(Dated: June 8, 2018)

We show that one can quantum simulate the dynamics of a Sachdev-Ye-Kitaev model with \( N \) Majorana modes for time \( t \) to precision \( \epsilon \) with gate complexity \( \mathcal{O}(N^{7/2}t + N \log(1/\epsilon)/\log(\log(1/\epsilon))) \). In addition to scaling sublinearly in the number of Hamiltonian terms, this gate complexity represents an exponential improvement in \( 1/\epsilon \) and large polynomial improvement in \( N \) and \( t \) over prior state-of-the-art algorithms which scale as \( \mathcal{O}(N^{10}t^2/\epsilon) \). Our approach involves a variant of the qubitization technique in which we encode the Hamiltonian \( H \) as an asymmetric projection of a signal oracle \( U \) onto two different signal states prepared by distinct state oracles, \( A(0) \rightarrow |A \rangle \) and \( B(0) \rightarrow |B \rangle \), such that \( H = \langle B|U|A \rangle \). Our strategy for applying this method to the Sachdev-Ye-Kitaev model involves realizing \( H \) using only Hadamard gates and realizing \( A \) as a random quantum circuit.

The Sachdev-Ye-Kitaev Model

The AdS/CFT correspondence is a conjectured relationship between the quantum physics of correlated many-body systems and the classical physics of gravity in one higher dimension [1]. Holographic dualities such as AdS/CFT have become increasingly important tools for studying quantum gravity; however, it has generally been difficult to find simple models that capture exotic features such as black holes [2]. Introduced by Kitaev [3] based on a variant of an earlier model by Sachdev and Ye [4], the Sachdev-Ye-Kitaev (SYK) model has been widely studied in recent years as an example of a simple quantum many-body system which may have an interesting holographic dual. The SYK model can be expressed as

\[
H = \frac{1}{4 \cdot 4!} \sum_{p,q,r,s=0}^{N-1} J_{pqrs} \gamma_p \gamma_q \gamma_r \gamma_s
\]

where \( \gamma_p \) are Majorana fermion mode operators. The anticommutation relation defining these operators, \( \{ \gamma_p, \gamma_q \} = 2 \delta_{pq} \), implies the following mapping to qubits under the Jordan-Wigner transform,

\[
\gamma_p = X_p \cdot Z_{p-1} \cdot Z_{p-2} \cdots Z_0,
\]

and the coefficients \( J_{pqrs} \) are real valued scalars drawn randomly from a normal distribution,

\[
P(J_{pqrs}) = \frac{1}{\sigma \sqrt{2\pi}} \exp \left[ -\frac{J_{pqrs}^2}{2\sigma^2} \right], \quad \sigma^2 = \frac{3!}{N^3} J^2.
\]

A feature of the SYK model is that for large \( N \) and strong coupling \( J \) it is possible to sum all of the Feynman diagrams to obtain (among other properties) out-of-order-time correlation functions [3]. Such methods reveal that the SYK model is maximally chaotic (having the same Lyapunov exponent as black holes in Einstein gravity) [3]. This property, in conjunction with the emergence of an approximate conformal symmetry at low temperatures, suggests that the holographic dual of the SYK model is a theory of Einstein gravity [5].

However, questions remain about the SYK model which have not yet been solved by analytical methods. Since quantum computers are widely conjectured to be capable of modeling otherwise intractable quantum systems [6], they may also prove useful tools for studying the quantum many-body side of such holographic duals. Earlier work [7] has proposed a scheme for quantum simulating SYK model dynamics using a Lie-Trotter based algorithm [8] with gate complexity \( \mathcal{O}(N^{10}t^2/\epsilon) \), where \( t \) is time and \( \epsilon \) is target precision. Yet such scaling suggests that interesting (e.g. \( N > 100 \)) SYK model quantum simulations would remain intractable for even a fault-tolerant quantum computer. In this paper we describe an algorithm to quantum simulate the SYK model with gate complexity \( \mathcal{O}(N^{7/2}t + N \log(1/\epsilon)/\log(\log(1/\epsilon))) \). We compile the bottleneck components of our approach to Clifford + T gates and find that interesting simulations are possible with fewer than ten million \( Jt \) T gates, which strongly suggests that this is a plausible application for the first generation of fault-tolerant quantum processors.

Asymmetric Qubitization

In order to simulate this Hamiltonian, we would like to implement it via a linear combination of unitaries, then use quantum signal processing techniques [9]. The standard linear combinations of unitaries (LCU) query model [10] for Hamiltonian simulation uses two unitary operations \( G \) and \( U \). The operation \( G \) initializes a particular state, \( G(0) \rightarrow |G \rangle \) in an ancilla register. Then \( U \) performs one of a set of unitaries on the target system controlled on the ancilla register. Finally, measurement of this ancilla register in the state \( |G \rangle \) gives the linear combination of unitaries applied to the target system.

In “qubitization” [11], it is required that \( \langle G|U|G \rangle = \frac{1}{2^{N+1}} \sum_{\{a_i\} = \{0,1\}^N} \epsilon_{\{a_i\}} U_{\{a_i\}} \).
\(H/\lambda\), which then enables Hamiltonian simulation to be achieved via quantum signal processing \([9]\). The operation \(U\) can be controlled unitaries on the target system, or a more general unitary. We have included a scaling factor \(\lambda\), because typically an operator proportional to the desired Hamiltonian is given. If the operation \(U\) is Hermitian as well as unitary, then it is self-inverse and therefore equivalent to a reflection. Then \(R_G = 2|G\rangle\langle G| - 1\) provides a second reflection, and a product of reflections has a spectrum given by Theorem 1 of \([12]\). Applying that theorem shows that \(W = R_G U\) has eigenvalues of \(e^{\pm i \arccos(h/\lambda)}\) for eigenvalue \(h\) of \(H\) \([11]\).

One can show that (see the proof of Lemma 6 of \([13]\) or Lemma 16 of \([14]\))

\[
\langle G|W^n|G\rangle = T_n(H/\lambda), \tag{4}
\]

where \(T_n(\cdot)\) is the \(n^{th}\) Chebyshev polynomial of the first kind. Using the Jacobi-Anger expansion gives

\[
e^{-iHt} = J_0(-\lambda t)1 + 2 \sum_{n=1}^{\infty} i^n J_n(-\lambda t)T_n(H/\lambda), \tag{5}
\]

where \(J_n(\cdot)\) is the \(n^{th}\) Bessel function of the first kind, and we have used \(\cos(\pm n \arccos(H/\lambda)) = T_n(H/\lambda)\). Therefore a polynomial in \(W\) can be used to approximate \(e^{-iHt}\), and this polynomial can be generated via quantum signal processing \([9]\). The order of the polynomial needed to approximate \(e^{-iHt}\) to within error \(\epsilon\) is

\[
O\left(\lambda t + \frac{\log(1/\epsilon)}{\log \log(1/\epsilon)}\right). \tag{6}
\]

For large \(\lambda t\), the multiplying factor here is close to 1. This also corresponds to the complexity of simulating \(e^{-iHt}\) via quantum signal processing, in terms of the number of queries to \(R_G\) and \(U\). That contributes a factor of 2 for the number of queries (see Theorem 1 of \([11]\)).

If \(U\) is not self-inverse, then it is possible to construct a modified \(U\) that is self-inverse (see Theorem 3 of \([11]\)). This procedure is equivalent to adding an ancilla qubit and using an operation with a block matrix representation (similar to the first equation of \([15]\)),

\[
\begin{bmatrix}
0 & U^T \\
U & 0
\end{bmatrix}.
\tag{7}
\]

For our SYK model simulation we would instead like the states to be asymmetric, so we have state preparations \(A\{0\} \mapsto |A\rangle\) and \(B\{0\} \mapsto |B\rangle\) such that \(\langle B|U|A\rangle = H/\lambda\). In order to use qubitization with these asymmetric states, we can bundle the operations \(A\) and \(B\) together with \(U\), so \(0\rangle B^T U A \{0\rangle = H/\lambda\). For our application \(U\) will be self-inverse, but \(B^T U A\) will not be self-inverse. It is possible to use qubitization for this purpose via the technique in Theorem 3 of \([11]\), as shown in Figure 1.

A drawback to directly using the technique in \([11]\) is that it doubles the complexity, and also requires operations to be made controlled. It is possible to avoid requiring the state preparation to be controlled using an additional copy of the register, as shown in Figure 2. The operation \(U\) is a controlled \(H_\ell\),

\[
U \equiv \sum_{\ell=0}^{L-1} |\ell\rangle\langle \ell| \otimes H_\ell, \tag{8}
\]

An ancilla qubit selects which of two copies of the control register is used. Using one of these registers effectively gives \(B^T U A\) whereas the other gives \(A^T U B\). This means that the effect is the same as for the technique of \([11]\).

For Hamiltonian simulation by quantum signal processing, these steps need to be made controlled. In both these cases, the step may be made controlled by performing a CNOT on the top qubit, and making the controlled \(H_\ell\) controlled on the additional qubit. Circuits to achieve the controlled steps are shown in Figure 3 and Figure 4.

An alternative approach is to use the fact that Eq. (4) holds for all steps in oblivious amplitude amplification,
regardless of symmetry. Define the step of oblivious amplitude amplification

$$U = A U^\dagger B R_0 B^\dagger U A,$$

where $R_0 \equiv 2 |0\rangle\langle 0| - \mathbb{1}$ is a reflection on the control register. This operation can very easily be made controlled, just by making the reflection $R_0$ controlled. Then,

$$
\langle 0 | U^n | 0 \rangle = T_{2n} (H/\lambda),
$$

$$
\langle 0 | B^\dagger U A H^n | 0 \rangle = T_{2n+1} (H/\lambda),
$$

Therefore, it is possible to generate both the even and odd terms required in Eq. (5) by using steps of $U$ or steps of $U$ followed by $B^\dagger U A$.

In order to generate the polynomial required by quantum signal processing, an ancilla qubit can be used, which controls whether the odd or even terms in the polynomial in Eq. (5) are generated. This qubit would primarily control the qubit rotations used in quantum signal processing. Ultimately this qubit would also control the operations $B^\dagger U A$, applying them to produce the odd terms.

In this approach, combining the odd and even terms via a linear combination of unitaries gives a success amplitude that is not unity. Amplitude amplification requires repeating the sequence of operations at least three times, giving an additional multiplicative overhead. In the scheme proposed in Figure 2, $U$ is applied only once. There is a factor of two for the preparations, but those have complexity that is logarithmic compared to the complexity of $U$. Thus, the scheme in Figure 2 is the most gate-efficient of the alternatives considered.

We now discuss the contribution to the cost from the lambda for asymmetric state preparation compared to symmetric state preparation. The value of lambda is independent of the approach to asymmetric qubitisation. Suppose that operators $A$ and $B$ prepare states $|A\rangle$ and $|B\rangle$ as

$$|A\rangle \equiv A |0\rangle^\otimes \log L = \sum_{\ell=0}^{L-1} \alpha_\ell |\ell\rangle,$$

$$|B\rangle \equiv B |0\rangle^\otimes \log L = \sum_{\ell=0}^{L-1} \beta_\ell |\ell\rangle.$$

Then, taking the register $|\psi\rangle$ to be the target subsystem on which the operators $H_\ell$ act,

$$\frac{H}{\lambda} |\psi\rangle = (0 | B^\dagger U A | 0 \rangle |\psi\rangle = \sum_{\ell=0}^{L-1} \alpha_\ell \beta_\ell^* H_\ell |\psi\rangle.$$

Thus, if we define $w_\ell$ to be the desired weightings,

$$H = \lambda \sum_{\ell=0}^{L-1} \alpha_\ell \beta_\ell^* H_\ell = \sum_{\ell=0}^{L-1} w_\ell H_\ell$$

so that for $\ell$, we require that $\lambda \alpha_\ell \beta_\ell^* = w_\ell$. Therefore, taking the absolute value and summing gives

$$\lambda \sum_{\ell=0}^{L-1} |\alpha_\ell |^2 = \sum_{\ell=0}^{L-1} |w_\ell| \leq \lambda,$$

which comes from the Cauchy-Schwarz inequality applied to normalized states $|A\rangle$ and $|B\rangle$. Hence, $\lambda$ takes its minimum value of $\sum_{\ell} |w_\ell|$ in the case that $|\alpha_\ell| = |\beta_\ell|$.

For some classes of Hamiltonians, the preparation can be made heavily asymmetric without much cost. In particular, consider the asymmetric case where

$$\alpha_\ell = \frac{w_\ell}{\sqrt{\sum_{\ell=0}^{L-1} |w_\ell|^2}}, \quad \beta_\ell = \frac{1}{\sqrt{L}}.$$

Then using Eq. (16) gives

$$\lambda \sum_{\ell=0}^{L-1} \frac{|w_\ell|}{\sqrt{\sum_{\ell=0}^{L-1} |w_\ell|^2}} \frac{1}{\sqrt{L}} = \sum_{\ell=0}^{L-1} |w_\ell|, \quad \lambda = \sqrt{L \sum_{\ell=0}^{L-1} \langle w_\ell \rangle^2} = L \lambda.$$

Using $(\cdot)$ to indicate the mean over $\ell$, this means that the overhead in complexity from using the asymmetric $|A\rangle$ and $|B\rangle$ over the symmetric case is $\sqrt{\langle \sum_{\ell=0}^{L-1} |w_\ell|^2 \rangle}/|\langle w_\ell \rangle|$. In the case where the $w_\ell$ are drawn from a normal distribution (e.g. the SYK model), the additional overhead is only $\sqrt{\pi/2} \approx 1.25$.

State Preparation Circuits

Our strategy for implementing $A$ and $B$ oracles which provide an efficient SYK model simulation is rather straightforward: the $B$ circuit will consist of Hadamard gates which initialize the symmetric superposition state and the $A$ circuit will be a random quantum circuit with orthogonal rotations. Let us assume for simplicity that the number of terms in our SYK model Hamiltonian ($L = N^4$) is a binary power. Then, one can initialize the state $|B\rangle$ such that $\beta_\ell = 1/\sqrt{L}$ by implementing the circuit $B$ as a sequence of $\log L$ Hadamard gates.

Consider the state $|A\rangle$ output by a random quantum circuit $A$ with orthogonal rotations. We will use orthogonal rotations in order to ensure that the amplitudes remain real. Using the definition in Eq. (12), known
properties of orthogonal random quantum evolutions [16] hold that the $\alpha_\ell$ are Gaussian distributed with zero mean and variance equal to the Hilbert space dimension. The asymmetric state preparation requires that the $\alpha_\ell$ are proportional to the desired weightings for the terms in the Hamiltonian. Because they have a normal distribution, they correctly generate the weights $w_{pqrs}$. There is a difference in the variance, but the variance only affects an overall scaling of the values of the $\alpha_\ell$, which is what we expect because the $\alpha_\ell$ correspond to the amplitudes of a normalized state. The scaling factor is taken into account in $\lambda$, giving the complexity of the calculation.

The value of $\lambda$ for this asymmetric state preparation is given by Eq. (19), which only depends on $w_\ell$ and the dimension. It does not explicitly depend on $\alpha_\ell$, because that proportionality is already taken into account by the fact that the $\alpha_\ell$ are normalized. For the SYK model,

$$w_{pqrs} = \frac{1}{4 \cdot 4!} J_{pqrs},$$

where we have changed the index to $pqrs$ to match the notation used for $J$. Then, the mean square value is

$$\langle |w_{pqrs}|^2 \rangle = \frac{1}{(4 \cdot 4!)^2} \langle J_{pqrs}^2 \rangle \approx \frac{1}{(4 \cdot 4!)^2} \frac{3!}{N^3} J^2.$$

There is an approximate equality here, because the mean of $w_{pqrs}$ indicates the mean summing over $pqrs$, not the expectation value of the probability distribution according to which $J_{pqrs}$ are chosen. Using Eq. (19) then gives

$$\lambda \approx L \sqrt{\frac{1}{(4 \cdot 4!)^2} \frac{3!}{N^3} J^2} = N^{5/2} \frac{\sqrt{3}}{4 \cdot 4!}. \quad (22)$$

An outstanding question is how large the orthogonal random quantum circuits should be in order to achieve sufficient convergence to the Gaussian distribution in the coefficients. There have been many theoretical results on related questions such as the convergence of random quantum circuits to $t$-designs of the Haar measure [17–19]. For a one dimensional random quantum circuit on log $L$ qubits, the circuit approaches an $\epsilon$-approximate $2$-design in gate complexity $\mathcal{O}(\log^2 L + \log(L/\epsilon))$ [17]. However, for circuits in higher dimension the gate complexity to achieve similar states is closer to $\mathcal{O}(\log(L/\epsilon))$ [18, 19].

While these works typically do not focus on the convergence of amplitudes to a Gaussian distribution, this topic was recently studied numerically in [20]. There, authors found rapid convergence of the probabilities (squared amplitudes) to the Porter-Thomas distribution [16], which corresponds to convergence of real and imaginary components of the amplitudes to a Gaussian distribution. Thus, to avoid an in depth discussion of the requisite circuit size, we will conservatively assume that to achieve amplitudes that are within $\epsilon$ distance of Gaussian distributed amplitudes, it suffices to use circuits of size $\mathcal{O}(\text{polylog}(L, 1/\epsilon)) = \mathcal{O}(\text{polylog}(N, 1/\epsilon))$. 

FIG. 5. Circuit to control the application of a Majorana operator as in Eq. (24). This circuit has a T-count of $4N - 4$, where $N$ is the size of the target register. The circuit acts on $N + 2 \log N + 1$ qubits, including log $N$ ancillae. Note that this diagram uses notation for setting an ancilla to the logical and of two other qubits, described in Figure 6. Our implementation of $U$ consists of four of these circuits, which would require a total of $16N - 16$ T gates and log $N$ ancillae. This circuit is explained in detail in Section 3B of [21].

FIG. 6. Computing and uncomputing AND operations [22], defined in terms of Toffoli gates and in terms of Clifford+T gates. Computing an AND consumes $4|T|$ states, and is equivalent to applying a Toffoli gate to a target qubit known to be $|0\rangle$. Uncomputing an AND consumes no $|T|$ states, and is equivalent to applying a Toffoli gate to a target qubit guaranteed to end up in $|0\rangle$ state. Drawing AND operations as “corners” instead of as $\oplus$ symbols is a visual cue that the target qubit will be (or was) OFF after (before) the operation.

**Hamiltonian Application Circuit**

The Hamiltonian application circuit, referred to in previous sections as $U$, should have the following action

$$U|p\rangle|q\rangle|r\rangle|s\rangle|\psi\rangle \mapsto |p\rangle|q\rangle|r\rangle|s\rangle\gamma_p\gamma_q\gamma_r\gamma_s|\psi\rangle. \quad (23)$$

To implement this with low gate complexity will rely on a technique which applies the following transformation

$$|\ell\rangle|\psi\rangle \mapsto |\ell\rangle\gamma_\ell|\psi\rangle = |\ell\rangle X_\ell \cdot Z_{\ell-1} \cdot Z_{\ell-2} \cdots Z_0 |\psi\rangle. \quad (24)$$

Circuits for exactly this transformation were introduced in Section 3B of [21], reproduced here in Figure 5. Though [21] developed these circuits independently, they share a primitive with circuits developed earlier in Appendix G4 of [23]. The T complexity of this circuit implementing the transformation of Eq. (24) is exactly $4N - 4$ and the Clifford complexity is also $\mathcal{O}(N)$. Clearly, four applications of this primitive are sufficient to implement
and helpful discussions about random quantum circuits. Dominic McClean, Zhang Jiang, and Sergio Boixo for help-
ful discussions about the SYK model and thank Jar-
rod McClean, Zhang Jiang, and Sergio Boixo for help-
ful discussions about random quantum circuits. Dominic

Conclusions

Using quantum signal processing, our simulation re-
quires a number of applications of $A$, $B$, and $U$ given by
Eq. (6). The total cost of our simulation is therefore

$$O \left( (C_A + C_B + C_U) \left( At + \frac{\log(1/\epsilon)}{ \log \log(1/\epsilon)} \right) \right) \tag{25}$$

where $C_A$, $C_B$ and $C_U$ are the cost of implementing $A$, $B$ and $U$, respectively. In terms of gate complexities of
the explicit implementations advocated for in this work,
$C_A = O(\text{polylog}(N,1/\epsilon))$, $C_B = O(\log N)$, and $C_U = O(N)$. We have found that $\lambda = O(N^{5/2})$. Putting these
costs together we see that the overall algorithm scales as

$$O \left( (N + \text{polylog}(N,1/\epsilon)) \left( N^{5/2}t + \frac{\log(1/\epsilon)}{ \log \log(1/\epsilon)} \right) \right) \approx O \left( N^{7/2}t + N \frac{\log(1/\epsilon)}{ \log \log(1/\epsilon)} \right) \tag{26}$$

where in the second line we have made the conservative
assumption that the cost of the random quantum circuit
implementing $A$ will be less than the cost of $U$.

Since we have compiled all bottleneck components
down to Clifford + T gates, we are also able to report
the leading order T complexity of the algorithm:

$$\frac{2}{\sqrt{6}} N^{7/2}Jt + O \left( N \text{polylog} \left( N, 1/\epsilon \right) \right). \tag{27}$$

Assuming reasonable precision goals, for $N = 100$ the
leading order T count is less than ten million $Jt$ and for
$N = 200$, the leading order T count is less than one hundred
million $Jt$. This should be compared to the roughly
$10^{14} - 10^{15}$ T gates required to simulate the active site of
FeMoco with 108 qubits (a molecule relevant to Nitrogen
fixation) [24], $10^8 - 10^9$ T gates required to simulate 100-
200 qubit interesting problems in solid-state electronic
structure [21] or the roughly $10^9$ T gates required to simu-
late a 100 qubit one-dimensional Heisenberg model for
classically intractable durations [23]. While the partic-
ular value of $Jt$ would depend on the application, this
analysis makes it clear that simulation of the SYK model
is one of the most viable applications of the first error-
corrected quantum computers.
