Abstract. Spatial concurrent constraint programming (SCCP) is an algebraic model of spatial modalities in constrained-based process calculi; it can be used to reason about spatial information distributed among the agents of a system. This work presents an executable rewriting logic semantics of SCCP with extrusion (i.e., process mobility) that uses rewriting modulo SMT, a novel technique that combines the power of term rewriting, matching algorithms, and SMT-solving. In this setting, constraints are encoded as formulas in a theory with a satisfaction relation decided by an SMT solver, while the topology of the spatial hierarchy is encoded as part of the term structure of symbolic states. By being executable, the rewriting logic specification offers support for the inherent symbolic and challenging task of reachability analysis in the constrained-based model. The approach is illustrated with examples about the automatic verification of fault-tolerance, consistency, and privacy in distributed spatial and hierarchical systems.

1 Introduction

The widespread availability of virtualization resources such as container and virtual machine technology are marking a new incarnation of distributed systems. Tasks such as fault-tolerant infrastructure monitoring and delivery of goods in unmanned aerial systems, preventing privacy breaches in social networks and cloud storage by managing information access, and saving lives by controlling and monitoring pace makers are now taking place in the presence of spatial hierarchies. This means that the usual high degree of safety criteria in such systems is now exposed to the presence of hierarchical computation (and sharing) of information among groups of distributed and concurrent agents, which makes it an even more challenging goal for formal modeling and verification purposes.

An interesting step towards mathematically understanding and formally modeling these highly distributed hierarchical systems has been taken by S. Knight et al. [16] and M. Guzmán et al. [14]. They introduce an algebraic model of spatial modalities in constrained-based process calculi where information (e.g., knowledge) can be shared in spatially distributed agents that interact with the global system by launching processes (e.g., programs). The scope of an agent is
given by a spatial operator indicating where a process resides within the space structure, where it queries and posts information in the local store. In the end, their proposal offers an algebraic framework to model and reason about important concepts of safety-critical systems such as fault-tolerance, consistency, and privacy within the setting of distributed hierarchical spaces and process extrusion (i.e., mobility).

This work addresses the key issue of automatically verifying reachability properties of distributed hierarchical systems based on the algebraic model of spatially constrained concurrent process with extrusion in [14,16]. The approach is based on the formal specification of such a model as a theory in rewriting logic [18], a semantic framework unifying a wide range of models of concurrency. The formal specification is executable in Maude [6], thus benefiting from formal analysis techniques and tools such as state-space exploration and automata-based LTL model checking. Safety criteria such as fault-tolerance (e.g., when and how does a local store first become inconsistent?), consistency (e.g., does a fault propagate to the global system?), and privacy (e.g., does a store ever gain enough information as to reveal private information?) can now be automatically queried in these systems.

The rewriting logic theory introduced in this work supports the constructs of constrained-based process calculi presented in in [14,16] such as posting and querying information from/to a local store, parallel composition of processes, recursion, and extrusion. The underlying constraint system is materialized with the help of SMT-solving technology. In particular, the constraints are quantifier-free formulas interpreted over the Booleans and integers, and the information entailment in the algebraic model is realized via semantic inference. By following the rewriting modulo SMT approach [23], simulation of the rewrite relation induced by the rewriting logic theory can be performed efficiently using matching and SMT-solving. In this setting, existential reachability queries can be automatically and efficiently performed using existing rewrite-based facilities available from Maude.

Continuing with the effort of putting epistemic concepts in the hands of programmers initiated in [16], a programming language is introduced in this work. This language provides programmers with the building blocks of a language based on the algebraic model of spatial modalities in constrained-based process calculi, with the executable semantics given by rewrite theory above-mentioned. Such a language is accompanied with an open-source graphical environment in which code can be edited and executed.

Outline. This work is organized as follows. Section 2 presents some preliminaries on concurrent constraint programming, rewriting logic, and SMT-solving. Section 3 overviews spatial concurrent constraint systems with extrusion. Section 4 introduces the rewriting logic semantics of the algebraic model and Section 4 presents the mechanical proofs obtained for ensuring the correctness of the operational semantics of the rewrite theory w.r.t. to its mathematical one. Section 6 explains how existential reachability properties can be automatically proved and
examples illustrating such a feature. The language and tool based on the algebraic model are explained in Section 7. Finally, Section 8 concludes the work.

2 Preliminaries

2.1 Concurrent Constraint Programming and Constraint Systems

Concurrent Constraint Programming (CCP) [26–28] (see a survey in [21]) is a model for concurrency that combines the traditional operational view of process calculi with a declarative view based on logic. This allows CCP benefit from the large set of reasoning techniques of both process calculi and logic. Under this paradigm, the conception of store as valuation in the von Neumann model is replaced by the notion of store as constraint and processes are seen as information transducers.

The CCP model of computation makes use of ask and tell operations instead of the classical read and write. An ask operation tests if a given piece of information (i.e., a constraint as in $\text{temperature} \geq 23$) can be deduced from the store. The tell operations post constraints in the store, thus augmenting/refining the information in it. A fundamental issue in CCP is then the specification of systems by means of constraints that represent partial information about certain variables. The state of the system is specified by the store (i.e., a constraint) that is monotonically refined by processes adding new information.

The basic constructs (processes) in CCP are: (1) the tell($c$) agent, which posts the constraint $c$ to the store, making it available to the other processes. Once a constraint is added, it cannot be removed from the store (i.e., the store grows monotonically). And (2), the ask process $c \rightarrow P$, which queries if $c$ can be deduced from the information in the current store; if so, the agent behaves like $P$, otherwise, it remains blocked until more information is added to the store. In this way, ask processes define a reactive synchronization mechanism based on entailment of constraints. A basic CCP process language usually adds parallel composition ($P \parallel Q$) combining processes concurrently, a hiding operator for local variable definition, and potential infinite computation by means of recursion or replication.

The CCP model is parametric in a constraint system (CS) specifying the structure and interdependencies of the partial information that processes can query (ask) and post (tell) in the shared store. The notion of constraint system can be given by using first-order logic. Given a signature $\Sigma$ and a first-order theory $\Delta$ over $\Sigma$, constraints can be thought of as first-order formulae over $\Sigma$. The (binary) entailment relation $\vdash$ over constraints is defined for any pair of constraints $c$ and $d$ by $c \vdash d$ iff the implication $c \rightarrow d$ is valid in $\Delta$. As an example, take the finite domain constraint system (FD) [29] where variables are assumed to range over finite domains and, in addition to equality, it is possible to have predicates (e.g., “$\leq$”) that restrict the values of a variable to some finite set.

An algebraic representation of CS is used in the present work.
Definition 1 (Constraint Systems). A constraint system (CS) \( C \) is a complete algebraic lattice \( (\text{Con}, \sqsubseteq) \). The elements of \( \text{Con} \) are called constraints. The symbols \( \sqcup, \text{true}, \text{false} \) are used to denote the least upper bound (lub) operation, the bottom, and the top element of \( C \), respectively.

In Definition 1, a CS is characterized as a complete algebraic lattice. The elements of the lattice, the constraints, represent (partial) information. A constraint \( c \) can be viewed as an assertion (or a proposition). The lattice order \( \sqsubseteq \) is meant to capture entailment of information: \( d \sqsubseteq c \), alternatively written \( c \sqsubseteq d \), means that the assertion \( c \) represents as much information as \( d \). Thus \( d \sqsubseteq c \) may be interpreted as saying that \( c \vdash d \) or that \( d \) can be derived from \( c \). The least upper bound (lub) operator \( \sqcup \) represents join of information and thus \( c \sqcup d \) is the least element in the underlying lattice above \( c \) and \( d \), asserting that both \( c \) and \( d \) hold. The top element represents the lub of all, possibly inconsistent, information, hence it is referred to as \text{false}. The bottom element \text{true} represents the empty information.

2.2 Order-sorted Rewriting Logic in a Nutshell

This section presents an overview of rewriting logic and how it can be used to obtain a rewriting logic semantics of a language. The reader is referred to \[6,18\] and \[20,25\], respectively, for an in-depth treatment of these topics.

Rewriting logic \[18\] is a general semantic framework that unifies a wide range of models of concurrency. Language specifications can be executed in Maude \[6\], a high-performance rewriting logic implementation and benefit from a wide set of formal analysis tools available to it, such as an LTL model checker and an inductive theorem prover.

Rewriting Logic. A rewriting logic specification or rewrite theory is a tuple \( R = (\Sigma, E \uplus B, R) \) where:

- \( (\Sigma, E \uplus B) \) is an order-sorted equational theory with \( \Sigma = (S, \leq, F) \) a signature with finite poset of sorts \( (S, \leq) \) and a set of function symbols \( F \) typed with sorts in \( S \); \( E \) is a set of \( \Sigma \)-equations, which are universally quantified Horn clauses with atoms that are \( \Sigma \)-equations \( t = u \) with \( t, u \) terms of the same sort; \( B \) is a set of structural axioms (e.g., associativity, commutativity, identity) such that there exists a matching algorithm modulo \( B \) producing a finite number of \( B \)-matching substitutions or failing otherwise; and
- \( R \) a set of universally quantified conditional rewrite rules of the form

\[
 t \rightarrow u \text{ if } \bigwedge_i \phi_i
\]

where \( t, u \) are \( \Sigma \)-terms of the same sort and each \( \phi_i \) is a \( \Sigma \)-equality.

Given \( X = \{X_s\}_{s \in S} \), an \( S \)-indexed family of disjoint variable sets with each \( X_s \) countably infinite, the set of terms of sort \( s \) and the set of ground terms of sort \( s \)
are denoted, respectively, by $T_\Sigma(X)_s$ and $T_{\Sigma,s}$; similarly, $T_\Sigma(X)$ and $T_\Sigma$ denote, respectively, the set of terms and the set of ground terms. The expressions $T_\Sigma(X)$ and $T_\Sigma$ denote the corresponding order-sorted $\Sigma$-term algebras. All order-sorted signatures are assumed prерегуляр [12], i.e., each $\Sigma$-term $t$ has a unique least sort $\text{ls}(t) \in S$ s.t. $t \in T_\Sigma(X)_s$ for all $s \in S$. It is also assumed that $\Sigma$ has nonempty sorts, i.e., $T_{\Sigma,s} \neq \emptyset$ for each $s \in S$. Many-sorted equational logic is the special case of order-sorted equational logic when the subset relation $\subseteq$ is restricted to be the identity relation over the sorts.

An equational theory $E = (\Sigma, E)$ induces the congruence relation $=_E$ on $T_\Sigma(X)$ (or simply $=_E$) defined for $t, u \in T_\Sigma(X)$ by $t =_E u$ if and only if $E \vdash t = u$, where $E \vdash t = u$ denotes $E$-provability by the deduction rules for order-sorted equational logic in [19]. For the purpose of this paper, such inference rules, which are analogous to those of many-sorted equational logic, are even simpler thanks to the assumption that $\Sigma$ has nonempty sorts, which makes unnecessary the explicit treatment of universal quantifiers. The expressions $T_\Sigma(X)$ and $T_\Sigma$ (also written $T_{\Sigma,E}(X)$ and $T_{\Sigma,E}$) denote the quotient algebras induced by $=_E$ on the term algebras $T_\Sigma(X)$ and $T_\Sigma$, respectively; $T_{\Sigma,E}$ is called the initial algebra of $(\Sigma, E)$.

A (topmost) rewrite theory is a tuple $R = (\Sigma, E, R)$ with top sort $\text{State}$, i.e., no operator in $\Sigma$ has $\text{State}$ as argument sort and each rule $l \rightarrow r$ if $\phi \in R$ satisfies $l, r \in T_\Sigma(X)_{\text{State}}$ and $l \neq X$. A rewrite theory $R$ induces a rewrite relation $\rightarrow_R$ on $T_\Sigma(X)$ defined for every $t, u \in T_\Sigma(X)$ by $t \rightarrow_R u$ if and only if there is a rule $(l \rightarrow r$ if $\phi) \in R$ and a substitution $\theta : X \rightarrow T_\Sigma(X)$ satisfying $t =_E \theta, u =_E r\theta$, and $E \vdash \phi\theta$. The tuple $T_R = (T_{\Sigma,E}, \rightarrow_R^*)$ is called the initial reachability model of $R$ [8].

Admissible Rewrite Theories. Appropriate requirements are needed to make an equational theory $E$ admissible, i.e., executable in rewriting languages such as Maude [6]. In this paper, it is assumed that the equations $E$ can be oriented into a set of (possibly conditional) sort-decreasing, operationally terminating, and confluent rewrite rules $E$ modulo $B$. The rewrite system $E$ is sort decreasing modulo $B$ if and only if for each $(t \rightarrow u$ if $\gamma) \in E$ and substitution $\theta$, $\text{ls}(u\theta) \supseteq \text{ls}(u)$ if $(\Sigma, B, E) \vdash \gamma\theta$. The system $E$ is operationally terminating modulo $B$ if and only if there is no infinite well-formed proof tree in $(\Sigma, B, E)$ (see [17] for terminology and details). Furthermore, $E$ is confluent modulo $B$ if and only if for all $t, t_1, t_2 \in T_\Sigma(X)$, if $t \rightarrow_{E/B} t_1$ and $t \rightarrow_{E/B} t_2$, then there is $u \in T_\Sigma(X)$ such that $t_1 \rightarrow^*_{E/B} u$ and $t_2 \rightarrow^*_{E/B} u$. The term $t \downarrow_{E/B} \in T_\Sigma(X)$ denotes the $E$-canonical form of $t$ modulo $B$ so that $t \rightarrow_{E/B}^* t \downarrow_{E/B}$ and $t \downarrow_{E/B}$ cannot be further reduced by $\rightarrow_{E/B}$. Under sort-decreasingness, operational termination, and confluence, the term $t \downarrow_{E/B}$ is unique up to $B$-equality.

For a rewrite theory $R$, the rewrite relation $\rightarrow_R$ is undecidable in general, even if its underlying equational theory is admissible, unless conditions such as coherence [31] are given (i.e., whenever rewriting with $\rightarrow_{R,E,B}$ can be decomposed into rewriting with $\rightarrow_{E,B}$ and $\rightarrow_{R,B}$). A key goal of [23] was to make such a relation both decidable and symbolically executable when $R$ is topmost.
and $E$ decomposes as $E_0 \uplus B_1$, representing a built-in theory for which formula satisfiability is decidable and $B_1$ has a matching algorithm.

**Rewriting Logic Semantics.** The rewriting logic semantics of a language $\mathcal{L}$ is a rewrite theory $R_\mathcal{L} = (\Sigma_\mathcal{L}, E_\mathcal{L} \uplus B_\mathcal{L}, R_\mathcal{L})$ where $\rightarrow_{R_\mathcal{L}}$ provides a step-by-step formal description of $\mathcal{L}$’s observable run-to-completion mechanisms. The conceptual distinction between equations and rules in $R_\mathcal{L}$ has important consequences that are captured by rewriting logic’s abstraction dial [20]. Setting the level of abstraction in which all the interleaving behavior of evaluations in $\mathcal{L}$ is observable, corresponds to the special case in which the dial is turned down to its minimum position by having $E_\mathcal{L} \uplus B_\mathcal{L} = \emptyset$. The abstraction dial can also be turned up to its maximal position as the special case in which $R_\mathcal{L} = \emptyset$, thus obtaining an equational semantics of $\mathcal{L}$ without observable transitions. The rewriting logic semantics presented in this paper is faithful in the sense that such an abstraction dial is set at a position that exactly captures the interleaving behavior of the concurrency model.

**Maude.** Maude [6] is a language and system based on rewriting logic. It supports order-sorted equational and rewrite theory specifications in functional and system modules, respectively. Admissibility of functional and system modules can be checked with the help of the Maude Formal Environment (MFE) [9,10], an executable formal specification in Maude with tools to mechanically verify such properties. The MFE includes the Maude Termination Tool, the Maude Sufficient Completeness Checker, the Church-Rosser Checker, the Coherence Checker, and the Maude Inductive Theorem Prover.

### 2.3 SMT-Solving

Satisfiability Modulo Theories (SMT) studies methods for checking satisfiability of first-order formulas in specific models. The SMT problem is a decision problem for logical formulas with respect to combinations of background theories expressed in classical first-order logic with equality. An SMT instance is a formula $\phi$ (typically quantifier free, but not necessarily) in first-order logic and a model $\mathcal{T}$, with the goal of determining if $\phi$ is satisfiable in $\mathcal{T}$.

In this work, the representation of the constraint system is based on SMT solving technology. Given an many-sorted equational theory $\mathcal{E}_0 = (\Sigma_0, E_0)$ and a set of variables $X_0 \subseteq X$ over the sorts in $\Sigma_0$, the formulas under consideration are in the set $QF_{\Sigma_0}(X_0)$ of quantifier-free $\Sigma_0$-formulas: each formula being a Boolean combination of $\Sigma_0$-equation with variables in $X_0$ (i.e., atoms). The terms in $T_{\mathcal{E}_0}$ are called built-ins and represent the portion of the specification that will be handled by the SMT solver (i.e., semantic data types). In this setting, an SMT instance is a formula $\phi \in QF_{\Sigma_0}(X_0)$ and the initial algebra $T_{\mathcal{E}_0}^+$, where $\mathcal{E}_0^+$ is a decidable extension of $\mathcal{E}_0$ such that

$$\phi \text{ is satisfiable in } T_{\mathcal{E}_0}^+ \iff (\exists \sigma : X_0 \rightarrow T_{\Sigma_0}) T_{\mathcal{E}_0} \models \phi \sigma.$$
Many decidable theories $\mathcal{E}^+_{\omega}$ of interest are supported by SMT solvers satisfying this requirement (see [23] for details). In this work, the latest alpha release of Maude that integrates Yices2 [11] and CVC4 [3] is used for reachability analysis.

3 Spatial Concurrent Constraint Systems with Extrusion

This section presents the syntax and the structural operational semantics of spatial concurrent constraints systems with extrusion, which is based mainly on [16]. This section also introduces an example to illustrate the main features of the language.

3.1 Spatial Constraint Systems

The authors of [16] extended the notion of CS to account for distributed and multi-agent scenarios where agents have their own space for local information and computation.

Locality and Nested Spaces. Each agent $i$ has a space function $[\cdot]_i$ from constraints to constraints (recall that constraints can be viewed as assertions). The function

$$[c]_i$$

can be interpreted as an assertion stating that $c$ is a piece of information that resides within a space attributed to agent $i$. An alternative epistemic interpretation of $[c]_i$ is an assertion stating that agent $i$ believes $c$ or that $c$ holds within the space of agent $i$ (but it may or may not hold elsewhere). Both interpretations convey the idea that $c$ is local to agent $i$. Following this intuition, the assertion

$$[[c]_j]_i$$

is a hierarchical spatial specification stating that $c$ holds within the local space the agent $i$ attributes to agent $j$. Nesting of spaces such as in $[[\ldots [c]_{i_m} \ldots]_{i_2}]_{i_1}$ can be of any depth.

Parallel Spaces. A constraint of the form

$$[c]_i \sqcup [d]_j$$

can be seen as an assertion specifying that $c$ and $d$ hold within two parallel/neighboring spaces that belong to agents $i$ and $j$. From a computational/concurrency point of view, it is possible to think of $\sqcup$ as parallel composition; from a logic point of view, $\sqcup$ corresponds to conjunction.

The notion of an $n$-agent spatial constraint system is formalized in Definition 2.
Definition 2 (Spatial Constraint System \[16\]). An \(n\)-agent spatial constraint system \((n\text{-SCS})\) \(C\) is a CS \((\text{Con}, \subseteq)\) equipped with \(n\) self-maps \([1]_1, \ldots, [1]_n\) over its set of constraints \(\text{Con}\) satisfying for each function \([\cdot]_i : \text{Con} \rightarrow \text{Con}\):

\[
\text{S.1 } [\text{true}]_i = \text{true}, \text{ and } \\
\text{S.2 } [c \sqcup d]_i = [c]_i \sqcup [d]_i \text{ for each } c, d \in \text{Con}.
\]

Property S.1 in Definition 2 requires space functions to be strict maps (i.e., bottom preserving) where an empty local space amounts to having no knowledge. Property S.2 states that space functions preserve (finite) lubs, and also allows to join and distribute the local information of any agent \(i\). Henceforth, given an \(n\)-SCS \(C\), each \([\cdot]_i\) is thought as the space (or space function) of the agent \(i\) in \(C\). The tuple \((\text{Con}, \subseteq, [1]_1, \ldots, [1]_n)\) denotes the corresponding \(n\)-SCS with space functions \([1]_1, \ldots, [1]_n\). Components of an \(n\)-SCS tuple shall be omitted when they are unnecessary or clear from the context. When \(n\) is unimportant, \(n\)-SCS is simply written as SCS.

Extrusion. Extrusion (i.e., mobility) plays a key role in distributed systems. Following the algebraic approach, it is possible to provide each agent \(i\) with an extrusion function \(\uparrow_i : \text{Con} \rightarrow \text{Con}\) \([14][15]\). The process \(c \uparrow_i\) within a space context \([\cdot]_i\) means that the process \(c\) must be executed outside of agent’s \(i\) space.

Definition 3 presents the extension of spatial constraint systems with extrusion.

Definition 3 (Spatial Constraint System with Extrusion \([14]\)). An \(n\)-agent spatial constraint system with extrusion \((n\text{-SCSE})\) is an \(n\)-SCS \(C\) equipped with \(n\) self-maps \(\uparrow_1, \ldots, \uparrow_n\) over \(\text{Con}\), such that each \(\uparrow_i\) is the right inverse of \([\cdot]_i\).

3.2 Spatial CCP with Extrusion

The spatial concurrent constraint programming with extrusion (SCCP+E) calculus presented in this section follows the developments of \([10]\) and \([14]\). The syntax of SCCP+E is parametric on an SCSE and it is presented in Definition 4.

Definition 4 (SCCP+E Processes). Let \(C = (\text{Con}, \subseteq)\) be a constraint system, \(A\) a set of \(n\) agents, and \(V\) an infinite countable set of variables. Let \((C, [\cdot]_1, \ldots, [\cdot]_n, \uparrow_1, \ldots, \uparrow_n)\) be an \(n\)-SCSE and consider the following EBNF-like syntax:

\[
P ::= 0 \mid \text{tell}(c) \mid \text{ask}(c) \rightarrow P \mid P \parallel P \mid [P]_i \mid P \uparrow_i \mid x \mid \mu x.P
\]

where \(c \in \text{Con}, i \in A,\) and \(x \in V\). An expression \(P\) in the above syntax is a process if and only if every variable \(x\) in \(P\) occurs in the scope of an expression of the form \(\mu x.P\). The set of processes of SCCP+E is denoted by Proc.
The SCCP+E calculus can be thought of as a shared-spaces model of computation. Each agent $i \in A$ has a computational space of the form $[i]$, possibly containing processes and other agents’ spaces. The basic constructs of SCCP+E are tell, ask, and parallel composition, and they are defined as in standard CCP [28].

A process $\text{tell}(c)$ running in an agent $i \in A$ adds $c$ to its local store $s_i$, making it available to other processes in the same space. This addition, represented as $s_i \sqcup c$, is performed even if the resulting constraint is inconsistent. The process $\text{ask}(c) \rightarrow P$ running in space $i$ may execute $P$ if $c$ is entailed by $s_i$, i.e., $c \subseteq s_i$. The process $P \parallel Q$ specifies the parallel execution of processes $P$ and $Q$; given $I = \{i_1, \ldots, i_m\} \subseteq A$, the expression $\prod_{i \in I} P_i$ is used as a shorthand for $P_{i_1} \parallel \ldots \parallel P_{i_m}$. A construction of the form $[P]_i$ denotes a process $P$ running within the agent $i$’s space. Any information that $P$ produces is available to processes that lie within the same space. The process $P \parallel \_i$ denotes that process $P$ runs outside the space of agent $i$ and the information posted by $P$ resides in the store of the parent of agent $i$. The behavior of recursive definitions of the form $\mu x.P$ is represented by $P[\mu x.P/x]$, i.e., every free occurrence of $x$ in $P$ is replaced with $\mu x.P$. In order to make recursive definitions finite, it is necessary for recursion to be guarded by an $\text{ask}$, i.e., every occurrence of $x$ in $P$ is within the scope of an ask process. Note that the process $P$ in a construction of the form $\text{ask}(true) \rightarrow P$ is unguarded.

**Example 1.** Consider the processes $P = \text{tell}(c)$ and $Q = \text{ask}(c) \rightarrow \text{tell}(d)$. Consider $[P]_i \parallel [Q]_i$; by the above intuitions the constraints $c$ and $d$ are added to store of agent $i$. A similar behavior is achieved by the process $[P \parallel Q]_i$, which also produces $c \cup d$ in the store of agent $i$ (note that $[c \cup d]_i$ is equivalent to $[c]_i \cup [d]_i$, by Property S.2 in Definition 2). In contrast, the process $[P]_j \parallel [Q]_i$ with $i \neq j$, does not necessarily add $d$ to the space of agent $i$ because $c$ is not made available for agent $i$; likewise in $P \parallel [Q]_i$, $d$ is not added to the space of agent $i$. Finally, consider $[P \parallel (Q \parallel_1)]_i$. In this case, because of extrusion, both $c$ and $d$ will be added to store of agent $i$. However, $[[P \parallel Q \parallel_1]]_i$, with $i \neq j$, results in the space of agent $i$ having $c$ and $d$, but neither are available for agent $j$. Note that in $[P]_i \parallel [Q \parallel_1]_j$, the constraint $c$ is added to the space of agent $i$, but since $Q$ cannot be extruded in $[Q \parallel_1]_j$, $d$ is not added to the spaces of $i$ or $j$.

Next, the notion of the projection of a spatial constraint $c$ for an agent $i$ is introduced.

**Definition 5 (Views).** The agent $i$’s view of $c$, denoted as $c^i$, is given by $c^i = \bigcup [d]_i \sqcup [e]_i \subseteq c$.

The intuition is that $c^i$ represents all the information the agent $i$ may see or have in $c$. For example if $c = [d]_i \sqcup [e]_j$ then agent $i$ sees $d$, so $d \subseteq c^i$.

### 3.3 Structural Operational Semantics of SCCP+E

The operational semantics of SCCP+E is defined over configurations. A configuration is a pair of the form $\langle P, c \rangle \in \text{Proc} \times \text{Con}$, where $P$ is a process and $c$ is
the spatial distribution of information available to it; the set of configurations is denoted by $Conf$. The structural operational semantics of SCCP+E is captured by the binary transition relation $\longrightarrow \subseteq Conf \times Conf$, defined by the rules in Figure 1.

$$
\begin{align*}
\langle \text{Tell}(c); d \rangle & \longrightarrow \langle 0; d \sqcup c \rangle & \text{Tell} \\
\langle \text{Ask} c; d \rangle & \longrightarrow \langle P; d \rangle & \text{Ask} \\
\langle P; d \rangle & \longrightarrow \langle P'; d' \rangle & \text{Par} \\
\langle P \parallel Q; d \rangle & \longrightarrow \langle P' \parallel Q; d' \rangle & \text{SP} \\
\langle [P]; c; d \rangle & \longrightarrow \langle [P']; c \sqcup [c'] \rangle & \text{Rec} \\
\langle \mu x. P; d \rangle & \longrightarrow \gamma & \text{Ext}
\end{align*}
$$

Fig. 1: Structural operational semantics of SCCP+E.

The rules $\text{Tell}$, $\text{Ask}$, $\text{Par}$, and $\text{Rec}$ for the basic processes and recursion are the standard ones in CCP. In order to avoid another version of the $\text{Par}$ rule for process $Q$, parallel composition is assumed to be (associative and) commutative. The rule $\text{Ext}$ is a context-dependent definition for extrusion, i.e., it requires a space process (i.e., $[\cdot]$ with $j = i$) and specifies extrusion in the sense explained before. In the rule $\text{SP}$, $c'$ represents all the information the agent $i$ may see or have in $c$; namely, $P$ runs with store $c'$, i.e., with the agent’s $i$ view of $c$. Also note the information $c'$ added to $c^i$ by the computation of $P$ corresponds to the information added by $[P]_i$ to the space of agent $i$.

Example 2. One way of understanding $\text{SP}$ is by considering a constraint $c$ as a tree-like structure. Each node in such a tree corresponds to the information
(constraint) contained in an agent’s space. Edges in the tree-like structure define the spatial hierarchy of agents. For example, given an appropriate SCSE, Figure 2 corresponds to the following store $d$:

$$d \overset{\text{def}}{=} (y = 1) \sqcup (x = 3 \sqcup (y = 3)) \sqcup (x > 0 \sqcup (x = 42)) \sqcup (x < 42) \sqcup (y > 0).$$

The configuration

$$\langle \text{ask} x = 42 \rightarrow P \rangle; d$$

is a deadlock, while

$$\langle \text{ask} x = 42 \rightarrow P \rangle; d \rightarrow \langle P \rangle; d$$

by the rules $\text{SP}$ and $\text{Ask}$, using the fact that $x = 42 \subseteq d^k$.

3.4 Example

This section includes an example that will be used throughout the paper. The example models a system where an agent sends messages to other agents through the spatial hierarchy.

As mentioned earlier, a distinctive property about SCCP+E is that it allows to have inconsistent information within spaces; i.e., one agent may have local information $c$ and the other some local information $d$ such that $c \sqcup d = \text{false}$ (e.g., $c$ and $d$ could be $x = 25$ and $x < 20$, respectively). This also means that an agent can send inconsistent information to different agents.

As an example of how hierarchical distributed processes evolve with respect to the SCCP+E’s structural operational semantics, consider the sequence of system states depicted in Figure 3. These states (figures 3a-3l) correspond to a step-by-step execution from the initial configuration (Figure 3a), with the process $P$ defined as follows:

$$P \overset{\text{def}}{=} [[P_1 \parallel P_2]]_0$$

and where:

$$P_1 \overset{\text{def}}{=} \text{tell}(Z \geq 10)$$

$$P_2 \overset{\text{def}}{=} \text{ask}(Y < 20) \rightarrow [[P_3]]_0$$

$$P_3 \overset{\text{def}}{=} \text{tell}(W < Y).$$

4 Rewriting Logic Semantics

The rewriting logic semantics of a language $L$ is a rewrite theory $\mathcal{R}_L = (\Sigma_L, E_L \cup B_L, R_L)$ where $\rightarrow_{\mathcal{R}_L}$ provides a step-by-step formal description of $L$’s observable run-to-completion mechanisms. The conceptual distinction between equations
Fig. 3: Execution of process $P$ and evolution of the SCCP+E system.
and rules in $\mathcal{R}_L$ has important consequences that are captured by rewriting logic’s abstraction dial [20]. Setting the level of abstraction in which all the interleaving behavior of evaluations in $\mathcal{L}$ is observable, corresponds to the special case in which the dial is turned down to its minimum position by having $E_L \uplus B_L = \emptyset$. The abstraction dial can also be turned up to its maximal position as the special case in which $R_L = \emptyset$, thus obtaining an equational semantics of $\mathcal{L}$ without observable transitions. The rewriting logic semantics $\mathcal{R}$ sets such an abstraction dial at a position that exactly captures the interleaving behavior of SCCP+E.

This section presents a rewriting logic semantics for SCCP+E in the form of a rewrite theory $\mathcal{R} = (\Sigma, E, R)$ with topsort $\text{Sys}$. The data types supporting the state structure are defined by the equational theory $(\Sigma, E)$ and the state transitions are axiomatized by the rewrite rules $R$. The constraint system, as detailed later in this section, is materialized by an equational theory $(\Sigma_0, E_0) \subseteq (\Sigma, E)$ of built-ins whose quantifier-free formulas are handled by SMT decision procedures. The complete specification of $\mathcal{R}$ can be found in Appendix 9.

Figure 4 depicts the module structure of $\mathcal{R}$. Maude offers three modes for importing a module, namely, protecting, extending, and including. When a functional module $M'$ protects a functional module $M$, it means that the data types from $M$ are kept the same in $M'$ (i.e., no junk and no confusion are added to the sorts of $M$). When a functional module $M'$ extends a functional module $M$, it means that the data types from $M$ can be extended with new terms, but existing terms are not identified (i.e., junk is allowed but confusion is not). When a functional module $M'$ imports a functional module $M$, it means that the data types from $M$ can be extended with new terms and existing terms can be identified (i.e., junk and confusion are allowed). In $\mathcal{R}$, modules are imported by protecting (denoted by a triple arrow $\Rightarrow$) or including (denoted by a single arrow $\rightarrow$) submodules. See [6] for details about the three different modes of module importation in Maude.

4.1 The Constraint System

The materialization of the constraint system in $\mathcal{R}$ uses SMT solving technology. Given a many-sorted (i.e., order-sorted without sort structure) equational theory $\mathcal{E}_0 = (\Sigma_0, E_0)$ and a set of variables $X_0 \subseteq X$ over the sorts in $\Sigma_0$, the formulas under consideration are in the set $QF_{\Sigma_0}(X_0)$ of quantifier-free $\Sigma_0$-formulas: each formula being a Boolean combination of $\Sigma_0$-equation with variables in $X_0$ (i.e., atoms). The terms in $T_{\Sigma_0}$ are called built-ins and represent the portion of the specification that will be handled by the SMT solver (i.e., semantic data types). Thus, an SMT instance is a formula $\phi \in QF_{\Sigma_0}(X_0)$ and the initial algebra $T_{\Sigma_0}^+$, where $\mathcal{E}_0^+$ is a decidable extension of $\mathcal{E}_0$ (typically by adding some inductive consequences and, perhaps, some extra symbols) such that

$$\phi \text{ is satisfiable in } T_{\Sigma_0}^+ \iff (\exists \sigma : X_0 \longrightarrow T_{\Sigma_0}) T_{E_0} \models \phi \sigma.$$

Many decidable theories $\mathcal{E}_0^+$ of interest are supported by SMT solvers satisfying this requirement (see [23] for details).
The INTEGER module implements the equational theory $E_0 = (\Sigma_0, E_0)$ of built-ins and the sort Boolean defines the data type used to represent the constraints. The topmost concurrent transitions in $R$ are then symbolic rewrite steps of state terms with subterms in the set $T_\Sigma(X_0)_{Sys}$ of $\Sigma$-terms of sort $Sys$ with variables over the built-in sorts in $\Sigma_0$.

**Lemma 1.** The pair $B = (QF_{\Sigma_0}(X_0), \models)$ is a constraint system, where $X_0$ are the variables ranging over the sorts Boolean and Integer.

The elements in $QF_{\Sigma_0}(X_0)$ are equivalence classes of quantifier-free $\Sigma_0$-formulas of sort Boolean modulo semantic equivalence in $T_{E_0}$ (this technicality guarantees, e.g., the uniqueness of least upper bounds). Therefore, by an abuse of notation, the constraint system $B$ has quantifier-free $\Sigma_0$-formulas of sort Boolean as the constraints and the inverse $\models$ of the semantic validity relation $\models$, w.r.t. the initial model $T_{E_0}$, as the entailment relation.

In order to use $B$ as the underlying constraint system, $R$ relies on the current version of Maude that is integrated with the CVC4 [3] and Yices2 [11] SMT solvers. The SMT-UTIL module encapsulates this integration, which requires the
The function \texttt{entails} implements the semantic validity relation \( \models \) (w.r.t. \( T_{E_0} \)) using the auxiliary functions \texttt{check-sat} and \texttt{check-unsat} (observe that the sort \texttt{Boolean} is different to the usual sort \texttt{Bool} for Boolean terms in Maude):

\begin{verbatim}
op entails : Boolean Boolean -> Bool .
op check-sat : Boolean -> Bool .
op check-unsat : Boolean -> Bool .
eq check-sat(B) = metaCheck(['INTEGER], upTerm(B)) .
eq check-unsat(B) = not(check-sat(B)) .
eq entails(C1, C2) = check-unsat(C1 and not(C2)) .
\end{verbatim}

The function invocation \texttt{check-sat(B)} evaluates to true iff \( B \) is satisfiable; alternatively, it evaluates to false if \( B \) is unsatisfiable or if the SMT solver times out. The function invocation \texttt{check-unsat(B)} returns true iff \( B \) is unsatisfiable. Note that if the constraints \( B \) are decidable, then \texttt{check-unsat} is not only sound but complete. More precisely, if \( \Gamma \) is a finite subset of decidable constraints in \( B \) and \( \phi \) is also a decidable constraint in \( B \), then the following equivalence holds:

\[
T_{E_0} \models \bigwedge_{\gamma \in \Gamma} \gamma \Rightarrow \phi \quad \text{iff} \quad \text{entails} \left( \bigwedge_{\gamma \in \Gamma} \gamma , \phi \right).
\]

### 4.2 System States

At the top level, the system is represented by the top sort \texttt{Sys} defined in \texttt{SCCP-STATE}:

\begin{verbatim}
sort Sys .
op {_} : Cnf -> Sys [ctor] .
\end{verbatim}

The argument of a state is the configuration of objects representing the setup of the agents and processes in the system. Sort \texttt{Cnf} is that of configuration of agents in an object-like notation. More precisely, sort \texttt{Cnf} represents multisets of terms of sort \texttt{Obj}, with set union denoted by juxtaposition. An object is by itself a configuration of objects, namely, the singleton one; constant \texttt{mt} denotes the empty configuration and it is the identity of the union operator. There are two types of objects: process objects and store objects. Process and stores objects are represented by triples \([_,_,_] \) (as \texttt{Obj}). The first two arguments of both a process and a store object are its type (either \texttt{process} or \texttt{store}, as \texttt{Cid}) and its identifier (as \texttt{Aid}). The third argument of a process object is the program it is executing (as \texttt{SCCPCmd}) and the third argument of a store object is a formula representing the constraint of its corresponding agent (as \texttt{Boolean}).

\begin{verbatim}
sorts Cid Obj Cnf .
subsorts Obj < Cnf .
\end{verbatim}
The idea is that in any observable state there can be many process objects executing in an agent’s space but there must be exactly one store object per agent (i.e., space). More precisely, in an observable state, each agent’s space is represented by a set of terms: some encoding the state of execution of all its processes and exactly one object representing its local store.

Process and store objects use a qualified name (sort \texttt{Aid}) identifying to which agent’s space they belong; this sort is defined in module \texttt{AGENT-ID}. Natural numbers (sort \texttt{iNat}), in Peano notation and with an equality enrichment \cite{13}, are used to specify agents’ identifiers. The hierarchical structure of spaces is modeled as a tree-like structure where the root space is identified by the constant \texttt{root}. Any other qualified name corresponds to a dot-separated list of agent identifiers, arranged from left to right. That is, \texttt{3 . 1 . root} denotes that agent 3 is within the space of agent 1, which in turn is within the top level of \texttt{root}.

The processes in \texttt{SCCP+E} are modeled as \textit{commands} (sort \texttt{SCCPCmd}) as defined in the module \texttt{SCCP-SYNTAX}:

\begin{verbatim}
ops store process : -> Cid .
op [_,_,_] : Cid Aid Boolean -> Obj [ctor] .
op [_,_,_] : Cid Aid SCCPCmd -> Obj [ctor] .
op mt : -> Cnf [ctor] .
op _- : Cnf Cnf -> Cnf [ctor assoc comm id: mt] .
op {_} : Cnf -> Sys [ctor] .
\end{verbatim}

The argument of a \texttt{tell_} command is a formula (as \texttt{Boolean}), namely, the formula to be added to the corresponding store. The \texttt{ask_}->\_ command has a formula (as \texttt{Boolean}) and a program (as \texttt{SCCPCmd}) as arguments, denoting that if the given formula is entailed by the corresponding store, then the process is to be executed next. Both arguments of the \texttt{||}\_\_ command are processes (as \texttt{SCCPCmd}). The arguments of the \texttt{<\_\>_\_}, \texttt{rec(_,\_)}, and \texttt{xtr(_,\_)} commands are a natural number (representing the identifier of a descendant, a variable, and the identifier of the ancestor, respectively) and a command to be executed.
Note that the syntax of each command is very close to the actual syntax in the SCCP+E model, e.g., constructs of the form $P \parallel Q$ and $[\! [P] \! ]$, in SCCP+E are represented in the syntax of SCCPCmd by terms of the form $P \mid Q$ and $<\!1\!>[P]$, respectively.

**Example 3.** Using the functional module `SCCP-STATE`, the SCCP+E space structure in Example 3a can be represented as follows:

\[
\{ \langle \text{store, root, true} \rangle, \\
\langle \text{store, 0 . root, X:Integer }= \text{25} \rangle, \\
\langle \text{store, s 0 . root, true} \rangle, \\
\langle \text{store, 0 . s 0 . root, Y:Integer }< \text{5} \rangle \}
\]

### 4.3 Auxiliary Operations

There are three auxiliary operations defined in the semantics. They are used to verify whether a condition is satisfied by the system before a transition happens and for replacing terms for the recursion command.

The function symbol `is-prefix?` is defined in `AGENT-ID` to verify recursively whether an agent is descendant of other agent based on its `Aid`. For instance, $1 . 2$ is descendant of $2$ because $2$ is prefix of $1 . 2$. By definition, `root` is prefix of every agent. The equations defining the `is-prefix?` function evaluate to `true` if the first argument is a prefix of the second one; otherwise, it is `false`.

\[
\begin{align*}
\text{op is-prefix? : Aid Aid } & \to \text{Bool .} \\
\text{eq is-prefix?(root, L)} & = \text{true .} \\
\text{eq is-prefix?(N . L, root)} & = \text{false .} \\
\text{eq is-prefix?(N0 . L0, N1 . L1)} & = (N0 . L0 \sim N1 . L1) \text{ or-else is-prefix?(N0 . L0, L1) .}
\end{align*}
\]

Some commands in SCCP+E require that a store exists in the system. For that reason the `exists-store?` function symbol is defined in module `SCCP-STATE`: it is used to look within a configuration of agents (as `Cnf`) for a store with an given `Aid`. The equation defining `exists-store?` evaluate to `true` if the store exists; otherwise, it is `false`.

\[
\begin{align*}
\text{op exists-store? : Cnf Aid } & \to \text{Bool .} \\
\text{eq exists-store?(mt, L)} & = \text{false .} \\
\text{eq exists-store?( \langle \text{process, L0, C0} \rangle X, L)} & = \text{exists-store?(X,L) .} \\
\text{eq exists-store?( \langle \text{store, L0, B0} \rangle X, L)} & = (L0 \sim L) \text{ or-else exists-store?(X, L) .}
\end{align*}
\]

Finally, the recursion construct $P[\mu x.P/x]$ in SCCP+E means that every free occurrence of $x$ in $P$ is replaced with $\mu x.P$. For this reason, the `replace` function symbol is defined as follows: given a program $P$, a variable identifier $N$
(as \text{iNat}), and a program \(C\), every free occurrence of \(N\) in \(P\) is substituted by \(C\).

\begin{verbatim}
  op replace : SCCPCmd iNat SCCPCmd -> SCCPCmd .
  eq replace( 0, N, C ) = 0 .
  eq replace( tell B, N, C ) = tell B .
  eq replace( ask B -> replace( C0, N, C ) ..
  = ask B -> replace( C0, N, C ) .
  eq replace( C0 || C1, N, C )
    = replace( C0, N, C ) || replace( C1, N, C ) .
  eq replace( < N0 >[ C0 ], N, C )
    = < N0 >[ replace( C0, N, C ) ] .
  eq replace( rec( NO, C0 ), N, C )
    = rec( NO, C0 ) .
  eq replace( xtr( NO, C0 ), N, C )
    = xtr( NO, replace( C0, N, C ) ) .
  eq replace( v(NO), N, C )
    = if (NO ~ N) then C else v(NO) fi .
\end{verbatim}

\textbf{4.4 System Transitions}

The state transitions in \(R\) comprise both invisible (given by equations) and observable (given by rules) transitions.

There are two types of invisible transitions that are specified with the help of equations. Namely, one to remove a 0 process from a configuration and another one to join the contents of two stores of the same space (i.e., two stores with the same \text{Aid}). The latter type of transition is important especially because when a new process is spawned in a agent’s space, a store with the empty constraint (i.e., \text{true}) is created for that space. If such space existed before, then the idea is that the newly created store is subsumed by the existing one (variable \(L\) is of sort \text{Aid}, \(X\) of sort \text{Cnf}, and \(B0,B1\) of sort \text{Boolean}):

\begin{verbatim}
  eq { [ process, L0, 0 ] X }
    = { mt X } .
  eq [ store, L0, B0 ] [ store, L0, B1 ]
    = [ store, L0, B0 and B1 ] .
\end{verbatim}

There are six rules capturing the concurrent observable behavior in the specification (variable \(L\) is of sort \text{Aid}, \(X\) of sort \text{Cnf}, \(B0,B1\) of sort \text{Boolean}, \(C0,C1\) of sort \text{SCCPCmd}, and \(N\) of sort \text{iNat}).

\text{rl}_{[\text{tell}]} : (rule [tell] :}
\begin{verbatim}
  { [ store, L0, B0 ] [ process, L0, tell B1 ] X }
  => { [ store, L0, B0 and B1 ] [ process, L0, 0 ] X } .
\end{verbatim}

\text{cr}_{[\text{ask}]} : (rule [ask] :}
\begin{verbatim}
  { [ store, L0, B0 ] [ process, L0, ask B1 -> C1 ] X }
\end{verbatim}
if entails(B0, B1) .

rl [parallel] :  
{ [ process, L0, C0 || C1 ] X }  
=> { [ process, L0, C0 ] [ process, L0, C1 ] X } .

rl [space] :  
{ [ store, L0, B0 ] [ process, L0, < N0 >[ C0 ] ] X }  
=> { [ store, L0, B0 ] [ process, L0, 0 ] [ process, N0 . L0, C0]  
[ store, N0 . L0, true ] X } .

rl [recursion]:  
{ [ process, L0, rec( N0, C0 ) ] X }  
=> { [ process, L0, replace( C0, N0, rec( N0, C0 ) ) ] X } .

rl [extrusion]:  
{ [ process, N0 . L0, xtr( N0, C0 ) ] X }  
=> { [ process, N0 . L0, 0 ] [ process, L0, C0 ] X } .

Rule [tell] implements the semantics of a process executing a tell command by posting the given constraint in the local store and by transforming such a process to the nil process. Rule [ask] executes command C1 when the guard B1 in ask B1 -> C1 holds: that is, when B1 is entailed by the local store B0. Rule [parallel] implements the semantics for parallel composition of process by spawning the two process in the current space. Rule [space] creates a new space denoted by N0 . L0 (as Aid) with an empty store (i.e., true) and starts the execution of program C0 within the space. Rule [recursion] defines the semantics of a process executing a rec command by using the aforementioned auxiliary function replace. Rule [extrusion] executes process C0 in the parent space of the agent and transitions the xtr process to the nil process. Note that recursion command can lead to non-termination. It is common in SCCP+E to guard such commands with an ask in order to tame the potential non-termination.

Example 4. Using the functional module SCCP-SYNTAX, the process P in Figure 3 can be represented as follows:

xtr(0,< s 0 >[tell (Z:Integer >= 10) || < 0 >[ask Y:Integer < 20 ->  
xtr(0,xtr(s 0,< 0 >[< s s 0 >[tell (W:Integer <  
Y:Integer)]))]))])

If this command is executed in the space of agent 0 . root from the initial state in Example 3 (and depicted in Figure 3a), it leads to the state

{ [store, root, true]  
[store, 0 . root, X:Integer == 25]  
[store, s 0 . root, Z:Integer >= 10]  
[store, s s 0 . 0 . root, W:Integer < Y:Integer]  
[store, 0 . s 0 . root, Y:Integer < 5] }  

which corresponds to the final state depicted in Figure 3c.
Theorem 1. If \( \langle P, c \rangle \) and \( \langle P', c' \rangle \) are configurations of SCCP+\( E \) with underlying constraint system \( B \) restricted to decidable formulas, then

\[
\langle P, c \rangle \xrightarrow{*} \langle P', c' \rangle \quad \text{iff} \quad \{ \langle P, c \rangle \} \xrightarrow{R} \{ \langle P', c' \rangle \},
\]

where \( \langle P, c \rangle \) and \( \langle P', c' \rangle \) are an encoding of the corresponding configurations in the syntax of \( R \).

Proof. The proof follows by structural induction on the \( \longrightarrow \) and \( \rightarrow_{R} \) relations. \( \square \)

5 Admissibility

This section presents a map \( R \mapsto R' \) that results in a rewrite theory \( R' \), equivalent in terms of admissibility to \( R \) (introduced in Section 4) under some reasonable assumptions, but in which dependencies to non-algebraic data types such as terms over the built-ins or at the meta-level in \( R \) have been removed. This section also presents proofs of admissibility of the rewrite theory \( R' \). Such proofs are obtained mechanically using the Maude Formal Environment (MFE) \( [9,10] \) and establish the correspondence (i.e., soundness and completeness) between the mathematical and operational semantics of \( R \). The specification \( R' \) can be found in Appendix 10.

The map \( R \mapsto R' \) consists of the following items, which make the specification amenable to mechanical verification in the MFE:

- Changing the sort \( \text{Bool} \) in \( \text{TRUTH-VALUE} \) to the sort \( \text{iBool} \) in the module \( \text{ITRUTH-VALUE} \) and adjusting the specification to account for this new definition of Boolean values.
- Removing all dependencies in \( \text{SMT-UTIL} \) of the module \( \text{META-LEVEL} \).
- Introducing a custom if-then-else-fi function symbol in \( \text{SCCP-SYNTAX} \) and adjusting the definition of the auxiliary function symbol \( \text{replace} \) to use this new version instead.

The module structure of the resulting specification \( R' \) is depicted in Figure 5. It is important to mention that the dependency of \( \text{META-LEVEL} \) in \( \text{SMT-UTIL} \) amounts at changing the definition of the function symbol \( \text{check-sat} \) to a constant value.

5.1 Equational Admissibility

Recall from Section 2 that an equational specification is admissible if it is sort-decreasing, operational terminating, and confluent.

Lemma 2. The equational subtheory of \( R' \) is admissible.

Proof. Termination of \( R' \) modulo axioms can be proved automatically using the Maude Termination Tool within the MFE with the following script:
Fig. 5: Module structure of $\mathcal{R}'$. 
Sort-decreasingness and confluence modulo axioms can be proved automatically using the Church-Rosser Checker within MFE with the following script:

Maude> (select tool CRC .)
rewrites: 76 in 4ms cpu (5ms real) (19000 rewrites/second)
The CRC has been set as current tool.

Maude> (ccr SCCP .)
rewrites: 35929405 in 45540 ms cpu (45539 ms real) (788963 rewrites/second)
Church-Rosser check for SCCP
All critical pairs have been joined.
The specification is locally-confluent.
The module is sort-decreasing.

\[ \]

5.2 Coherence

Coherence follows from the fact that there are not critical pairs between the equations and the rules in $\mathcal{R}'$: the key observation is that $\mathcal{R}'$, similar to $\mathcal{R}$, is topmost.

Lemma 3. The rewrite theory $\mathcal{R}'$ is coherent modulo axioms.

Proof. Coherence of $\mathcal{R}'$ can be proved automatically using the Maude Coherence Checker within the MFE with the following script:

Maude> (select tool ChC .)
rewrites: 76 in 16ms cpu (14ms real) (4750 rewrites/second)
The ChC has been set as current tool.

Maude> (cch SCCP .)
rewrites: 8004447 in 7844 ms cpu (7843ms real) (1020454 rewrites/second)
Coherence checking of SCCP
All critical pairs have been rewritten and no rewrite with rules can happen at non-overlapping positions of equations left-hand sides.

\[ \]

5.3 Admissibility

The admissibility of $\mathcal{R}'$ is a logical consequence of its equational admissibility and coherence.

Theorem 2. The rewrite theory $\mathcal{R}'$ is admissible.

Proof. It follows from lemmas 2 and 3.
Finally, the admissibility of $\mathcal{R}$ can be asserted under the assumption that Maude’s META-LEVEL is admissible. In particular, it is required that the meta-level functionality used for querying the SMT solver is correct.

**Corollary 1.** If Maude’s META-LEVEL is admissible, then $\mathcal{R}$ is admissible.

**Proof (Sketch).** The equational admissibility of $\mathcal{R}$ follows from the admissibility of $\mathcal{R}'$ by observing that:

- the equational subtheory of $\mathcal{R}'$ is basically the same one of $\mathcal{R}$ but with some sorts being renamed, introducing a new if-then-else-fi construct (with the same evaluation strategy that Maude’s built-in equivalent).
- by assumption, Maude’s META-LEVEL is admissible.

The coherence of $\mathcal{R}$ follows from the coherence of $\mathcal{R}'$ and by the fact that there are no critical pairs between the equations in Maude’s META-LEVEL module and the rules in the SCCP module.

6 Symbolic Reachability Analysis

The goal of this section is to explain how the rewriting logic semantics $\mathcal{R}$ of SCCP+E and rewriting modulo SMT can be used as an automatic mechanism for solving existential reachability goals in the initial model $\mathcal{T}_\mathcal{R}$. This approach can be especially useful for symbolically proving or disproving safety properties of $\mathcal{T}_\mathcal{R}$ such as fault-tolerance, consistency, and privacy. The approach presented in this section mainly relies on Maude’s search command, but it can be easily extended to be useful in the more general setting of Maude’s LTL Model Checker.

In this section, a state in $\mathcal{R}$ with $n$ stores is represented as a term $t(\phi_1, \ldots, \phi_n)$, where each $\phi_i$ denotes the contents of a store. Given two state terms $t(\phi_1, \ldots, \phi_n)$ and $u(\psi_1, \ldots, \psi_k)$, the existential reachability question of whether there is a ground substitution $\theta$ and concrete states $t' \in t(\phi_1, \ldots, \phi_n)\theta$ and $u' \in u(\psi_1, \ldots, \psi_k)\theta$ such that $t' \xrightarrow{\mathcal{R}} u'$ is of special interest for many safety properties. For example, $u'$ can represent a ‘bad state’ and the goal is to know if reaching such a state is possible.

6.1 Fault-tolerance and Consistency

Fault tolerance is the property that ensures a system to continue operating properly in the event of the failure; consistency means that a local failure does not propagate to the entire system. In $\mathcal{R}$, this means that if a store becomes inconsistent, it is not the case that such an inconsistency spreads to the entire system. Of course, inconsistencies can appear in other stores due to some unrelated reasons.

Finding an inconsistent store can be logically formulated by the following model-theoretic satisfaction:

$$\mathcal{T}_\mathcal{R} \models (\exists \overline{\theta}, i \in [1..k]) \ t(\phi_1, \ldots, \phi_n) \xrightarrow{\mathcal{R}} u(\psi_1, \ldots, \psi_k) \wedge \text{unsat}(\psi_i).$$
Answering this query in the positive would mean that from some initial state satisfying the pattern \(t(\phi_1, \ldots, \phi_n)\), there is a state in which a store becomes inconsistent.

Such queries can be easily implemented with the help of \(R\) and the rewriting modulo SMT approach by using Maude's `search` command. As an example, consider the following `search` command:

```
search in SCCP :
  ( [store, root, true]
    [store, s 0 . root, X:Integer === 25]
    [store, 0 . root, true]
    [store, 0 . s 0 . root, Y:Integer < 5]
    [process, 0 . root, xtr(0, < s 0 > [tell (Z:Integer >= 10) ||
          < 0 >[ask Y:Integer < 20 -> xtr(0,xtr(s 0,  
          < 0 >[< s s 0 >[tell (W:Integer < Y:Integer)])])])]) ]
=>* { [store, A:Aid, B:Boolean, B0:Boolean] C:Cnf } such that check-unsat(B0:Boolean).
```

Note that a store is inconsistent if it is unsatisfiable, thereby checking whether a store is inconsistent is accomplished with the function `check-unsat`. The aforementioned command generates the following output:

```
No solution.
states: 19 rewrites: 1103 in 104ms cpu (101ms real)
(10605 rewrites/second)
```

The command does not find an inconsistent store in the 19 reachable states. However, it is possible to make a store inconsistent by adding inconsistent information, for example \(Z \geq 10\) and \(Z = 9\) by changing the process `tell(Z >= 10)` to `tell(Z >= 10) || tell(Z == 9)`: 

Solution 1 (state 14)
```
states: 15 rewrites: 678 in 76ms cpu (76ms real)
(8921 rewrites/second)
```

```
C:Cnf --> [process,s 0 . root,< 0 >[ask Y:Integer < 20 ->
    xtr(0,xtr(s 0,< 0 >[< s s 0 >[tell (W:Integer < Y:Integer)])]])])
    [store,root,true]
    [store,0 . root,X:Integer == (25).Integer]
    [store,0 . s 0 . root,Y:Integer < 5]
A:Aid --> s 0 . root
B0 --> Z:Integer >= (10).Integer and Z:Integer == (9).Integer
```

Solution 16 (state 54)
```
states: 55 rewrites: 3160 in 300ms cpu (299ms real)
(10533 rewrites/second)
```

```
C:Cnf --> [store,root,true]
```
6.2 Knowledge Inference

Knowledge inference refers to acquiring new knowledge from existing facts. In the setting of ${\mathcal{R}}$, this means that from a given initial state an agent, at some point, has gained enough information to infer – from the rules of first-order logic – new facts:

\[
T_{\mathcal{R}} \models (\exists \mathcal{P}, i \in [1..k]) \, \text{t}(\phi_1, \ldots, \phi_n) \rightarrow_{\mathcal{R}} \text{u}(\psi_1, \ldots, \psi_k) \land \psi_i \Rightarrow \tau,
\]

where $\tau$ is the formula representing the new fact and ‘$\Rightarrow$’ denotes logical implication. Answering the above query in the positive, means that from some initial state satisfying the pattern $t(\phi_1, \ldots, \phi_n)$ there is at least an agent as part of a configuration satisfying the pattern $u(\psi_1, \ldots, \psi_k)$ that has enough information to infer $\tau$.

Such queries can be easily implemented with the help of $\mathcal{R}$ and the rewriting modulo SMT approach by using Maude’s \texttt{search} command. As an example, consider the following \texttt{search} command:

\texttt{search in SCCP :}
\[
\{ [\text{store, root, true}] \\
[\text{store, root, X:Integer === 25}] \\
[\text{store, root, Y:Integer < 5}] \\
[\text{process, root, xtr(0, s 0 > [tell (Z:Integer >= 10) || xtr(0, xtr(s 0, 0) -> xtr(0, xtr(s 0, 0) & [tell (W:Integer < Y:Integer)])])])} ] \\
=>*
\]
\[
\{ [\text{store, A:Aid, B0:Boolean} ] \text{C:Cnf } \\
such that entails(B0:Boolean, Y:Integer > 9) .
\]

It checks if there is a state, reachable from the given initial state, in which some store logically implies $Y > 9$. The output below shows that such a state does not exist:
No solution.
states: 19 rewrites: 1535 in 116ms cpu (116ms real)
(13232 rewrites/second)

However, if the condition in the command is changed to find a store logically implying $Z > 9$, the query finds 8 solutions:

Solution 1 (state 4)
states: 5 rewrites: 318 in 28ms cpu (27ms real)
(11357 rewrites/second)
C:Cnf --> [process,s 0 . root,< 0 >[ask Y:Integer < 20 ->
 xtr(0,xtr(s 0,< 0 >[< s s 0 >[tell (W:Integer < Y:Integer)]
 ]))]
 [store,root,true]
 [store,0 . root,X:Integer === (25).Integer]
 [store,0 . s 0 . root,Y:Integer < 5]
A:Aid --> s 0 . root
B0:Boolean --> Z:Integer >= (10).Integer

...

Solution 8 (state 18)
states: 19 rewrites: 1520 in 120ms cpu (120ms real)
(12666 rewrites/second)
C:Cnf --> [store,root,true]
 [store,0 . root,X:Integer === (25).Integer]
 [store,0 . s 0 . root,Y:Integer < 5]
 [store,s s 0 . 0 . root,W:Integer < Y:Integer]
A:Aid --> s 0 . root
B0:Boolean --> Z:Integer >= (10).Integer

No more solutions.
states: 19 rewrites: 1535 in 124ms cpu (121ms real)
(12379 rewrites/second)

6.3 Same Knowledge

Formally, this type of reachability query can be specified as follows for $R$:

$$T_R = (\exists \phi, i, j \in [1..k]) \ t(\phi_1, \ldots, \phi_n) \Rightarrow_R u(\psi_1, \ldots, \psi_k) \land \psi_i \Leftrightarrow \psi_j \land i \neq j,$$

where $\Leftrightarrow$ denotes logical equivalence. Answering this query in the positive means that two stores have gained the same knowledge.

As an example, consider the following Maude search command, querying for two stores having the same information when they are non-empty:

search in SCCP :
{ [store, root, true]
 [store, 0 . root, X:Integer === 25] }
Using Figure [3] is easy to check that it is never the case that there are two stores with the same information, which agrees with the output shown below.

No solution.
states: 19 rewrites: 3899 in 472ms cpu (471ms real)
(8260 rewrites/second)

Replacing the process tell(W < Y) with tell(Z > 9) leads to a state where two stores have the same information, namely, tell(Z > 9) and tell(Z >= 10). The output for the search command in this case is the following:

Solution 1 (state 18)
states: 19 rewrites: 3862 in 464ms cpu (462ms real)
(8323 rewrites/second)

Solution 2 (state 18)
states: 19 rewrites: 3914 in 472ms cpu (471ms real)
(8292 rewrites/second)

No more solutions.
states: 19 rewrites: 3917 in 472ms cpu (471ms real)
(8298 rewrites/second)
7 An SCCP+E-based Programming Environment Prototype

This section presents a programming environment prototype based on SCCP+E and whose executable semantics is given by \( \mathcal{R} \). The goal of this prototype is to provide programmers with the theoretical fundamentals and expressiveness of SCCP+E, an easy syntax, and a front-end to interact with \( \mathcal{R} \).

7.1 Syntax of the Programming Language

The syntax of the programming language is presented using the EBNF notation in Figure 6. A program \( \langle \text{system} \rangle \) has two sections: the header \( \langle \text{variables} \rangle \) and the body \( \langle \text{body} \rangle \). The former contains the variable declarations by a name \( \langle \text{id} \rangle \) and a type (viz., \text{Bool} and \text{Int}), it is not possible to declare two variables with the same name and different type. The latter contains an unsorted list of agents and processes, one per line, between the keywords ‘begin’ and ‘end’. Note that each line describing an agent or a process shall end with the character ‘.’. Since the purpose is to provide an easier way to write SCCP+E systems, it is possible to declare Boolean (as \text{Bool}) and integer (as \text{Int}) variables in order to make agents and processes expressions simpler.

7.2 Examples

The Example 3.4 can be represented in the programming language as follows:

\[
\begin{align*}
\text{var } & W, X, Y, Z \text{ Int} \\
\text{begin} & \\
\text{root } & ; \text{true } . \\
0 . & \text{root } ; X = 25 . \\
1 . & \text{root } ; \text{true } . \\
0 . & 1 . \text{root } ; Y < 5 . \\
[ x( [ \text{tell}(Z > 10) ] | [ \text{ask} Y < 20 -> x( [ [ \text{tell}(W < Y)]_2 ]_0 \\
) _1 ]_0 ]_1 )_0 ]_0 . \\
\text{end}
\end{align*}
\]

Note that every variable used in a constraint is declared or defined before the keyword \text{begin}, regardless of its type (\text{Bool} or \text{Int}). Since SCCP+E configurations are represented in Maude as a soup of agents and processes, the order in which these are defined does not matter. However, it is a good idea to define agents first for the ease of reading and self-documentation.

Example 5. Consider the following program,

\[
\begin{align*}
\text{var } & B0, B1 \text{ Bool} \\
\text{var } & X, C \text{ Int} \\
\text{var } & Y, B \text{ Int} \\
\text{begin} & \\
\text{ask } & \text{true } -> \text{tell}(X >= 5) .
\end{align*}
\]
\[ \langle \text{system} \rangle ::= \langle \text{variables} \rangle ^* \langle \text{body} \rangle \]
\[ \langle \text{variables} \rangle ::= \text{\'var\'} \langle \text{idList} \rangle + ('\text{Int}' | '\text{Bool}') \]
\[ \langle \text{idList} \rangle ::= \langle \text{id} \rangle (',' \langle \text{id} \rangle) ^* \]
\[ \langle \text{body} \rangle ::= \text{\'begin\'} \langle \text{line} \rangle + \text{\'end\'} \]
\[ \langle \text{line} \rangle ::= (\langle \text{agent} \rangle | \langle \text{process} \rangle) \text{\'\',} \]
\[ \langle \text{agent} \rangle ::= \langle \text{location} \rangle \text{\'\';} \langle \text{constraint} \rangle \]
\[ \langle \text{process} \rangle ::= \langle \text{tell} \rangle (\langle \text{constraint} \rangle \text{\'\'} \rangle \text{\'\'} \langle \text{process} \rangle \text{\'\'} \langle \text{ask} \rangle \langle \text{constraint} \rangle \text{\'\rightarrow\'} \langle \text{process} \rangle \text{\'\'} \langle \text{parallel} \rangle \langle \text{process} \rangle \text{\'\'} \langle \text{space} \rangle \langle \text{extrusion} \rangle \langle \text{variable} \rangle \langle \text{recursion} \rangle \]
\[ \langle \text{constraint} \rangle ::= \langle \text{boolean} \rangle \]
\[ \langle \text{location} \rangle ::= (\langle \text{integer} \rangle \text{\'\'.}) ^* \text{\'root\'} \]
\[ \langle \text{expression} \rangle ::= \langle \text{id} \rangle \langle \text{operator} \rangle (\langle \text{id} \rangle | \langle \text{integer} \rangle) \]
\[ \langle \text{operator} \rangle ::= \text{\'\>' | \'\<\' | \'\=' | \'=/=\' | \'\>=\' | \'\<=\'} \]
\[ \langle \text{boolean} \rangle ::= \text{\'true\'} | \text{\'false\'} \]
\[ \langle \text{integer} \rangle ::= [0-9]+ \]
\[ \langle \text{id} \rangle ::= [A-Z] [A-Z0-9]* \]

Fig. 6: Syntax of the programming language prototype.
This program shall be reduced to the final state showed in Figure 7. There are some points to recall:

– it is not necessary to include agents in the description of the system, because these can come of processes,
– the process \([\text{ask } Y < 3 \rightarrow r(1,v(1) || \text{tell}(false)) ]_1\) shall not be reduced due to the fact that \(Y < 3\) is not entailed by \(Y < X\), i.e., \(Y < 3 \nsubseteq Y < X\),
– the space of an agent can be represented by a boolean variable (\(\text{Bool}\)).

The provided programming environment is a graphical tool where a programmer can execute SCCP+E programs using the aforementioned programming language. This tool is developed with Python 3 and tkinter. Figure 8 shows an example of the tool’s GUI: it has a main window 8a where programs can be written. Once a valid program is written and executed, the final state of the SCCP+E system is shown on an auxiliary window 8b.

8 Related Work and Concluding Remarks

Rewrite-based executable semantics of process-based formalisms have been proposed before in the realm of rewriting logic and Maude (see, e.g., \[4,7,30\]). They
Fig. 8: Programming environment for the SCCP+E-based programming language.
are part of a larger set of formal interpreters developed over the years that have helped in exploring the features of rewriting logic as a semantic framework. The work presented here is a significant extension of the preliminary work initiated in [24]. In particular, this work adds support for the recursion and extrusion primitives present in SCCP⁺E. The related work in [2], presents an interpreter for epistemic and spatial modalities in Prolog.

This paper has presented a symbolic rewriting logic semantics – based on the rewriting modulo SMT approach – of SCCP⁺E [2,15,16]: a recent extension of the CCP model [26,28] with spaces and extrusion. The executable rewriting logic semantics follows the structural operational semantics of SCCP⁺E and implements the underlying constraint system using SMT-solving technology. As such, it offers a complete and sound decision procedure for symbolic reachability analysis in SCCP⁺E for existential formulas, that can be automatically mechanized in Maude. Several examples have been used to illustrate the main concepts and a programming environment prototype has been introduced. The novel idea of combining term rewriting and constrained data structures, as it is the case in the rewriting modulo SMT approach [23], is an active area of research. Ultimately, this approach strengthens with symbolic support the battery of techniques that can now be used to implement formal and symbolic executable semantics of languages in Maude.

As described in [21], there are several extensions and applications of the CCP model, e.g., the epistemic and spatial modalities, mobile behavior, linear and soft modalities, probabilistic behavior, and timed concurrent constraint programming. As future work, extensions of SCCP⁺E with probabilities and time are a promising line of research. Moreover, providing the rewriting logic semantics of such extensions can lead to interesting case studies for PMaude [1] and Real-Time Maude [22]. Finally, new case studies with applications to emergent systems such as cloud computing and social networks should be pursued with the help of the rewriting logic semantics presented in this work.
