL}^* K \Delta \) formula. We build an equivalent instance \((M', \Phi')\) of the model-checking problem for \( \text{CTL}^* K \); in particular, \( M' \) contains a single observation relation, and \( \Phi' \) does not use the observation-change operator \( \Delta^o \).

Assume that \( M = (AP, S, T, V, \{\sim_o \}_{o \in O}, s', o') \). We first define the model \( M' \). For each observation symbol \( o \in O \) we create a copy \( M_o \) of the original model \( M \). Moving to copy \( M_o \) will simulate switching to observation \( o \). To make this possible, we need to introduce transitions between each state \( s_o \) of a copy \( M_o \) to state \( s_{o'} \) of copy \( M_{o'} \), for all \( o \neq o' \).

Let \( M' = (AP \cup \{p_o | o \in O\}, S', T', V', \sim', s') \), where

- for each \( o \in O \), \( p_o \) is a fresh atomic proposition,
- \( S' = \bigcup_{o \in O} \{s_o | s \in S\} \),
- \( T' = \{(s_o, s_{o'}) | o \in O \text{ and } (s, s') \in T \} \)
  \[ \cup \{(s_o, s_{o'}) | s \in S, o, o' \in O \text{ and } o \neq o' \} \]
- \( V'(s_o) = V(s) \cup \{p_o\} \), for all \( s \in S \) and \( o \in O \),
- \( \sim' = \bigcup_{o \in O} \{(s_o, s_{o'}) | s \sim_o s' \} \), and
- \( s' = s_{s'} \).

We now define formula \( \Phi' \). The transformation \( \text{tr}^o \) is parameterised with an observation \( o \in O \) and is defined by induction on \( \Phi \) as follows:

\[
\text{tr}^o(\Delta^o \varphi) = \begin{cases} 
\text{tr}^{o'}(\varphi) & \text{if } o = o' \\
AX(p_{o'} \rightarrow \text{tr}^{o'}(\varphi)) & \text{otherwise}
\end{cases}
\]

\[
\text{tr}^o(A\psi) = A(Gp_o \rightarrow \text{tr}^o(\psi))
\]

All other cases simply distribute over operators. We finally let \( \Phi' = \text{tr}^{o'}(\Phi) \).

Using the alternative semantics it is rather easy to see that the following holds:

**Lemma 31.** \( M \models \Phi \text{ if, and only if, } M' \models \Phi' \).

This establishes the correctness of the reduction, and because we know how to model-check \( \text{CTL}^* K \), provides a model-checking procedure for \( \text{CTL}^* K \Delta \). However this algorithm does not provide optimal complexity. Indeed, the model \( M' \) is of size \( |M| \times |O| \), and the best known model-checking algorithm for \( \text{CTL}^* K \) runs in time exponential in the size of the model and the size of the formula [3]. Going through this reduction thus yields a procedure that is exponential in the number of observations. Our direct model-checking procedure, which
generalises techniques used for the classic case of static observations, provides instead a
decision procedure which is only polynomial in the number of observations (Theorem 16).

The reduction described above can be easily generalised to the multi-agent case, by creating
one copy $M_o$ of the original model $M$ for each possible assignment $o$ of observations to agents.
We thus get a model $M'$ of size $|M| \times |O|^{|Ag|}$, and since the best known model-checking
procedure for $\text{CTL}^*K_m$ is $k$-exponential in the size of the model [8], this reduction provides a
procedure which is $k$-exponential in the number of observations and $k + 1$-exponential in
the number of agents. The direct approach provides an algorithm that is only polynomial
in the number of observations, exponential in the number of agents, and whose combined
complexity is $k$-exponential time (Theorem 25).

9 Conclusion and future work

Epistemic temporal logics play a central role in MAS as they permit to describe in an elegant
way the knowledge of agents along the evolution of a system. Previous works in this field have
treated agents’ observation power as a static feature. However, in many real life scenarios,
agents’ observation power may change along computations.

In this work we introduced $\text{CTL}^*K_\Delta$, a logic that can express such dynamic changes of
observation power, and we demonstrated how this can be used to express relevant properties
in practical scenarios. We studied the model checking of $\text{CTL}^*K_\Delta$ over both mono- and
multi-agent systems and proved that in both cases, the ability to express observation changes
comes at no complexity cost, but strictly increases expressivity. We also showed how to reduce
the model-checking problem for our logic to that of $\text{CTL}^*K$, removing the observation-change
operator. This provides a model-checking procedure for $\text{CTL}^*K_\Delta$, but given the complexity
of the best-known model-checking algorithm for $\text{CTL}^*K$, this procedure is not as efficient as
the direct algorithm we provide.

As future work, we plan to build upon the techniques developed here to investigate
epistemic extensions of strategic logics with imperfect information. Several such logics have
been defined and studied recently [2, 5, 6, 3, 4], and [6] in particular already presents the
feature of dynamic observation change via change of strategy. We believe that the present
work will help to establish new results on the model checking of such logics.

A Proof of Theorem \ref{log}

Theorem \ref{log} directly follows from the following lemma:

Lemma 32. For every history formula \( \varphi \), model \( M \), history \( h \) and observation record \( r \) that stops at \( h \),

\[ h, r \models \varphi \iff \text{last}(h), I(h, r), O(h, r) \models_1 \varphi \]

and for every path formula \( \psi \), every path \( \pi \), point in time \( n \in \mathbb{N} \) and observation record \( r \) that stops at \( n \),

\[ \pi, n, r \models \psi \iff \pi_{\leq n}, I(\pi_{\leq n}, r), O(\pi_{\leq n}, r) \models_1 \psi. \]

Proof. We prove the result by mutual induction on \( \varphi \) and \( \psi \). Let \( M \) be a model, \( h \) a history and \( r \) an observation record that stops at \( h \).

\( \varphi = p \): We have \( h, r \models p \iff p \in V(\text{last}(h)) \iff \text{last}(h), I(h, r), O(h, r) \models_1 p \), by applying the definitions.

\( \varphi = \neg \varphi' \) and \( \varphi = \varphi_1 \land \varphi_2 \): Simple application of the induction hypothesis.

\( \varphi = A \psi \): We start with the left-to-right implication. Assume that \( h, r \models A \psi \). We need to prove that for all \( \pi \) such that \( \pi_0 = \text{last}(h) \), \( \pi, I(h, r), O(h, r) \models_1 \psi \). If \( \pi_0 = \text{last}(h) \), we have \( h \preceq h \cdot \pi_0 \) since \( h, r \models A \psi \) we thus get that \( h \cdot \pi_0, |h| - 1, r \models \psi \). By induction hypothesis we have \( (h \cdot \pi_0)_{> |h| - 1}, I((h \cdot \pi_0)_{> |h| - 1}, r), O((h \cdot \pi_0)_{> |h| - 1}, r) \models_1 \psi \), that is to say \( \pi, I(h, r), O(h, r) \models_1 \psi \), as \( \pi_0 = \text{last}(h) \).

For the other direction, assume that \( \text{last}(h), I(h, r), O(h, r) \models_1 A \psi \), i.e., for all \( \pi \) such that \( \pi_0 = \text{last}(h) \), it holds that \( \pi, I(h, r), O(h, r) \models_1 \psi \). Let \( \pi \) be such that \( h \not\preceq \pi \); we prove that \( \pi, |h| - 1, r \models \psi \). Because \( h \not\preceq \pi \), we have that \( (\pi_{\geq |h| - 1})_0 \not= \text{last}(h) \). By assumption, it follows that \( \pi_{\leq |h| - 1}, I(h, r), O(h, r) \models_1 \psi \), that is \( \pi_{\leq |h| - 1}, I(\pi_{\leq |h| - 1}, r), O(\pi_{\leq |h| - 1}, r) \models_1 \psi \). Then by induction hypothesis we finally get that \( \pi, |h| - 1, r \models \psi \).

\( \varphi = K \varphi' \): For the first direction, assume that \( h, r \models K \varphi' \), i.e., for all \( h' \preceq^* h \), we have \( h', r \models \varphi \). We prove that \( \text{last}(h), I(h, r), O(h, r) \models_1 K \varphi' \), i.e., for all \( s', I(h, r), O(h, r) \models_1 \varphi' \). Let \( s' \in I(h, r) \). By definition of the information set, there exists \( h' \preceq^* h \) such that \( h' \preceq^* h \) and \( \text{last}(h') = s' \). By assumption, \( h', r \models \varphi \), and by induction hypothesis, \( \text{last}(h'), I(h', r), O(h', r) \models_1 \varphi \). Because \( h' \preceq^* h \), \( I(h', r) = I(h, r) \) and \( O(h, r) = O(h', r) \). It follows that \( s', I(h, r), O(h, r) \models_1 \varphi \).

For the other direction, we assume that for all \( s' \in I(h, r), s', I(h, r), O(h, r) \models_1 \varphi' \), and we prove that \( h, r \models K \varphi' \), i.e., for all \( h' \preceq^* h \), \( h', r \models \varphi' \). Let \( h' \) be such that \( h' \preceq^* h \). By definition, \( \text{last}(h') \in I(h, r) \). By assumption, \( \text{last}(h'), I(h, r), O(h, r) \models_1 \varphi' \). Because \( h' \preceq^* h \), \( I(h', r) = I(h, r) \) and \( O(h, r) = O(h', r) \), and we get that \( \text{last}(h'), I(h', r), O(h', r) \models_1 \varphi' \). By induction hypothesis, \( h', r \models \varphi' \).

\( \varphi = \Delta^0 \varphi' \): By definition, \( h, r \models \Delta^0 \varphi \iff h, r, (o, |h| - 1) \models \varphi \). By induction hypothesis, \( h, r, (o, |h| - 1) \models \varphi \iff \text{last}(h), I(h, r, (o, |h| - 1)), O(h, r, (o, |h| - 1)) \models_1 \varphi \). By Proposition \ref{approx}, because \( r \) stops at \( |h| - 1 \), this is equivalent to \( \text{last}(h), U_{\Delta}(I(h, r)), o \models_1 \varphi \), which by definition is equivalent to \( \text{last}(h), I(h, r), O(h, r) \models_1 \Delta^0 \varphi \).

Let \( \pi \) be a path, \( n \) a natural number and \( r \) an observation record that stops at \( n \).

\( \psi = \varphi \): By definition, \( \pi, n, r \models \varphi \iff \pi_{\leq n}, r \models \varphi \). By induction hypothesis, the latter is equivalent to \( \text{last}(\pi_{\leq n}), I(\pi_{\leq n}, r), O(\pi_{\leq n}, r) \models_1 \varphi \). Because \( (\pi_{\geq n})_0 = \text{last}(\pi_{\leq n}) \), by definition this is also equivalent to \( \pi_{\geq n}, I(\pi_{\leq n}, r), O(\pi_{\leq n}, r) \models_1 \varphi \), which concludes.
\[ \psi = -\psi' \text{ and } \psi = \psi_1 \land \psi_2: \] By application of the induction hypothesis.

\[ \psi = X\psi': \] By definition, \( \pi, n, r \models X\psi' \iff \pi, n + 1, r \models \psi' \). By induction hypothesis we get

\[ \pi, n, r \models X\psi' \iff \pi_{\geq n+1}, I(\pi_{\leq n+1}, r), O(\pi_{\leq n+1}, r) \models I \psi'. \] (1)

Because \( r \) stops at \( n \), we have that \( O(\pi_{\leq n+1}, r) = O(\pi_{\leq n}, r) \). Using Proposition 13, we also have that \( I(\pi_{\leq n+1}, r) = U r(I(\pi_{\leq n}, r), \pi_{n+1}, O(\pi_{\leq n}, r)) \). Thus becomes

\[ \pi, n, r \models X\psi' \iff \pi_{\geq n+1}, U r(I(\pi_{\leq n}, r), \pi_{n+1}, O(\pi_{\leq n}, r)), O(\pi_{\leq n}, r) \models I \psi'. \] (2)

Because \( \pi_{n+1} = (\pi_{\geq n})_1 \), by definition we finally get that

\[ \pi, n, r \models X\psi' \iff \pi_{\geq n}, I(\pi_{\leq n}, r), O(\pi_{\leq n}, r) \models I \psi'. \]

\[ \psi = \psi_1 U \psi_2: \] According to the definitions, it suffices to prove that for all path \( k \geq 0 \) and \( \psi \in \{ \psi_1, \psi_2 \} \), \( \pi, n + k, r \models \psi \iff \pi_{\geq (n+k)} U r(I(\pi_{\leq n}, r), \pi_{\geq n}, O(\pi_{\leq n}, r)) \models I \psi. \)

This can be proven by induction on \( k \), using for the inductive step a reasoning similar to that for \( \psi = X\psi' \).

\[ \blacksquare \]

**B Proof of Proposition 22**

1. **Proposition 22.** For every history \( h \cdot s \), record tuple \( r \) that stops at \( h \), observation tuple \( o \) and integer \( k \), it holds that

\[
I^k(h \cdot s, r) = U^k_r(I^k(h, r), s, o(h, r)), \text{ and } I^k(h, r \cdot (a, |h| - 1)_a) = U^k_\Delta(I^k(h, r), o, a).
\]

**Proof.** The proof is by induction on \( k \).

- **\( k = 0 \):** the result is immediate from the definitions.

- **\( k + 1 \):** We start with the first part of the proposition.

By definition \( I^{k+1}(h \cdot s, r) = \langle s, I_1, \ldots, I_m \rangle \), where for each \( i \),

\[ I_i = \{ I^k(h', s', r) \mid h' \cdot s' \approx r_{a_i} h \cdot s \}. \]

On the other hand, letting \( I^{k+1}(h, r) = \langle \text{last}(h), I'_1, \ldots, I'_m \rangle \) and \( o = o(h, r) \), we have by definition that \( U^k_r(I^{k+1}(h, r), s, o) = \langle s, I'_1, \ldots, I'_m \rangle \), where for each \( i \),

\[ I'_i = \{ U^k_r(I^k, s', o) \mid I^k \in I'_1, s' \sim_{o_i} s \text{ and } r(I^k)T s' \}. \]

It thus suffices to show that for each \( i \), \( I_i = I'_i \). Observe that because \( r \) stops at \( h \), \( h' \cdot s' \approx r_{a_i} h \cdot s \) iff \( h' \approx r_{a_i} h \) and \( s' \sim_{o_i} s \). We thus have that

\[ I_i = \{ I^k(h', s', r) \mid h' \approx r_{a_i} h, s' \sim_{o_i} s \text{ and } \text{last}(h')T s' \}. \]

By induction hypothesis, this becomes

\[ I_i = \{ U^k_r(I^k(h', r), s', o(h', r)) \mid h' \approx r_{a_i} h, s' \sim_{o_i} s \text{ and } \text{last}(h')T s' \}. \]

For each \( h' \approx r_{a_i} h \), we have that \( o(h', r) = o(h, r) = o \).

It remains to observe that by definition, for each \( i \), \( I'_i = \{ I^k(h', r) \mid h' \approx r_{a_i} h \} \), and we get that \( I_i = I'_i \), which concludes the first part of the proposition.
We now prove the second part of the proposition, assuming that $a = a_j$.

By definition $I^{k+1}(h, r \cdot (o, |h| - 1)_{a_i}) = \langle \text{last}(h), I_1, \ldots, I_m \rangle$, where for each $i$,

$$I_i = \{ I^k(h', r \cdot (o, |h| - 1)_{a_i}) \mid h' \approx_{r^{(o,|h|-1)_{a_j}}} h \}.$$

On the other hand, letting $I^{k+1}(h, r) = \langle \text{last}(h), I'_1, \ldots, I'_m \rangle$, we have by definition that

$$U^k_{\Delta}(I^{k+1}(h, r), o, a_j) = \langle \text{last}(h), I'_1, \ldots, I'_m \rangle,$$

where for each $i, I_i = \{ I^k(h', r \cdot (o, |h| - 1)_{a_i}) \mid I^k \in I'_i \}$, and

$$I''_i = \{ U^k_{\Delta}(I^k, o, a_j) \mid I^k \in I'_i \}.$$

We now show that for all $i$, $I_i = I''_i$.

First, by induction hypothesis, for each $i$ we have

$$I_i = \{ U^k_{\Delta}(I^k(h', r), o, a_j) \mid h' \approx_{r^{(o,|h|-1)_{a_i}}} h \}.$$

Also, by definition, for each $i$, we have $I'_i = \{ I^k(h', r) \mid h' \approx_{o_i} h \}$.

Next, for $i \neq j$ we have that $h' \approx_{r^{(o,|h|-1)_{a_j}}} h$ iff $h' \approx_{o_i} h$, and by definition of the perfect-recall relation, for $i = j$, it holds that $h' \approx_{r^{(o,|h|-1)_{a_j}}} h$ iff $h' \approx_{o_i} h$ and last($h'$) $\sim_o$ last($h$).

It is then easy to see that for all $i$, $I_i = I''_i$, which concludes.
