ABSTRACT

Motivation: Super-resolution fluorescence microscopy, with a resolution beyond the diffraction limit of light, has become an indispensable tool to directly visualize biological structures in living cells at a nanometer-scale resolution. Despite advances in high-density super-resolution fluorescent techniques, existing methods still have bottlenecks, including extremely long execution time, artificial thinning and thickening of structures, and lack of ability to capture latent structures.

Results: Here we propose a novel deep learning guided Bayesian inference approach, DLBI, for the time-series analysis of high-density fluorescent images. Our method combines the strengths of deep learning and statistical inference, where deep learning captures the underlying distribution of the fluorophores that are consistent with the observed time-series fluorescent images by exploring local features and correlation along time-axis, and statistical inference further refines the ultrastructure extracted by deep learning and endues physical meaning to the final image. In particular, our method contains three main components. The first one is a simulator that takes a high-resolution image as the input, and simulates time-series low-resolution fluorescent images based on experimentally calibrated parameters, which provides supervised training data to the deep learning model. The second one is a multi-scale deep learning module to capture both spatial information in each input low-resolution image as well as temporal information among the time-series images. And the third one is a Bayesian inference module that takes the image from the deep learning module as the initial localization of fluorophores and removes artifacts by statistical inference. Comprehensive experimental results on both real and simulated datasets demonstrate that our method provides more accurate and realistic local patch and large-field reconstruction than the state-of-the-art method, the 3B analysis, including super-resolution imaging (LEDIG et al. 2016; Kim et al. 2016; Lim et al. 2017). Among different deep learning architectures, the generative adversarial network (GAN) (Goodfellow et al. 2014) achieved the state-of-the-art performance on single image super-resolution (SISR) (Ledig et al. 2016). However, there are two fundamental differences between the SISR and super-resolution fluorescence microscopy. First, the input of SISR is a downsampled (i.e., low-resolution) image of a static high-resolution image and the expected output is the original image, whereas the input of super-resolution fluorescence microscopy is a time-series of low-resolution fluorescent images and the output is the high-resolution image containing estimated locations of the fluorophores (i.e., the reconstructed structure). Second, the nature of SISR ensures that there are readily a huge amount of existing data to train deep learning models, whereas for fluorescence microscopy, there are only limited time-series datasets. Furthermore, most of these datasets do not have the ground-truth high-resolution images, which make supervised deep learning infeasible.

In this paper, we propose a novel deep learning guided Bayesian inference framework, DLBI, for structure reconstruction of high-resolution fluorescence microscopy. Our framework combines the strength of stochastic simulation, deep learning and statistical inference. To our knowledge, this is the first deep learning-based super-resolution...
fluorescent microscopy method. In particular, the stochastic simulation module simulates time-series low-resolution images from high-resolution images based on experimentally calibrated parameters of fluorophores and stochastic modeling, which provides supervised training data for deep learning models. The deep learning module takes the simulated time-series low-resolution images as inputs, captures the underlying distribution that generates the ground-truth super-resolutions images by exploring local features and correlation along time-axis of the low-resolution images, and outputs a predicted high-resolution image. To achieve this goal, we develop a generative adversarial network (GAN) in which a generator network and a discriminator network contest with each other. The generator network tries to learn the distribution of the high-resolution images in a multi-scale manner, whereas the discriminator network tries to discriminate the ground-truth images and the images produced by the generator network. In order to capture the deep features in the images, we further ease the degradation issue by integrating residual networks into our GAN model, where degradation means that stacking more network layers does not lead to better accuracy. The high-resolution image produced by the deep learning module is often very close to the ground-truth image. However, it can still contain some artifacts, and more importantly, lacks the physical meaning. Thus, we develop the Bayesian inference module to take the predicted high-resolution image from deep learning, run Bayesian inference from the initial locations of fluorophores in the predicted image, and predict a more accurate high-resolution image.

Comprehensive experimental results on two simulated and three real-world datasets demonstrate that DLBI provides more accurate and realistic local-patch as well as large-field reconstruction than the state-of-the-art method, the 3B analysis. Meanwhile, our method is more than 100 times faster than the 3B analysis.

2 MATERIALS AND METHODS

As shown in Fig. 1, DLBI contains three modules: (i) stochastic simulation (Section 2.1), (ii) deep neural networks (Section 2.2), and (iii) Bayesian inference (Section 2.3).

![Fig. 1: The overall workflow of DLBI. The three modules are shown in solid boxes: the simulation module (green), the deep learning module (red), and the Bayesian inference module (blue). The training (orange) and testing (purple) procedures are shown in dashed boxes. For training, time-series low-resolution images simulated from the simulation module are used to train the deep learning module in a multi-scale manner, from 2X, 4X, to 8X resolution. For testing, given certain time-series low-resolution images, the deep learning module predicts the 2X to 8X super-resolution images, and the Bayesian inference module takes the predicted 8X image (which contains artifacts) and produces the final high-resolution image.](image)

Although deep learning has proved its great superiority in various fields, it has not been used for fluorescent microscopy image analysis. One of the possible reasons is the lack of supervised training data, which means the number of time-series low-resolution image datasets is limited and even for the existing datasets, the ground-truth high-resolution images are often unknown. Here, a stochastic simulation based on the experimentally calibrated parameters is designed to solve this issue, without the need of collecting a massive amount of real fluorescent images. This empowers our deep neural networks to effectively learn the latent structures under the low-resolution, high-noise and stochastic fluorescing conditions. The primitive super-resolution images produced by deep neural networks still contain artifacts and lack physical meaning, we finally develop a Bayesian inference module based on the mechanism of fluorophore switching to produce high-confident images.

Our method combines the strength of deep learning and statistical inference, where deep learning captures the underlying distribution that generates the training super-resolution images by exploring local features and correlation along time-axis, and statistical inference removes artifacts and refines the ultrastructure extracted by deep learning, and further endues physical meaning to the final image.

2.1 The stochastic simulation module

The input of our simulation module is a high-resolution image that depicts the distribution of the fluorophores and the output is a time-series of low-resolution fluorescent images with different fluorescing states. We refer the readers to Section S1 for terminologies in fluorescence microscopy.

In our simulation, Laplace-filtered natural images and sketches are used as the ground-truth high-resolution images that contain the fluorophore distribution. If a gray-scale image is given, the depicted shapes are considered as the distribution of fluorophores and each pixel value on the image is considered as the density of fluorophores at the location. We then create a number of simulated fluorophores that are distributed according to the distribution and the densities. For each fluorophore, it switches according to a Markov model, i.e., among states of emitting (activated), not emitting (inactivated), and bleached. The emitting state means that the fluorophore emits photons and a spot according to the point spread function (PSF) is depicted on the canvas. All the spots of the emitting fluorophores thus result in a high-resolution image. Applying the Markov model on the initial high-resolution image generates a time-series of high-resolution images. After adding the background to the high-resolution images, they are downsampled to low-resolution images and noise is finally added. Fig. 2 summarizes the stochastic simulation procedure.

Here, the success of simulation relies on three factors: (i) the principal of the linear optical system, (ii) experimentally calibrated parameters of fluorophores, and (iii) stochastic modeling.

2.1.1 Linear optics A fluorescence microscope is considered as a linear optical system, in which the superposition principle is valid, i.e., Image(Obj1 + Obj2) = Image(Obj1) + Image(Obj2). The behavior of fluorophores is considered invariant to mutual interaction. Therefore, for high-density fluorescent images, the pixel density can be directly calculated from the light emitted from its surrounding fluorophores.

When a fluorophore is activated, an observable spot can be recorded by the sensor, the shape of which is called the point spread function (PSF). Considering the limitation of sensor capability, the PSF of an isotropic point source is often approximated as a Gaussian function:

\[
I(x, y) = I_0 \exp\left(-\frac{1}{2\sigma^2}((x-x_0)^2 + (y-y_0)^2)\right),
\]

where \(\sigma\) is calculated from the fluorophore in the specimen that specifies the width of the PSF, \(I_0\) is the peak intensity and is proportional to the
photon emission rate and the single-frame acquisition time, \((x_0, y_0)\) is the location of the fluorophore.

While PSF describes the shape, the full width at half maximum (FWHM) describes the distinguishability. It is defined to be the half width of the maximum amplitude of PSF. If PSF is modeled as a Gaussian function, the relationship between FWHM and \(\sigma\) is given by

\[
\text{FWHM} = 2 \sqrt{2 \ln 2} \sigma = 2.355 \sigma. \tag{2}
\]

Considering the probability of linear optics, a high-density fluorescent image is composed by PSFs of the fluorophores.

2.1.2 Calibrated parameters of fluorophores In most imaging systems, the characteristics of a fluorescent protein can be calibrated by experimental techniques. With all the calibrated parameters, it is not difficult to describe and simulate the fluorescent switching of a specialized protein.

The first characteristic of a fluorophore is its switching probability. A fluorophore always transfers among three states, emitting, not emitting and bleached, which can be specified by a Markov model (Fig. 3). If the fluorophore transfers from not emitting to bleached, it will not emit any photon anymore. As linear optics, each fluorophore’s transitions are assumed to be independent.

In our simulation, a log-normal distribution \(\text{Cox et al., 2012; Zhu et al., 2012}\) is used to approximate the experimentally measured single fluorophore photon number distribution. Firstly, a table of fluorophore's experimentally calibrated FWHM parameters is used to initialize the PSF table in our simulation, according to Eq.1 and Eq.2. Then for each fluorophore recorded in the high-resolution image, the state of the current image frame is calculated according to the transfer table \([P1, P2, P3, P4, P5]\) (Fig. 3) and a random PSF shape is produced if the corresponding fluorophore is at the “emitting” state. This procedure is repeated for each fluorophore, which results in the final fluorescence image.

2.1.3 Stochastic modeling The illumination of real-world objects is different at different time. In general, the illumination change of real-world objects can be suppressed by high-pass filtering with a large Gaussian kernel. However, this operation will sharpen the random noise and cannot remove the background (or DC offset). To make our simulation more realistic, several stochastic factors are introduced. First, for a series of simulated fluorescent images, a background value calculated from the multiplication between a random strength factor and the average image intensity is added to the fluorescent images to simulate the DC offset. For the same time-series, the strength factor remains unchanged but the background strength changes with the image intensity. Second, the high-resolution fluorescent image is downsampled and random Gaussian noise is added to the low-resolution image. Here, the noise is also stochastic for different time-series and close to the noise strength that is measured from the real-world microscopy.

The default setting of our simulation takes a 480 × 480 pixel high-resolution image as the input and simulates 200 frames of 60 × 60 pixel (i.e., 8x binned) low-resolution images.

2.2 The deep learning module

We build a deep residual network under the generative adversarial network (GAN) framework \(\text{Goodfellow et al., 2014; Ledig et al., 2016}\) to estimate the primitive super-resolution image \(I_{HR}\) (the latent structure features) from time-series of low-resolution fluorescent images \(T = [I_{HR}^{1}, I_{HR}^{2}, \ldots, I_{HR}^{K}]\). Instead of building just one generative model, our approach builds a pair of models, a generator model, \(G\), which produces the estimation of the underlying structure of the training images, and a discriminator model, \(D\), which is trained to distinguish the reconstructed super-resolution image from the ground-truth one. Fig. 4 demonstrates the overview of our deep learning framework.

For the discriminator network \(D\), \(D(x)\) represents the probability of the data being the real high-resolution image rather than from \(G\). When training \(D\), we try to maximize its ability to differentiate ground-truth from the generated image, to force \(G\) to learn better details. When training \(G\), we try to minimize \(\log(1 - D(G(T_n, \theta_G), T_n))\), which is the log likelihood of \(D\) being able to tell that the image generated by \(G\) is not ground-truth. That is, we minimize the following function:

\[
\min_{\theta_G} \max_{\theta_D} \mathbb{E}_{P_{HR}}[\log(D(I_{HR}, \theta_D))] + \mathbb{E}_{P_{LR}}[\log(1 - D(G(T_n, \theta_G), \theta_D))]. \tag{4}
\]

In this way, we force the generator to optimize the generative loss, which is composed of perceptual loss, content loss and adversarial loss (more details of the loss function will be introduced in Section 2.2.2).

2.2.2 Model architecture Our network is specialized for the analysis of time-series images through: (1) 3D filters in the neural network that...
take all the image frames into consideration, which extracts the time-dependent information naturally, (2) two specifically designed modules in the generator residual network, i.e., Monte Carlo dropout \cite{Gal2015} and denoise shortcut, to cope with the stochastic switching of fluorophores and random noise, and (3) a novel incremental multi-scale architecture and parameter tuning scheme, which is designed to suppress the error accumulation in large upsampling factor neural networks.

2.2.3 Model training and testing GAN is known to be difficult to train \cite{Salimans2016}. We use the following techniques to obtain stable models. For the generator model, we do not train GAN immediately after initialization. Instead, we pretrain the model. During the pretrain process, we minimize the mean squared error between the super-resolution image and the ground-truth, i.e., with the pixel-wise MSE loss as

\[
    l_{MS E}^{SR}(I_{SR}) = \frac{1}{\mu^2 WH} \sum_{y} \sum_{x} (G(T, \theta_{G}))_{y,x} - (H_{SR})_{y,x}^2, \tag{5}
\]

where \( W \) is the width of the low-resolution image, \( H \) is the height of the low-resolution image, and \( \mu = 2,4,8 \) is the upsampling factor. During pretraining, we optimize \( l_{MS E}^{SR}, l_{G}^{SR}, l_{D}^{SR} \) simultaneously, instead of optimizing the sum of them.

Only after the model has been well-pretrained do we start training the GAN. During that process, we also use VGG19 \cite{Simonyan2014} to implement the high-confidence super-resolution image embedding (Section S2), element-wise. At the end of the first layer to suppress noise. To further alleviate the noise issue, we use another technique, the denoise shortcut. It is similar to the identical shortcut in the residual network block. However, instead of being exactly the same as the input, we set each channel of the input feature map as the average of all the channels. The denoise shortcut is added to the output of the convolutional layer, which is after 16 residual blocks (Section S2), element-wise. After this feature map extraction process, we use a pixel shuffle layer combined with the convolutional layer to increase the dimensionality of the image gradually (upsampling Conv X2 in Fig. 5).

Here we adopt a novel multi-scale tuning process to stabilize the 8× images. As shown in Fig. 5, our generator can output and thus calculate the training error of multi-scale super-resolution images, ranging from 2× to 8×, which means that our model has multiple training interfaces for back propagation. Thus during training, we use the 2×, 4×, 8× high-resolution ground-truth images to train the model simultaneously, instead of introducing too much fake detail.

For the discriminator network, we adopt the traditional convolutional neural network, which contains eight convolutional layers, one residual block and one sigmoid layer (Section S2). The convolutional layers increase the number of channels gradually to 2048 and then decrease it using 1 by 1 filters. Those convolutional layers are followed by a residual block, which further increases the model ability of extracting features. Section S2 provides detailed descriptions of the generator and discriminator networks.

As shown in Fig. 5, a fluorophore has three states: emitting (light), not emitting and bleached. In classic Bayesian-based time-series analysis, the switching procedure of fluorophores is limited in pixels. We use Tensorflow combined with TensorLayer \cite{Dong2017} to implement the deep learning module. Trained on a workstation with one Pascal Titan X, the model gets converged in around 8 hours.

### 2.3 The Bayesian inference module

Our Bayesian inference module takes both the time-series low-resolution images and the primitive super-resolution image produced by the deep learning module as inputs, and generates a set of optimized fluorophore locations, which are further interpreted as a high-confidence super-resolution image. Since the deep learning module has already depicted the ultrastructures in the image, we use these structures as the initialization of the fluorophore locations, re-sampling with a random punishment against artifacts. For each pixel, we re-sample the fluorophore intensity by \( \sqrt{\lambda_{ij}} \) and the location by \((x, y) \pm rand(x, y)\), where \( \lambda_{ij} \) is the pixel value in the image produced by deep learning, \( rand(x, y) \) is limited in a8. In this way, the extremely high illumination can be suppressed and fake structures will be re-estimated.

#### 2.3.1 Basic concepts

As shown in Fig. 5, a fluorophore has three states: emitting (light), not emitting and bleached. In classic Bayesian-based time-series analysis, the switching procedure of fluorophores is modeled by Bayesian inference, i.e., given an observed region \( R \), deciding
whether there is a fluorophore \((F)\) or not \((N)\) by

\[
P(F|R) = \frac{P(R|F)P(F)}{P(R|F)P(F) + P(R|N)P(N)},
\]

where \(P(F)\) and \(P(N)\) are constants which are based on experimental prior, \(P(R|F)\) is the probability of the observed data region \(R\) given the location of the fluorophore, \(P(R|N)\) is the probability of the observed data region \(R\) if there is no fluorophore, which can be calculated by integrating all the probability of observing pixels given the noise model.

For a single fluorophore, the switching procedure can be modeled by a hidden Markov model (HMM) \((\text{Ribnitz}1989)\), as shown in Fig. 6A. However, for high-density fluorophores, each fluorophore transfers the state independently with a stable probability \((\text{Cox et al.} 2012)\) and all the fluorophores together can be modeled by a factorial hidden Markov model (FHMM) \((\text{Shahram and Jordan} 1998)\), as shown in Fig. 6B, which has been used and proved in \((\text{Xu et al.} 2017)\).

2.3.2 Refining results with physical meaning Although HMM and FHMM are capable of modeling the fluorophore switching process, they are localization-guided, which often ignore the global information, and are computationally expensive to learn. Thus, we initialize the fluorophores’ locations by using the image generated by deep learning and use Bayesian inference to further refine the results.

We apply the FHMM model to deal with high-density fluorescent microscopy. The parameters of FHMM are estimated by the expectation-maximization (EM) algorithm:

\[
Q(\phi^{\text{new}}|\phi) = E \left[ \log P \left( \{ F_i, D_i \} | \phi^{\text{new}} \} | \phi_i(D_i) \right) \right],
\]

where the observation sequence has \(T\) frames, \(\{D_i\}, i = 1, \ldots, T\). The hidden states are \(\{F_i\}\), where each fluorophore has three possible states in the model. \(Q\) is a function of the fluorophore parameters \(\phi^{\text{new}}\) given the current parameter estimation and the observation sequence \(\{D_i\}\). The procedure iterates between a step that fixes the current parameters and computes posterior probabilities over the hidden states \((\text{E-step})\), and a step that uses these probabilities to maximize the expected log likelihood of the observations as a function of the parameters \((\text{M-step})\).

In the E-step, we fix the fluorophore parameters in the model and utilize the hybrid of Markov chain Monte Carlo and forward algorithm to sample the initial model. When a new fluorophore is determined, we take samples of this fluorophore using the forward filtering backward sampling algorithm \((\text{Godsil et al.} 2004)\). Thus, the sampled image sequence contains this fluorophore. In the M-step, we optimize the fluorophore parameters and find the maximum a posteriori (MAP) fluorophore positions using the conjugate gradient. Then, based on already known positions of fluorophores, the surrounding fluorophores with high probability are expended. The final super-resolution image is obtained by iterating these two steps until convergence.

The detailed method description and parameter setting are given in Section S3.

3 EXPERIMENTAL RESULTS

3.1 Training deep learning To train our deep learning module, the stochastic simulation module was used to simulate time-series low-resolution images from 12000 grayscale high-resolution images. These images were downloaded from two databases: (i) 4000 natural images were downloaded from ILSVRC \((\text{Russakovsky et al.} 2015)\) and Laplace filtered, and (ii) 8000 sketches were downloaded from the Sketchy Database \((\text{Sangkloy et al.} 2016)\).

Note that our simulation is a generic method, which does not depend on the type of the input images. Thus any gray-scale image can be interpreted as the fluorophore distribution and used to generate the corresponding time-series low-resolution images.

To initialize all the weights of the deep learning models, we used the random normal initializer with the mean as 0 and standard deviation as 0.02. As for the Monte Carlo dropout layer, we set the keep ratio as 0.8.

In terms of the Adam optimizer \((\text{Kingma and Ba} 2014)\), we followed the setting in \((\text{Li et al.} 2018)\) and \((\text{Dai et al.} 2017)\) and set the learning rate as \(1 \times 10^{-4}\) and the beta1, which is the exponential decay rate for the first moment estimates, as 0.9. During training, we set the batch size as 8, the initialization training epoch as 2 and the GAN training epoch as 40. When performing the real GAN training, we utilized the learning rate decay technique, reducing the learning rate by half every 10 epochs.

3.2 Evaluation datasets Two simulated datasets and three real-world datasets are used to evaluate the performance of the proposed method. Simulated datasets are used due to the availability of ground-truth.

The first two datasets are simulated datasets, for which the ground-truth (i.e., high-resolution images) is downloaded from the Single Molecule Localization Microscopy (SMLM) challenge \((\text{Sage et al.} 2015)\). The two datasets correspond to two structures: MT0.N1.HD (abbr. MT) and Tubulin ConJAl647 (abbr. Tub). For each structure, single molecule positions were downloaded and then transformed to fluorophore densities according to Section 2.1. For simulation, the photo-convertible fluorescent protein (PCFP) mEos3.2 \((\text{Zhang et al.} 2012)\) and its associated PSF, FWHM and state transfer table were used. For the convenience of calculation, we cropped the large-field structure into four separate areas, each with 480 \(\times 480\) pixels \((1px = 20nm)\). For each high-resolution image, 200 frames of low-resolution fluorescent images were generated, each with \(60 \times 60\) pixels.

The third dataset is a real-world dataset, which was used in recent work \((\text{Xu et al.} 2017)\). The actin was labeled with mEos3.2 \(^3\) in U2OS cells (abbr. Actin1) and taken with an exposure time of 50 ms per image frame. The actin network is highly dynamic and exhibits different subtype structures criss-crossing at various distances and angles, including stress fibers and bundles with different sizes and diameters. The dataset has 200 frames of high-density fluorescent images, each with \(249 \times 395\) pixels \((1px = 160nm)\) in the green channel. This is a good benchmark set that has been well tested which can compare our method with SIMBA \((\text{Xu et al.} 2017)\), a recent Bayesian approach based on dual-channel imaging and photo-convertible fluorescent proteins.

Two other real-world datasets labeled with mEos3.2 were also used. One is an actin cytoskeleton network (abbr. Actin2), which is labeled and taken under a similar exposure condition with Actin1, but is completely new and has not been used by previous works. The other one is an Endoplasmic reticulum structure (abbr. ER), which has a more complex structure. It is a type of organelle that forms an interconnected network of flattened, membrane-enclosed sacs or tubes known as cisternae, which exhibits different circular-structures and connections at different scales.

\(^3\) http://bigwww.epfl.ch/smlm/datasets/

\(^4\) For the convenience of cellular labeling and instrument setup, here all the experiments were carried out by mEos3.2.
For the ER dataset, the exposure time is 6.7 ms per frame. The resolution of each image in Actin2 is 263 × 337 pixels (1 px = 160 nm) and that in ER is 256 × 170 pixels (1 px = 100 nm). Both datasets have 200 frames of high-density fluorescent images and the same photographing parameters as Actin1. These datasets were used to demonstrate the power of our method in diverse ultrastructures. The detailed procedure for collecting the real-world datasets is given in Section S4.

Since the 3B analysis (Cox et al., 2012) is one of the most widely used high-density fluorescent super-resolution techniques, which can deal with high temporal and spatial resolutions (Lida et al., 2012; Cox et al., 2012), it was chosen to compare with our method.

3.3 Performance on simulated datasets

3.3.1 Visual performance Fig. 7 shows the visualization of the ground-truth high-resolution images, representative low-resolution input images, the reconstruction results of the 3B analysis, and the results of our method on the simulated datasets. Due to the space limitation, we illustrate three representative areas of each dataset and leave the fourth in Section S5.

As shown in Fig. 7, the ground-truth images have very clear structures while the low-resolution image frames are very blurry and noisy (8× downsampled). To reconstruct the ultrastructures, we ran the 3B analysis with 240 iterations and ran our Bayesian inference module after the deep learning module with 60 iterations. In each iteration, the Bayesian inference module of our method searches four neighbor points for each fluorophore, whereas the 3B analysis takes isolated estimation strategy. Thus the difference in iteration numbers is comparable. Due to the high computational expense of the 3B analysis, each 60 × 60 image was subdivided into nine overlapped subareas for multi-core process, whereas for our method, the entire image was processed by a single CPU core.

It is clear that the reconstructions of our method are very similar to the ground-truth in terms of smoothness, continuity, and thickness. On the other hand, the reconstructions of the 3B analysis consist of a number of interrupted short lines and points with thin structures. In general, two conclusions can be drawn from the visual inspection.

First, DLBI discovered much more natural structures than the 3B analysis. For example, in the bottom part of Fig. 7(B), there are two lines overlapping with each other and a bifurcation at the tail. Due to the very low resolution in the input time-series images (e.g., Fig. 7(H)), neither DLBI nor the 3B analysis was able to recover the overlapping structure. However, DLBI reconstructed the proper thickness of that structure (Fig. 7(T)), whereas the 3B analysis only recovered a very thin line structure (Fig. 7(N)). Moreover, the bifurcation structure was reconstructed naturally by DLBI. Similar conclusions can be drawn on the more complex structures in the Tub dataset (columns 4-6 in Fig. 7).

Second, DLBI discovered much more latent structures than the 3B analysis. The Tub dataset consists of a lot of lines (tubulins) with diverse curvature degrees (Fig. 7(D),(E),(F)). The reconstructions of the 3B analysis successfully revealed most of the tubulin structures but left the crossing parts interrupted (Fig. 7(P),(Q),(R)). As a comparison, the reconstruction results of DLBI recovered both the line-like tubulin structures and most of the crossing parts accurately (Fig. 7(V),(W),(X)).

3.3.2 Quantitative performance For single-molecule super-resolution fluorescence microscopy, the quantitative performance has been measured by assessing the localization accuracy of single-emitters in each frame (Ram et al., 2006; Small, 2009; Huang et al., 2011). For high-density super-resolution fluorescence microscopy, the entire time-series are analyzed and the production is the probability map of the locations of fluorophores.

Table 1. Performance comparison between the 3B analysis and DLBI on the four areas of the two simulated datasets in terms of peak signal-to-noise ratio (PSNR) and structural similarity (SSIM). The best performance is shown in bold.

Since the ground-truth is known for the simulated datasets, here we use peak signal-to-noise ratio (PSNR) and structural similarity (SSIM) to measure the reconstruction performance, both of which are widely-used criteria for image reconstruction in computer vision. The performance of the 3B analysis and DLBI on the two simulated datasets are given in Table 1. Here, we denote the four areas (Section 3.2) of each dataset as...
“01”, “02”, “03” and “04”, respectively. It can be seen that DLBI clearly outperforms the 3B analysis in terms of both PSNR and SSIM on all the areas of the two datasets.

### 3.4 Performance on real datasets

Fig. 8 shows the first frame of the time-series fluorescent images for each of the three real-world datasets. Here we evaluate the performance of our method for both local-patch reconstruction (areas selected by green rectangles) and large-field reconstruction (areas selected by yellow rectangles).

**3.4.1 Local-patch reconstruction** Fig. 8 shows the first frames of the low-resolution images of the three local-patches, and the reconstruction results of the 3B analysis and DLBI. The regions of interests of the selected patches are (60, 60, 60, 60), (120, 120, 60, 60) and (60, 60, 60, 60) for the three datasets, respectively.

The temporal resolutions for the two actin datasets and the ER dataset were 10s and 1.34s respectively, according to the exposure time of the image frames.

It can be seen that the reconstruction results of the 3B analysis capture the main structures in the fluorescent images, but mainly consist of isolated high-illuminating spots, with details being interrupted (Fig. 8(D),(E),(F)). In contrast, the results of DLBI recover most of the latent ultrastructures, and the reconstructed structures have well-estimated fluorophore distribution and continuous depiction (Fig. 8(G),(H),(I)).

**Table 2.** Performance comparison between the 3B analysis and DLBI on the real datasets in terms of RSP and RSE with SQUIRREL. The higher RSP and lower RSE values, the higher the image quality is. The best performance is shown in bold.

We further assessed the reconstruction quality of the 3B analysis and DLBI by SQUIRREL (super-resolution quantitative image rating and reporting of error locations) (Calley et al. 2018). SQUIRREL compares the diffraction-limited image (the reference image) and the reconstructed equivalents to generate a quantitative map, in which two scores are calculated: the resolution-scaled Pearson coefficient (RSP) and the resolution-scaled error (RSE). The higher RSP and lower RSE values, the higher the image quality is. Table 2 shows the RSP and RSE scores for the 3B analysis and DLBI. It is clear that DLBI significantly outperforms the 3B analysis. More detailed comparisons are given in Section S5.3.

**3.4.2 From deep learning to Bayesian inference** Our method combines the strength of deep learning guided Bayesian inference, where deep learning captures both local features in the images and the time-course correlation, and statistical inference removes artifacts from deep learning and enhances physical meaning to the final results. Conceptually, this is equivalent to using the power of deep learning to automatically and systematically explore and extract spatial and temporal features, and taking advantages of the explicit and rigorous mathematical foundation of probabilistic graphical models. Here we investigate the effectiveness of this combination.

Fig. 10 demonstrates the outputs of the deep learning module and the Bayesian inference module. It can be seen that the super-resolution images outputted from the deep learning module are very close to the final images from the Bayesian inference module, except for some artifacts and false structures. This is due to two reasons: (i) the abundance of training data provided by our simulation module, which are simulated under the real experimentally-calibrated parameters, enable deep learning to effectively learn spatial and temporal features; and (ii) the high diversity of biological structures is still a challenge, which causes the artifacts and false structures to be learned by deep learning.

for the Actin2 and ER datasets, these structures were further corrected by the Bayesian inference module.

3.4.3 Runtime analysis After being trained, running the deep learning model is very computationally inexpensive. Furthermore, the results of deep learning provide a close-to-optimal initialization for Bayesian inference, which also significantly reduces trial-and-error and leads to faster convergence. Fig. 11 shows the runtime comparison of the deep learning module, the entire DLBI pipeline, and the 3B analysis on the nine reconstruction tasks (i.e., the six areas of the simulated datasets shown in Fig. 7 and the three local patches of the real datasets shown in Fig. 8). It can be seen that the runtime for the deep learning module ranges between 1 to 3 minutes and that of DLBI ranges between 30 to 40 minutes. In contrast, the runtime for the 3B analysis is around 75 hours, which is more than 110 times higher than that for DLBI. Our results have demonstrated that the super-resolution images from the deep learning module alone is a good estimation to the ground-truth. Therefore, for users who value time and can compromise accuracy, the results from the deep learning module provide a good tradeoff, and thus a good estimation of the ground-truth.

![Fig. 11: Runtime comparison of the deep learning module (DN), the entire DLBI pipeline (DLBI), and the 3B analysis (3B) on the nine reconstruction tasks (i.e., the six areas of the simulated datasets shown in Fig. 7 and the three local patches of the real datasets shown in Fig. 8). The runtime was measured on a Fedora 25 system with 128 Gb memory and E5-2667v4 (3.2 GHz) CPU.](image)

3.4.4 Large-field reconstruction To analyze a dataset with 200 frames, each with about 200 × 300 pixels, it takes our method about 7 ~ 10 hours on a single CPU core. Therefore, our method is able to achieve large-field reconstruction on the yellow areas shown in Fig. 8. Fig. 12 shows the large-field reconstruction images of the three real datasets. For the Actin1 dataset, the selected area is 200 × 300 pixels and the reconstructed super-resolution image is 1600 × 2400 pixels. For the Actin2 dataset, the selected area is 250 × 240 pixels and the reconstructed image is 2000 × 1920 pixels. And for the ER dataset, the selected area is 200 × 150 pixels and the reconstructed image is 1600 × 1200 pixels.

As shown in Fig. 12(A) and (B), the actin networks in the two datasets have been successfully recovered by DLBI. The thinning and thickening trends of the cytoskeleton have been clearly depicted, as well as the small latent structures, including actin filaments, actin bundles and ruffles. For the endoplasmic reticulum structure (Fig. 12(C)), the circular-structures and connections of the cytoskeleton have also been accurately reconstructed.

For the Actin1 dataset, the single-molecule reconstruction of the red channel is available (Fig. 12(D)). This reconstruction was produced by PALM (Hess et al., 2006) using 20,000 frames, whereas the reconstruction image of DLBI (Fig. 12(A)) used only 200 frames. We further overlaid the image produced by DLBI with that of PALM to check how well they overlap (Fig. 12(E)). It is clear that the main structures of the two images almost perfectly agree with each other. In addition, our method was able to recover the latent structure on the top-left part which was not photographed by PALM due to out of range of views in dual-channel photographing. If we carefully check the original low-resolution fluorescence images, we could find that this predicted structure indeed exists, which is consistent with our reconstruction.

4 DISCUSSION AND CONCLUSION

In this paper, we proposed a deep learning guided Bayesian inference method for structure reconstruction of super-resolution fluorescence microscopy. Our method combines the strength of deep learning and statistical inference. We further overcame the high data requirement bottleneck of deep learning by a novel stochastic simulation module based on the experimentally-calibrated parameters and problem-specific physical models. It should be noted that although our simulation provides close-to-realistic data to train the deep learning module, it still contains bias and unrealistic parts, which will be learned by the deep learning module. Bayesian inference, on the other hand, can correct and refine the ultrastructure learned by deep learning, and thus enhance the physical meaning of the final super-resolution image.

We have comprehensively evaluated the quality of the reconstructed super-resolution images. The future work includes evaluating how well the framework can rediscover the parameters used in the simulation module.
