(Dated: November 21, 2019)

We focus on the fact that light-pulse atom interferometers measure the atoms’ acceleration with only three data points per drop. As a result, the measured effect of gravity gradient is systematically larger than the true one, an error almost unnoticed so far. We show how it affects the absolute measurement of the gravitational acceleration $g$ as well as ground and space experiments with gravimeters based on atom interferometry such as those designed for space geodesy, the measurement of the universal constant of gravity and the detection of gravitational waves. Tests of the weak equivalence principle with atom interferometers require to drop two different atom species. If both species can be operated with the same laser the error reported here cancels out. If not, the fractional differences in pulse timing and momentum transfer must satisfy extremely stringent requirements. This is why almost all tests use isotopes of the same Rb atom which however differ in composition by two neutrons only.

Light-pulse Atom Interferometers (AIs) are based on quantum mechanics. As the atoms fall, the atomic wave packet is split, redirected, and finally recombined via three atom-light interactions at times 0, $T$, $2T$. The phase that the atoms acquire during the interferometer sequence is proportional to the gravitational acceleration that they are subjected to.

Although one might think that the phase shift depends on quantum mechanical quantities “. . . this is merely an illusion since we can write the scale factor [between the phase shift and the gravitational acceleration] in terms of the parameters we control experimentally, i.e. Raman pulse vector $k$ and pulse timing $T$. It then takes the form $kT^2$. . . . We can simply ignore the quantum nature of the atom and model it as a classical point particle that carries an internal clock and can measure the local phase of the light field.” ([1], Sec. 2.1.3). The same reference also demonstrates that, in the case of a gravitational field with a linear gradient, both the exact path integral approach and the purely classical one lead to the same exact closed form for the phase shift and free fall acceleration measured by the AI, which is then expanded in power series for the phase shift and free fall acceleration measured by the AI, while including the quantum mechanical details related to the internal degrees of freedom is needed to account for smaller effects, such as the finite length of the light pulses.

We focus on the fact that AIs measure the atoms’ position along the trajectory only 3 times per drop (in correspondence of the 3 light pulses), unlike laser interferometers in falling corner-cube gravimeters which make hundreds to a thousand measurements per drop [3]. Hence, although predicted exactly, the gravitational acceleration measured by AIs is the true one only in a uniform field.

The predicted value of the measured acceleration first appeared in [5], and it has been confirmed ever since [1, 6–9]. However, none of these works mentions that in the presence of gravity gradient this value is the average free fall acceleration (at time $T$ of the middle pulse) based on 3 position measurements. This is of course only an approximation to the true acceleration, expressed mathematically by the second time derivative of the position, or obtained experimentally with a large enough number of measurements per drop.

Initially the lack of precise measurements made the difference unimportant, and by the time the precision improved nobody went back to this issue. However, its physical consequences do deserve to be carefully addressed. Using the classical approach [1] we point them out when AIs are used to measure the absolute value of the gravitational acceleration $g$, for gravity gradiometry and for testing the Universality of Free Fall (UFF), both on ground and in space.

Since UFF tests are included, we allow from the start the possibility that the equivalence of inertial and gravitational mass may be violated for atoms of different species $A, B$ in the field of Earth (violation of the Weak Equivalence Principle, WEP), hence violating UFF [10]. We therefore write the masses as $m_{A,B}^g = m_{i,A,B}^i (1 + \eta_{A,B})$, $M_{\oplus}^g = M_{\oplus}^i (1 + \eta_{\oplus})$, where superscripts $i, g$ refer to inertial or gravitational mass and the Eötvös parameters $\eta_A, \eta_B, \eta_{\oplus}$ may not be exactly zero (although they must be smaller than 1 by many orders of magnitude [11, 12]).
The equation of motion for atoms A or B reads:

$$\ddot{z}_{A,B} = -\frac{GM_{\oplus}}{(R_{\oplus} + z_{A,B})^2}(1 + \eta_{\oplus} + \eta_{A,B})$$  \hspace{1cm} (1)

where $R_{\oplus}$ is the Earth’s radius and the z axis points upwards. When UFF is tested by measuring the differential acceleration $\ddot{z}_A - \ddot{z}_B$, $\eta_{\oplus}$ cancels out and a violation is detected only if $\eta = \eta_{B} - \eta_{A} \neq 0$, i.e. what matters is the different composition of the atoms under test, which therefore should be maximized [13,15]. Hence we assume $M^2_{\oplus} = M^2_\oplus = M_{\oplus}$. Using a perturbative approach for a gravity field with a linear gradient $\gamma$ (see e.g. [16]) the equation of motion reads:

$$\ddot{z}_{A,B} \simeq -g_0(1 + \eta_{A,B}) - \frac{1}{2}g_0\gamma t^2 - v^0_{A,B}t - z^0_{A,B}$$ \hspace{1cm} (2)

where $g_0 = GM_{\oplus}/R^2_{\oplus}$ $\simeq 9.8$ $\text{m/s}^2$, $\gamma = g_0/R_{\oplus}$ $\simeq 3.1 \times 10^{-5}$ $\text{s}^{-2}$ and $z^0_{A,B}$ and $v^0_{A,B}$ are the initial position and velocity errors of the atoms at release (the exact values are assumed to be zero). The solution is:

$$z_{A,B}(t) \simeq z^0_{A,B} + v^0_{A,B}t - \frac{1}{2}g_0(1 + \eta_{A,B})t^2 + \frac{1}{24}g_0^2t^4 - \frac{1}{6}v^0_{A,B}t^3 - \frac{1}{2}z^0_{A,B}$$ \hspace{1cm} (3)

We compute the phase shift $\delta \phi_{A,B}$ measured by the AI following the step-by-step algorithm outlined in [1]. Assuming the same $k$ for all 3 pulses ($hk$ is the momentum transfer, with $h$ the reduced Planck constant) and the same time interval $T$ between subsequent pulses, it is:

$$\delta \phi_{A,B} = \phi_{A,B}(2T) - 2\phi_{A,B}(T) + \phi_{A,B}(0) = k[z_{A,B}(2T) - 2z_{A,B}(T) + z_{A,B}(0)] \hspace{1cm} (4)$$

and, using [3]:

$$\delta \phi_{A,B}(T) \simeq -kT^2[g_0(1 + \eta_{A,B}) + \frac{1}{12}g_0^2T^2 - v^0_{A,B}T - z^0_{A,B}]$$ \hspace{1cm} (5)

With the scale factor $kT^2$ ($k$ and $T$ measured experimentally) this gives the free fall acceleration $g_{A,B \text{meas}}(T)$ that the AI is predicted to measure at time $T$ of the middle pulse. In modulus:

$$g_{A,B \text{meas}}(T) \simeq g_0(1 + \eta_{A,B}) + \gamma \left(\frac{7}{12}g_0T^2 - v^0_{A,B}T - z^0_{A,B}\right)$$ \hspace{1cm} (6)

If $\eta_{A,B} = 0$ (WEP and UFF hold) this is the same as in [1], it is the expansion to order $\gamma$ of an exact result which can be obtained in closed form by an exact path integral treatment or within a purely classical description.

In a gravitational field with a linear gradient the free fall acceleration of the atoms at time $T$ is (in modulus):

$$|\ddot{z}_{A,B}(T)| \simeq g_0(1 + \eta_{A,B}) + \gamma \left(\frac{1}{2}g_0T^2 - v^0_{A,B}T - z^0_{A,B}\right)$$ \hspace{1cm} (7)

while the AI measurement gives, at the same time $T$, the value [9], which is systematically larger than the true one by the amount:

$$\Delta a = \frac{1}{12}g_0T^2$$ \hspace{1cm} (8)

with a relative error $\frac{\Delta a}{g_0} = \frac{1}{12}\gamma T^2$. The discrepancy was pointed out in [17] where it was explained with the simple algebra involved in computing [5] from [4] and [3]. In physical terms it is due to the limitation, intrinsic to the AI instrument, of making only 3 position measurements per drop. Whether it can be neglected or not will depend on the specific experiment.

With the same perturbative approach the calculation can be extended to order $\gamma^2$ by using the solution $z_{A,B}(t)$ to first order in $\gamma$ as given by [3], rather than to order zero (i.e. $z_{A,B}(\gamma = 0) = -\frac{1}{2}g_0t^2 + v^0_{A,B}t + z^0_{A,B}$), as used in [2]. The new equation of motion reads:

$$\ddot{z}_{A,B} \simeq -[g_0(1 + \eta_{A,B}) + \gamma(\frac{1}{2}g_0t^2 - v^0_{A,B}t - z^0_{A,B}) + \frac{1}{24}\gamma^2(\frac{1}{6}v^0_{A,B}t^3 - \frac{1}{2}z^0_{A,B})] \hspace{1cm} (9)$$

Its solution leads to the phase shift, hence to the acceleration measured by the AI to order $\gamma^2$:

$$g_{A,B \text{meas}}(T) \simeq g_0(1 + \eta_{A,B}) + \gamma \left(\frac{7}{12}g_0T^2 - v^0_{A,B}T - z^0_{A,B}\right) + \frac{1}{24}\gamma^2 \left(\frac{31}{360}g_0T^4 - \frac{1}{4}v^0_{A,B}T^3 - \frac{7}{12}z^0_{A,B}T^2\right)$$ \hspace{1cm} (10)

The result is the same as Eq. (2.19) in [1] (where it was obtained by expanding to second order the exact result in closed form) and it is generally accepted. However, it differs from the true acceleration given by [9], at the same time $T$ with a relative systematic error:

$$\frac{\Delta a}{g_0} = \frac{1}{12}\gamma T^2 + \frac{1}{45}\gamma^2 \left(\frac{2}{12}T^4 - \frac{1}{12}v^0_{A,B}T^3 - \frac{1}{12}z^0_{A,B}T^2\right)$$ \hspace{1cm} (11)

though we limit our analysis to order $\gamma$.

Let us now consider an AI experiment in space, inside a spacecraft in low Earth orbit such as the International Space Station (ISS). The ISS is Earth-pointing, the AI axis is aligned with the radial direction and the nominal point O of atoms’ release (origin of the radial axis $\zeta$
pointing away from Earth) is at distance \( h \) from the center of mass of the s/c (e.g., closer to Earth than the center of mass itself). When testing UFF with atom species \( A \) and \( B \) we can assume \( \eta_{B/c} = \eta_B = 0 \) since they cancel out anyway \[13\]. The equation of motion reads:

\[
m_{A,B}^i \ddot{\zeta}_{A,B} = -\frac{GM_{\oplus}}{r^3}m_{A,B}^i(1 + \eta_{A,B}) + m_{A,B}^i \dot{r}^2(\dot{r} - h + \zeta_{A,B})
\]

with \( r \) the orbital radius of the \( s/c \) (constant for simplicity) and \( n \) its orbital angular velocity obeying Kepler’s third law \( n^2r^3 = GM_{\oplus} \). Since \( (h - \zeta_{A,B})/r \ll 1 \), we can write:

\[
\dot{\zeta}_{A,B} \simeq -a_{\text{tide}} + \gamma_{\text{orb}} \eta_{A,B} + \gamma_{\text{orb}} \zeta_{A,B}
\]

where \( a_{\text{tide}} = \gamma_{\text{orb}} h \) is the tidal acceleration at the nominal release point and \( \gamma_{\text{orb}} = GM_{\oplus}/r^2 \simeq 8.7\text{ms}^{-2} \), \( \gamma_{\text{orb}} = 3g_{\text{orb}}/r \simeq 3.8 \times 10^{-6}s^{-2} \) are the gravitational acceleration and gravity gradient of Earth (the numerical values refer to an orbiting altitude of \( \approx 400\text{km} \)). This equation shows that in orbit the largest acceleration is the tidal one, with \( \frac{a_{\text{tide}}}{g_{\text{orb}}} \approx \frac{3}{r} \ll 1 \) while the driving acceleration of UFF violation is \( g_{\text{orb}} \), meaning that when the free fall accelerations of two atom species are subtracted a composition-dependent violation signal would be \( g_{\text{orb}} \eta_{A,B} \), with \( \eta = \eta_{B} - \eta_{A} \). The violation signal, if any, is an anomalous acceleration in the same direction (and unknown sign) as the monopole gravitational attraction from the source body, in this case the radial direction to the Earth’s center of mass. Hence the equation of motion \[13\] contains the tidal acceleration (due to gravity gradient) in the radial direction and not its transversal component \[19\] \[20\]. The ratio of the variable acceleration \( \gamma_{\text{orb}} \zeta_{A,B} \) relative to the constant term \( a_{\text{tide}} \) is

\[
\frac{\gamma_{\text{orb}} \zeta_{A,B}}{a_{\text{tide}}} = \frac{\zeta_{A,B}}{h} \simeq \frac{1}{2} \gamma_{\text{orb}} T^2,
\]

in analogy to the corresponding ratio on ground \( \frac{\zeta_{A,B}}{g_{\text{orb}}} \simeq \frac{1}{2} \gamma_{\text{orb}} T^2 \). Note that \( \gamma_{\text{orb}} \) is only slightly larger than \( \gamma \) while it is expected that \( T \) can be several times larger in space than on ground, because of near weightlessness conditions. Indeed, this is considered the key motivation for moving the experiment to space, since it means, for a given free fall acceleration, a larger phase shift, hence higher sensitivity (as \( T^2 \)). However, it also means a larger gradient effect (also as \( T^2 \)). With this warning we proceed with a perturbative approach as on ground. To order \( \gamma_{\text{orb}} \) it is:

\[
\zeta_{A,B} \simeq -\left(a_{\text{tide}} + g_{\text{orb}} \eta_{A,B} + \gamma_{\text{orb}} \left(\frac{1}{2} a_{\text{tide}} t^2 - \zeta_{A,B}^o - \dot{\gamma}_{A,B} t \right)\right)
\]

where \( \zeta_{A,B}^o \) and \( \dot{\gamma}_{A,B} \) are position and velocity errors at release and the last term is of order \( \gamma_{\text{orb}}^2 \) but cannot be neglected because the free fall acceleration – the quantity to be measured – is of order \( \gamma_{\text{orb}} \). We are led to the measured acceleration (in modulus):

\[
a_{A,B}^{\text{meas}}(T) \simeq a_{\text{tide}} + g_{\text{orb}} \eta_{A,B} + \gamma_{\text{orb}} \left(\frac{7}{12} \gamma_{\text{orb}} h T^2 - \zeta_{A,B}^o - \gamma_{A,B} T\right)
\]

which, by comparison with its theoretical counterpart \[14\] shows a systematic relative error \( \frac{\delta a}{a_{\text{tide}}} = \frac{1}{2} \gamma_{\text{orb}} T^2 \), similarly to the experiment on ground.

When testing UFF release errors result in position and velocity offsets between the two atom clouds which – because of gravity gradient – give rise to a systematic differential acceleration error that mimics a violation signal \[17\]. The effect of release errors is known to be a major issue in all UFF experiments based on “mass dropping”, while it does not occur if the test masses oscillate around an equilibrium position, as in torsion balance tests or in the proposed “Galileo Galilei (GG)” experiment in space \[21\]. As proposed by Roura \[22\], the effect of release errors coupled to the local gradient can be eliminated if the momentum transfer of the second laser pulse is modified by a small quantity of order \( \gamma \) such that the atoms fall as if they were moving in a uniform field. On ground the nominal value \( k_2 \) to be applied at the second pulse is \( k_2 = k + \Delta k_2 = k + k_2^1 \gamma T^2 \). A residual acceleration \( \gamma_{\text{res}} \left( \zeta_{A,B}^o + v_{A,B}^o T \right) \) remains if this value is not implemented exactly (a successful reduction \( \gamma_{\text{res}}/\gamma \simeq 10^{-2} \) has been reported \[3\]):

\[
\delta \phi_{\Delta k_2} = -k T^2 \left[g_{\text{orb}} (1 + \eta_{A,B}) + \gamma_{\text{res}} \left( \zeta_{A,B}^o + v_{A,B}^o T \right) \right] + \frac{1}{12} \gamma_{\text{orb}} T^2
\]

However, the acceleration term \[8\] remains too, in which the gradient is unaffected by whatever reduction has been achieved for the previous one, as pointed out in the Comment \[23\] and acknowledged by Roura \[24\]. This is inevitable because \( \Delta k_2 \) has been computed in order to nullify the effect of the local gradient on the atoms whose motion is governed by \[2\]. Instead, the acceleration measured by the AI and used for tuning the change \( \Delta k_2 \), is affected by the error \[8\] which cannot therefore be compensated. Indeed, it is questionable that attempts should be made to compensate it, since this would alter the true acceleration of the atoms and force it to equal a measured value which (already to first order in \( \gamma \)) is not fully correct.

The very fact that in proposing the gravity gradient compensation scheme Roura did not address the acceleration term \[8\] indicates that the systematic error made by taking only three measurements per drop has not been recognized.

A similar approach in space leads to a residual gradient \( \gamma_{\text{orb}} - \gamma_{\text{res}} < \gamma_{\text{orb}} \) after applying Roura’s scheme, and to the
phase difference:
\[
\delta \phi_{A,B,orb}(T) \approx -kT^2 \left[ a_{tide} + g_{orb}\eta_{A,B} + \gamma_{orb-res}(s_{A,B} + \Gamma_{A,B}T) + \frac{1}{12}\gamma_{orb}a_{tide}T^2 \right]
\]
(17)
where the error given by the last term contains \( \gamma_{orb} \), but amounts to \( \frac{1}{12}\gamma_{orb}T^2 \) relative to \( a_{tide} = \gamma_{orb}h \), which is the quantity to be measured, and therefore cannot be ignored as hinted by [23, 24].

A previous approach to reducing gravity gradient and initial offset errors in a proposed test of UFF on the ISS was based on the idea of rotating the interferometer axis [25]. For a dedicated mission the idea of rotating the whole s/c has been proposed by Rasel’s group as the key to reduce tidal effects [26]. In both cases the authors invoke a similarity with MICROSCOPE space experiment [12].

In MICROSCOPE the offset vectors between the centers of mass of the macroscopic test bodies –being due to construction and mounting errors– are fixed with the apparatus and therefore follow its rotation at all time, allowing the main tidal effect to be distinguished from a violation signal during the offline data analysis of a sufficiently long run –this is not a mass dropping experiment [21]. Instead, mass dropping tests with AIs require a huge number of drops to reduce single shot noise, each one with its own initial conditions and mismatch vector between different atom clouds, and the assumption that all these vectors are fixed with the apparatus cannot be taken for granted. The argument presented by [25] that the proposed instrument “has random but specified mismatch tolerances” is a weak one. Being systematic, this error must be below the target acceleration of the test in all drops, otherwise –should mismatch reversal not occur even in a small number of drops during the entire run (which is hard to rule out by direct measurement)– the resulting average acceleration will be larger than the target, thus questioning the significance of a possible “violation” detection.

Roura’s compensation scheme [22] is therefore to be preferred, as long as the acceleration term (8) is recognized and dealt with, if necessary.

On ground the error [6] affects the absolute measurement of \( g \). The best such measurement has achieved \( \Delta g/g \approx 3 \times 10^{-9} [7, 27] \), only about 3 times worse than obtained by the absolute gravimeter with free falling corner-cube and laser interferometry [28]. With \( T = 160 \) ms, the acceleration \( \frac{7}{12}\gamma g_T^2 \) in (18) exceeds the target error and has required a series of \( ad hoc \) measurements (drops from different heights) to be modelled and reduced below the target. Should it be possible to improve the sensitivity of the instrument by increasing \( T \), and to reduce the gradient and its effect coupled to initial condition errors as proposed by [22], the error [6] would still remain and should be taken care of for the absolute measurement of \( g \) to be improved.

In gravity gradiometers two spatially separated AIs with atoms of the same species interrogated by the same laser (hence \( \Delta T = 0 \) and \( \Delta k = 0 \)) measure their individual free fall accelerations at their specific location and compute their difference. The advantage is that the differential (tidal) acceleration is less affected than \( g \) by common mode disturbances, such as vibration noise. They are used for geodesy applications, but also for the measurement of the universal constant of gravity \( G \) and the detection of gravitational waves. On ground, if the release points \( A \) and \( B \) are separated vertically by \( \Delta h \) (\( A \) at the reference level and \( B \) higher by \( \Delta h \)), the differential acceleration is:

\[
|g_{B theory} - g_{A theory}| \approx \gamma \Delta h + \gamma \left( \frac{7}{8}\gamma g_T^2 + (v_B^2 - v_A^2)T + z_B^2 - z_A^2 \right)
\]
(18)
while the gradiometer measures:

\[
|g_{B meas} - g_{A meas}| \approx \gamma \Delta h + \gamma \left( \frac{49}{48}\gamma g_T^2 + (v_B^2 - v_A^2)T + z_B^2 - z_A^2 \right)
\]
(19)
with a systematic acceleration error proportional to \( \gamma^2 \) which cannot be neglected relative to the tidal acceleration measured by the gradiometer, the fractional error being \( \frac{7}{8}\gamma T^2 \). In space, with the release point \( A \) as in [12], and \( B \) at a radial distance \( \Delta h \) (farther away from Earth), the gradiometer would measure:

\[
\delta \phi_B - \delta \phi_A \approx kT^2 \left[ \gamma_{orb}\Delta h + \gamma_{orb}\frac{7}{12}\gamma g_T^2 + (\gamma v_B^2 - \gamma v_A^2)T + z_B^2 - z_A^2 \Gamma_{A,B} \right]
\]
(20)
with a fractional systematic error \( \frac{7}{12}\gamma_{orb}T^2 \). The error –like the physical quantity to be measured– contains the gradient. Therefore, depending on the target precision and accuracy of the experiment, \( ad hoc \) independent measurements are needed in order to model and reduce it below the target.

In tests of UFF with AIs different atoms \( A \) and \( B \) are dropped “simultaneously”, the individual phase shifts are measured and their difference is computed, to yield zero if no composition-dependent effect is detected (i.e. \( \eta = \eta_B - \eta_A = 0 \), UFF and WEP hold).

If the time interval \( T \) between laser pulses is the same for both species the term \( \frac{7}{12}\gamma g_T^2 \) on ground, or \( \frac{7}{12}\gamma_{orb}a_{tide} T^2 \) in space cancels out [23, 24]. However, should the species selected need different lasers a requirement arises, for a given target \( \eta \) of the UFF test, on the time difference \( \Delta T \). The synchronization issue has been raised by [23] and [24] in relation to the term [8] that remains after applying Roura’s proposal [22], making it clear that this term cancels out only if \( \Delta T = 0 \). However, the effect of \( \Delta T \neq 0 \) is dominated by the fact that for
each species the phase shift grows as $T^2$ times the leading constant term of the free fall acceleration measured by the interferometer, while the gradient term considered in [29] is a factor $\frac{7}{12} \gamma T^2$, or $\frac{1}{12} \gamma T^2$, smaller. On ground this leads to a requirement on $\Delta T/T$ which competes directly with $\eta$:

$$\frac{\Delta T}{T} < \frac{\eta}{2} \quad (21)$$

whereby it must be $\Delta T/T < 5 \times 10^{-14}$ even to reach the level $\eta \approx 10^{-13}$ already established by torsion balances [11].

\[ ^{87}\text{Rb} \text{ and } ^{39}\text{K} \text{ have been tested for WEP violation to a few parts in } 10^7 \text{ by Rashel's group [30]. By chirping the lasers at a particular rate a wave acceleration is applied in order to compensate exactly (for each species) the leading term of the free fall acceleration of the atoms which gives a phase shift proportional to $kT^2$, giving rise to the very stringent requirement on $\Delta T/T$ and similarly on $\Delta k/k$. However, even in the ideal case that both species fall with constant accelerations (zero gravity gradient and no noise of any sort) whereby a non zero acceleration difference would be ascribed solely to WEP violation, any difference remaining after laser chirping would have the same signature as a WEP violation signal and would therefore be indistinguishable from it.

Different laser frequencies ($\Delta k \neq 0$) also mean different momentum transfers, hence different scale factors between the two species, with the fractional error $\Delta k/k$ competing directly with $\eta$ and requiring $\Delta k/k < \eta$. In space the leading free fall acceleration is $a_{tide}$ while the violation signal is $g_{orb}\eta$, resulting in more relaxed requirements $\frac{\Delta T}{T} < \frac{\eta}{2a_{tide}}$ and $\frac{\Delta k}{k} < \frac{\eta}{g_{orb}}$ which however must compete with better results obtained or expected in orbit [12,31].

The importance of testing different atom species (as opposed to different isotopes of the same atom) in order to maximize the experiment for composition dependent effects whose detection would lead to new physics [11,31] is gradually being recognized, despite much greater experimental challenges [32,33].

In [32] the authors consider $^{87}\text{Rb}$ and $^{39}\text{K}$ and plan to solve the matching problem, which involves both $k$ and $T$, by properly adjusting the time intervals $T$ of the two species so that their ratio makes the product $S = kT^2$ the same (to some extent) for both species. With $k_K = (4\pi/767) \text{ nm}^{-1}$ and $k_{Rb} = (4\pi/780) \text{ nm}^{-1}$, this would require $T_{Rb}/T_K \sim 1.008$. With such adjustment of the interrogation time and an appropriate Bayesian analysis of the data it is possible to reduce the effect of vibration noise. However, even with no noise at all and zero gravity gradient the spurious differential acceleration resulting from an error in the scale factor $S$ must be smaller than the target violation signal, since this means $\frac{\Delta T}{T} = \frac{\Delta k}{k} + 2\frac{\Delta T}{T} < \eta$, which requires both $\frac{\Delta T}{T} < \frac{\eta}{2}$ and $\frac{\Delta k}{k} < \eta$.

Another method to significantly reduce vibration noise in WEP tests with different atom species has been proposed in [33]. By using the same mirror for both lasers the perturbing acceleration due to vibration noise is the same for the two species ( unlike a violation signal) and, although the induced phase shifts are different for the two species their ratio, assuming $T$ to be the same, is fixed as the ratio $\frac{k_{Rb}}{k_{K}}$ of their respective $k$. As the authors show, this fact can be exploited to reduce the impact of vibration noise on the target violation signal by many orders of magnitude. However, again they concentrate on reducing the differential effect of a small perturbation while neglecting the differential effect in the leading, much larger, acceleration term. Different $T$ and $k$ between the two species produce a differential effect in the phase induced by the leading acceleration which would mimic a violation, even in absence of any perturbation. Therefore, the accuracy of matching $T$ and $k$ ought to be addressed, prior to discussing any other disturbing effects.

When trying to compete with tests based on macroscopic test masses these requirements are very stringent, even with frequency comb technology. They severely limit the choice of different atoms that AIs can test and the possibility for these experiments to be optimized for composition dependence. This is why almost all tests, especially if aiming at high precision [34] use two isotopes of the same atom, $^{87}\text{Rb}$ and $^{85}\text{Rb}$, which however differ by two neutrons only. Earth’s gradient can be reduced as proposed by Roura [22], thus relaxing the requirement on initial position and velocity offsets. Nonetheless, this requirement must be met in all drops and demonstrated to be so by direct measurements for the test to be meaningful [17,22].

AIs have the advantage that atoms provide both the test mass and the read-out. However, they have only 3 time-position measurements each drop to recover the acceleration, unlike falling corner-cube gravimeters which can rely on hundreds to a thousand data points per drop. The resulting systematic error grows linearly with the gradient and quadratically with the time interval $T$ between laser pulses. This error must be addressed in attempts to improve the absolute measurement of $g$ and must be proved to be irrelevant – or taken care of – in gravity gradiometers for the measurement of the absolute value of the universal constant of gravity $G$, for space geodesy and for the detection of gravitational waves.

This work has been supported by ESA through an ITI type B grant. Thanks are due to Neil Ashby, Giuseppe Catastini and Chris Overstreet for useful discussions.
