Abstract: The physics of transition of a smooth laminar flow to turbulence still poses a great challenge in physics. In this study, the singularity of Navier-Stokes equations is discovered through the derivation of the Navier-Stokes equations and the analysis of the velocity profile. This is for the first time that the singularity is found where the velocity is zero. It is the inflection point on the velocity profile that leads to the discontinuity and the instability. This singularity is the origin of the spanwise vortex and the genesis of the vortex head of the hairpin vortex formed afterwards. The singularity of the Navier-Stokes equations is the cause of turbulent transition and the inherent mechanism of sustenance of fully developed turbulence.

Key words: Navier-Stokes Equations; Singularity; Turbulent transition; Pressure driven flow; Inflection instability

1 Introduction

Turbulence is one of the most important scientific problems in physics. Reynolds pioneered the work for pipe flow in 1883, which proved that there are two types of flow states, laminar flow and turbulence [1]. Since then, substantial work has been done in theories, experiments and simulations on turbulence during the past 130 years or so. Although great progress has been made, the physical mechanism of turbulence is still poorly understood.

Over the years, it has been suggested that transition of laminar flow to turbulence is caused by the instability of laminar flow. The flow between two parallel plates is a classical flow problem. Heisenberg [2] obtained an approximate solution of the stability equation by the derivation of the linearized Navier-Stokes equations and gave the boundary of stability on
the diagram of wave number versus the Re number. Lin [3] proved by mathematical asymptotic analysis that the flow between the two parallel plates would be unstable and obtained the critical Re number to be 8000. However, whether or not turbulence would occur after flow instability setting in was not clarified. Orszag obtained the critical Re number to be 5772 by calculating with the spectral method [4]. This is the most accurate value recognized in the literature. However, the critical Re number of turbulent transition obtained from experiments is about 1000. This inconsistency between the theory and the experiment has been perplexing the understanding of turbulent transition [4-7].

A large quantity of experimental data and numerical calculations show that turbulence is a local phenomenon when it first starts [8-14]. With the increase of Re and the development of disturbance, the inflection point first appears on the velocity profile in laminar flow, followed by the formation of hairpin vortices which leads to the turbulence spots. During the transition, the velocity profile is subjected to a continuous modification [7,11,14-16]. It is found that the appearance of the velocity inflection point is a key step of turbulent transition [11-16] and recently experiment confirmed that turbulence is indeed sustained by an inflection point instability [13]. More studies indicate that there is a very large scale motions (VLSMs) in the outer layer of boundary layer and channel flows and they are related to the spanwise vortices and the velocity inflections [17-24].

Dou and co-authors proposed an energy gradient method for the study of flow stability and turbulent transition [25-33]. It is found that the inflection point on the velocity profile for the pressure driven flow is a singular point hidden in the Navier-Stokes equations. It is obtained for pressure driven flows that the necessary and sufficient condition for the turbulent transition is the existence of an inflection point on the velocity profile [25,27,29,30]. However, the characteristics of velocity change at the inflection point have not been given, and the discontinuity of flow parameters has not been accurately described.

Large quantities of theoretical, experimental and direct numerical simulation results show that the Navier-Stokes equations are the governing equations to correctly describe both the laminar flow and the turbulent flow. As such, the physical mechanism of turbulent transition should exist in the Navier-Stokes equations. The mechanism of turbulence generation should be consistent and unique, no matter what type of turbulence such as wall
bounded turbulence or free boundary turbulence.

There is discontinuity in the time-averaged Navier-Stokes equations during the transition from laminar flow to turbulence, as commonly observed from the drag coefficient [34-35]. It is very important to determine the mechanism of discontinuity in the equations from mathematics and physics, to understand the origin of turbulent transition as well as the mechanism of fully developed turbulence.

In this paper, the singularity of Navier-Stokes equations will be analyzed through the derivation of the Navier-Stokes equations and the analysis of the velocity profile for plane Poiseuille flow. The origin of turbulent transition and the mechanism of fully developed turbulence sustenance will then be discussed.

2 Discovering the Singularity of Navier-Stokes equations

The time-averaged Navier-Stokes equations of incompressible fluid are as follows for laminar and turbulent flows, respectively [34-35],

\[
\rho \left( \frac{\partial u}{\partial t} + u \cdot \nabla u \right) = -\nabla p + \mu \nabla^2 u . \tag{1}
\]

\[
\rho \left( \frac{\partial \bar{u}}{\partial t} + \bar{u} \cdot \nabla \bar{u} \right) = -\nabla p + \mu \nabla^2 \bar{u} + \nabla \cdot \tau_t , \tag{2}
\]

where \( \mu \) is the fluid dynamic viscosity, \( p \) is the static pressure, \( \rho \) is the fluid density, \( \bar{u} \) is the velocity vector, and \( \tau_t \) is the turbulent stress tensor.

Thus, it can be observed from Eqs.(1) and (2) that there is discontinuity from laminar flow to turbulence in the time-averaged Navier-Stokes equations due to existence of \( \tau_t \). Therefore, there must be a discontinuity in laminar flow from which the flow transits to turbulence (Fig.1). This discontinuity indicates that there is singularity in the time-averaged Navier-Stokes equations of the laminar flow.

For the pressure driven flow between two parallel walls (Fig.2), the continuity and the Navier-Stokes equations of the laminar flow for incompressible fluid can be written as follows by neglecting the gravitational force [34-35],

\[
\nabla \cdot \bar{u} = 0 . \tag{3a}
\]

\[
\rho \left( \frac{\partial \bar{u}}{\partial t} + \bar{u} \cdot \nabla \bar{u} \right) = -\nabla p + \mu \nabla^2 \bar{u} . \tag{3b}
\]
and the boundary condition is
\[ u = 0. \quad \text{(on the walls).} \quad (3c) \]

With the identity,
\[ u \cdot \nabla u = \nabla (\frac{1}{2} V^2) - u \times \nabla \times u. \quad (4) \]

The Eq.(3b) is rewritten as
\[ \rho \frac{\partial u}{\partial t} + \nabla E = \mu \nabla^2 u + \rho (u \times \nabla \times u). \quad (5) \]

Here, \( V \) is magnitude of the total velocity and \( E = p + \frac{1}{2} \rho V^2 \) is the total mechanical energy of unit volumetric fluid.

The Eq.(5) can be written as follow along the streamline direction,
\[ \rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} = \mu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) \quad (6) \]

For parallel flow, \( \frac{\partial^2 u}{\partial x^2} \ll \frac{\partial^2 u}{\partial y^2} \), \( \frac{\partial^2 u}{\partial x^2} \approx 0 \), Eq.(6) is rewritten as,
\[ \rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} = \mu \frac{\partial^2 u}{\partial y^2} \quad (7) \]

The omitting of the term \( \frac{\partial^2 u}{\partial x^2} \) from Eq.(6) to Eq.(7) will not affect the conclusions obtained in the following sections.

For incompressible flow, the total mechanical energy is constant along a streamline in inviscid flow, \( \frac{\partial E}{\partial x} = 0 \), while it will decrease along a streamline in viscous flow, \( \frac{\partial E}{\partial x} < 0 \), due to viscous friction. This statement is only correct for pressure driven flows, for example, plane Poiseuille flow and pipe Poiseuille flow [25]. For shear driven flow, this statement is not correct due to the input of external work, for example, in plane Couette flow [26, 28].

When there is an inflection point on the velocity profile, the flow status can be classified as the following three cases (Fig.3), (a) inflection point is not located at the wall; (b) inflection point is located at the wall; (c) inflection point is not located at the wall, but the velocity profile shows \( u'' > 0 \) at the wall. Here, \( u'' \) expresses the second derivative of the
velocity to $y$, $\frac{\partial^2 u}{\partial y^2}$.

In the following, the behavior of the inflection point is first analyzed for case (a), as shown in Fig.4. The incoming velocity profile is a laminar profile; for $y > 0$, $u > 0$ and $u'' < 0$ (Fig.4(a)).

With the flow forward, due to interaction of the disturbance with the streamwise velocity, inflection point may be produced on the velocity profile. Assuming that the inflection point is produced firstly at $y = y_A$, $u = u_A$, $u_A > 0$, $u_A'' = 0$ (Fig.4(b)). From Eq.(7), Eq.(8) is obtained at the inflection point,

$$\rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} = 0$$

(8)

Since there may be $\frac{\partial u}{\partial t} > 0$ or $\frac{\partial u}{\partial t} < 0$ in unsteady flow, there is at least one moment where $\frac{\partial E}{\partial x} = 0$ at $y = y_A$. According to the principle of viscous flow, $\frac{\partial E}{\partial x} = 0$ leads to $u_A = 0$.

However, the viscous term does not appear in Eq.(8) at the inflection point. Someone might argue that the flow at the inflection point is dominated by inviscid flow mechanism. As such, at the inflection point, $\frac{\partial E}{\partial x} = 0$ could not lead to the result of $u_A = 0$. In order to present a comprehensive insight, the following detailed derivations are shown.

Fig.4 shows how the velocity $u_A$ at $y = y_A$ varies with the time. Since the flow is unsteady, the position of the inflection point may have a minute (infinitely small) oscillation around $y = y_A$. When the inflection point has a minute displacement upward, for example, to position $B$ (Fig.4(c)), the second derivative of the velocity at $y = y_A$ will become $u_A'' > 0$. According to Eq.(7), we obtain Eq.(9) at $y = y_A$,

$$\rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} > 0$$

(9)
Since the flow is unsteady, there may be the both cases $\frac{\partial u}{\partial t} > 0$ and $\frac{\partial u}{\partial t} < 0$ at $y = y_A$.

Thus, Eq. (9) must lead to $\frac{\partial E}{\partial x} > 0$ at $y = y_A$, and therefore $u_A < 0$, as shown in Fig.4(c).

It is demonstrated above that when the inflection point moves upward from point A to point B, the velocity at $y = y_A$ changes from $u_A > 0$ to $u_A < 0$. Thus, there must be a moment where $u_A = 0$ during this time interval. This means that discontinuity appears at $y = y_A$ as shown in Fig.5.

When the inflection point has a minute displacement downward, for example, to position C (Fig.4(d)), the second derivative of the velocity at $y = y_A$ will become $u_A'' < 0$.

According to Eq.(7), Eq.(10) is obtained at $y = y_A$,

$$\rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} < 0$$

Since the flow is unsteady, there may be the both cases $\frac{\partial u}{\partial t} > 0$ and $\frac{\partial u}{\partial t} < 0$ at $y = y_A$.

Thus, this must lead to $\frac{\partial E}{\partial x} < 0$ at $y = y_A$, and therefore $u_A > 0$, as shown in Fig.4(d).

It is demonstrated above that when the inflection point moves downward from point A to point C, the velocity at $y = y_A$ keeps $u_A > 0$. In this case, there is no discontinuity at $y = y_A$.

In summary, in unsteady laminar flow, the position of the inflection point may move oscillationally around the initial inflection position $y = y_A$. Discontinuity appears at $y = y_A$ when the inflection point moves upward, while it does not appear when the inflection point moves downward. Since there is always oscillation of the inflection point in unsteady flow, discontinuity must occur when an inflection point is produced.

In the case of an inflection point appearing at the wall, shown in Fig.3(b), the velocity at the inflection point always equals to the wall velocity, $u = 0$. Thus, the problem of discontinuity of velocity does not exist in this case.

In the case of an inflection point appearing not at the wall, but $u'' > 0$ near the wall,
shown in Fig. 3(c), this case only occurs in flows with adverse pressure gradient, for example, divergent flows [34-35]. This case of non-parallel flows will not be discussed in this study.

3 Discussions

For pressure driven laminar flows of incompressible fluid in parallel flow configurations, we have obtained in the previous section that the inflection point on the velocity profile is a singular point of the Navier-Stokes equations. Thus, as the fluid reaches the inflection point, discontinuity will induce strong oscillation of flow parameters. On the other hand, the value of velocity after this discontinuity will be indefinite. This is the reason why turbulence is generated (Fig. 5). Therefore, a laminar flow can lose its stability and transit to turbulence via this singular point.

Dou and co-authors have reached the conclusion before by employing the energy gradient method that the inflection point on the velocity profile is a singularity of the Navier-Stokes equations [27, 29, 30].

As early as in 1880, Rayleigh obtained by linear stability analysis that the necessary condition for instability of inviscid flow is the existence of an inflection point on the velocity profile[36]. Later, Tollmien proved that the inflection point on the velocity profile is also a sufficient condition for instability of inviscid parallel flows with a symmetric profile [37].

It needs to be pointed out that the physical mechanism of the inflection point in inviscid flow is completely different from that of the inflection point in viscous flow. In inviscid flow, there is no discontinuity at the inflection point. In viscous flow, there is discontinuity at the inflection point. In inviscid flow, there is no loss of the total mechanical energy along the streamline in the whole flow field. In viscous flow, there is a drop of the total mechanical energy along the streamline, except at the inflection point. Here, the effect of viscosity does not appear at the inflection point due to $u'' = 0$.

For plane Couette flow, $u'' = 0$ does not mean that viscosity does not play a role, because input of external work counteracts the energy loss due to viscosity. Thus, there is no discontinuity at a position where $u'' = 0$ [28].

For turbulent flow in plane Poiseuille flow configuration, the time-averaged
Navier-Stokes equation along the streamwise direction can be written as follows [34-35]:

$$
\rho \frac{\partial u}{\partial t} + \frac{\partial E}{\partial x} = (\mu + \mu_t) \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right)
$$

(11)

where $\mu_t$ is the turbulent eddy viscosity.

For turbulence flows, it can also be proved that the inflection point on the velocity profile is still a discontinuity point by applying the above procedure using Eq.(11). The flow is always unstable due to singularity of the governing equations at the inflection point. This instability is the main mechanism of maintaining the turbulence.

In fully developed turbulent flow, there may be numerous inflection points distributed in the flow field, large scales or small scales. Therefore, it may be said that turbulence is composed of a large quantity of singularities. The flow is trapped into singularity at the inflection point. After that, the velocity is not predictable. These singularities are somewhat similar to black holes in astrophysics.

Based on these analyses, the coherent structure of wall bounded turbulence can be reasonably explained. The streamwise vortices help the formation of velocity inflection of the streamwise velocity [24]. The inflection point on the velocity profile leads to instability due to discontinuity, and a transverse velocity can be generated at this position. Then, a spanwise vortex can be formed around the inflection point, which is farther from the wall than the streamwise vortices, as shown in [17-24]. Finally, a hairpin vortex is generated through three dimensional evolutions of spanwise vortex and streamwise vortices, which forms the core part of a turbulent spot [17-24]. Compared to spanwise vortices, the streamwise vortices play less role in the transition since the velocity magnitude in the plane perpendicular to the streamwise direction is very low. The vortex head of the hairpin vortex will be the “driving force” to sustain turbulence since it causes intensive oscillation via discontinuity. It also plays a role to transmit energy into the vortex from the streamwise flow by the rolling up process.

As previous discussed, the moving up of the inflection point causes instability and the moving down of it does not. This behavior can be used to explain the mechanism of rise of the vortex head of hairpin vortices as the fluid moves downstream.
From the present study, it is clear that turbulence cannot be duplicated due to the singularity of Navier-Stokes equations at a velocity inflection point and that the turbulence is composed of numerous singularities. This may be useful information for the question in the millennium prize problems [38].

4 Conclusions

The following conclusions can be drawn and the following questions can be answered from this study.

(1) For the pressure driven incompressible flow, the singularity of Navier-Stokes equations is discovered through the derivation of the Navier-Stokes equations and the analysis of the velocity profile. It is found that the value of the velocity at the inflection point is zero in viscous parallel flows, which is singular in the flow field.

(2) It is the inflection point on the velocity profile which leads to the discontinuity and the instability. The singularity of the Navier-Stokes equations is the cause of turbulent transition and the inherent mechanism of sustenance of fully developed turbulence.

(3) A laminar flow, no matter how it develops, if it cannot make the Navier-Stokes equations singular, turbulent transition cannot occur. This is also the reason why the linear stability theory failed to predict the transition of turbulence.

(4) Turbulence is dominated by spanwise vortices via the discontinuity, and turbulence is composed of numerous singularities of Navier-Stokes equations with various scales.

(5) This new finding supports the criterion of turbulent transition for pressure driven flows proposed based on the energy gradient method that the necessary and sufficient condition for turbulent transition is the existence of an inflection point on the velocity profile.

Now, the following questions can be answered from this study:

(1) Why can a smooth laminar flow be transited to turbulence? This is due to singularity of Navier-Stokes equations at an inflection point. The value of the velocity of fluid particle passing this position will be indefinite.

(2) Why is there strong oscillation in turbulence? This is caused by the discontinuity of flow parameters at inflection point. Any magnitude of velocity must drop to zero at this location.
(3) Why can a turbulent flow not be duplicated? This is determined by the property of Navier-Stokes equations at singularity.

(4) Why is there intermittency in turbulence? Intermittency is caused by the vortices including singularity which pass the observation location.

(5) Why does the vortex head of the hairpin vortex in turbulent flow rise gradually downstream? This is due to that the inflection point moving downward does not cause instability, while it moving upward causes instability.
