Abstract

Complex computer simulations are commonly required for accurate data modelling in many scientific disciplines, making statistical inference challenging due to the intractability of the likelihood evaluation for the observed data. Furthermore, sometimes one is interested on inference drawn over a subset of the generative model parameters while taking into account model uncertainty or misspecification on the remaining nuisance parameters. In this work, we show how non-linear summary statistics can be constructed by minimising inference-motivated losses via stochastic gradient descent.

1 Introduction

Simulator-based inference is currently at the core of many scientific fields, such as population genetics, epidemiology, and experimental particle physics. In many cases the implicit generative procedure defined in the simulation is stochastic and/or lacks a tractable probability density \( p(x|\theta) \), where \( \theta \in \Theta \) is the vector of model parameters. Given some experimental observations \( D = \{x_0, ..., x_n\} \), a problem of special relevance for these disciplines is statistical inference on a subset of model parameters \( \omega \in \Omega \subseteq \Theta \). This can be approached via likelihood-free inference algorithms such as Approximate Bayesian Computation (ABC) \([1]\), simplified synthetic likelihoods \([2]\) or density estimation-by-comparison approaches \([3]\).

Because the relation between the parameters of the model and the data is only available via forward simulation, most likelihood-free inference algorithms tend to be computationally expensive due to the need of repeated simulations to cover the parameter space. Furthermore, when data are high-dimensional, likelihood-free inference can rapidly become inefficient, so low-dimensional summary statistics \( s(D) \) are used instead of the raw data for tractability. The choice of summary statistics for such cases becomes of the utmost importance, given that naive choices might cause loss of relevant information and a corresponding degradation of the power of resulting statistical inference.

As a motivating example we consider data analyses at the Large Hadron Collider (LHC), such as those carried out to establish the discovery of the Higgs boson \([4][5]\). In this framework, the ultimate aim is to extract information about Nature from the large amounts of high-dimensional data on the subatomic particles produced by energetic collision of protons, and acquired by highly complex detectors built around the collision point. Accurate data modelling is only available via stochastic simulation of a complicated chain of physical processes, from the underlying fundamental interaction to the subsequent particle interactions with the detector elements and their readout. As a result, the density \( p(x|\theta) \) cannot be analytically computed.

The inference problem in particle physics is commonly posed as hypothesis testing based on the acquired data. An alternate hypothesis \( H_1 \) (e.g. a new theory that predicts the existence of a new fundamental particle) is tested against a null hypothesis \( H_0 \) (e.g. an existing theory, which explain previous observed phenomena). The aim is checking whether the null hypothesis can be rejected in favour of the alternate hypothesis at a certain confidence level \( \alpha \) (\( \alpha = 3 \times 10^{-7} \) is commonly required for claiming discovery), also known as Type I error rate. Because \( \alpha \) is fixed, the sensitivity
of an analysis is determined by the power $1 - \beta$ of the test, where $\beta$ is the probability of rejecting a false null hypothesis, also known as Type II error rate.

Due to the high dimensionality of the observed data, a low-dimensional summary statistic has to be constructed in order to perform inference. A well-known result of classical statistics, the Neyman-Pearson lemma[6], establishes that the likelihood-ratio $\Lambda(x) = p(x|H_0)/p(x|H_1)$ is the most powerful test when two simple hypotheses are considered. As $p(x|H_0)$ and $p(x|H_1)$ are not available, simulated samples are used in practice to obtain an approximation of the likelihood ratio by casting the problem as supervised learning classification.

In many cases, the nature of the generative model (a mixture of different processes) allows the treatment of the problem as signal (S) vs background (B) classification [7], when the task becomes one of effectively estimating an approximation of $p_S(x)/p_B(x)$ which will vary monotonically with the likelihood ratio. While the use of classifiers to learn a summary statistic can be effective and increase the discovery sensitivity, the simulations used to generate the samples for the classifier often depend on additional uncertain parameters (commonly referred as nuisance parameters). These nuisance parameters are not of immediate interest but have to be accounted for in order to make quantitative statements about the model parameters based on the data. Classification-based summary statistics cannot easily account for these effects, so the inference power is degraded when these additional nuisances are taken into account.

In this work, we present a new machine learning method to construct non-linear sample summary statistics that directly optimise the expected amount of information about the subset of parameters of interest using simulated samples, taking into account the effect of nuisance parameters. In addition, the learned summary statistics can be used to build synthetic sample-based likelihoods and perform robust and efficient classical or Bayesian inference from the observed data, so they can be readily applied in place of current classification-based or domain-motivated summary statistics in current scientific data analysis workflows.

## 2 Problem Statement

Let us consider a set of $n$ i.i.d. observations $D = \{x_0, ..., x_n\}$ where $x \in \mathcal{X} \subseteq \mathbb{R}^d$, and a generative model which implicitly defines a probability density $p(x|\theta)$ used to model the data. The generative model is a function of the vector of parameters $\theta \in \Omega \subseteq \mathbb{R}^p$, which includes both relevant and nuisance parameters. We want to learn a function $s : D \subseteq \mathbb{R}^{d \times n} \rightarrow S \subseteq \mathbb{R}^h$ that computes a summary statistic of the dataset and reduces its dimensionality so likelihood-free inference methods can be applied effectively. From here onwards, $h$ will be used to denote the dimensionality of the summary statistic $S(D)$.

While there might be infinite ways to construct $s(D)$, we are only interested in those summary statistics that are informative about the subset of interest $\omega \in \Omega \subseteq \Theta$ of the model parameters. The concept of statistical sufficiency is especially useful to evaluate whether summary statistics are informative. Classical sufficiency can be characterised by means of the factorisation criterion:

$$p(D|\omega) = h(D)g(s(D)|\omega)$$

(1)

where $h$ and $g$ are non-negative functions. If $p(D|\omega)$ can be factorised as indicated, the summary statistic $s(D)$ will yield the same inference about the parameters of interest $\omega$ as the full set of observations $D$. For the problems of interest of this work, the probability density is not explicit so the general task of finding a sufficient summary statistic cannot be tackled directly. Hence, alternative methods to build summary statistics have to be specified.

For simplicity, let us consider a problem where we are only interested on statistical inference on a single one-dimensional model parameter $\omega = \{\omega_0\}$ of given some observed data. Be given a summary statistic $s$ and a statistical procedure to obtain an unbiased interval estimate of the parameter of interest which accounts for the effect of nuisance parameters. The resulting interval can be characterised by its width $\Delta\omega_0 = \hat{\omega}_0 - \hat{\omega}_0^-$. The expected magnitude of the interval depends on the summary statistic $s$ chosen: in general, summary statistics that are more informative about the parameters of interest will provide narrower confidence or credible intervals on their value. Under this figure of merit, the problem of choosing an optimal summary statistic can be formally expressed as finding a summary statistic $s^*$ that minimises the interval width:

$$s^* = \arg\min_s \Delta\omega_0.$$  

(2)
The above construction can be extended to several parameters of interest by considering the interval volume or any other function of the resulting confidence or credible regions.

3 Method

In this section, a machine learning technique to learn non-linear sample summary statistics is described in detail. The method is based on minimising the expected variance of the parameters of interest obtained via a non-parametric simulation-based synthetic likelihood. A graphical description of the technique is depicted on Fig. 1. The parameters of a neural network are optimised by stochastic gradient descent within an automatic differentiation framework, where the considered loss function accounts for the details of the statistical model as well as the expected effect of nuisance parameters.

The family of summary statistics $s(D)$ considered in this work is composed by a neural network model applied to each dataset observation $f(x; \phi) : \mathcal{X} \subseteq \mathbb{R}^d \rightarrow \mathcal{Y} \subseteq \mathbb{R}^b$, whose parameters $\phi$ will be learned during training by means of stochastic gradient descent, as will be discussed later. Therefore, using set-builder notation the family of summary statistics considered can be denoted as:

$$s(D, \phi) = \{ f(x_i; \phi) \mid \forall x_i \in D \}$$  \hspace{1cm} (3)

where $f(x; \phi)$ will reduce the dimensionality from the input observations space $\mathcal{X}$ to a lower-dimensional space $\mathcal{Y}$. The next step is to map observation outputs to a dataset summary statistic, which will in turn be calibrated and optimised via a non-parametric likelihood $L(D; \theta, \phi)$ created using a set of simulated observations $G_s = \{ x_0, ..., x_g \}$, generated at a certain instantiation of the simulator parameters $\theta_s$.

In experimental high energy physics experiments, which are the scientific context that initially motivated this work, histograms of observation counts are the most common non-parametric density estimator because the resulting likelihoods can be expressed as the product of Poisson counts in each of the bins. A naive sample summary statistic can be built from the output of the neural network by simply assigning each observation $x$ to a bin corresponding to the cardinality of the maximum element of $f(x; \phi)$, so each element of the sample summary will correspond to the following sum:

$$s_i(D; \phi) = \sum_{x \in D} \begin{cases} 1 & i = \arg\max_j \{ f_j(x; \phi) \} \\ 0 & i \neq \arg\max_j \{ f_j(x; \phi) \} \end{cases}$$  \hspace{1cm} (4)

which can in turn be used to build the following likelihood, where the expectation for each bin is taken from the simulated sample $G_s$:

$$L(D; \theta, \phi) = \prod_{i=0}^b \text{Pois} \left( s_i(D; \phi) \mid \left( \frac{n}{g} \right) s_i(G_s; \phi) \right)$$  \hspace{1cm} (5)

where the $n/g$ factor accounts for the different number of observations in the simulated samples. In cases where the number of observations is itself a random variable providing information about the
parameters of interest, or where the simulated observation are weighted, the choice of normalisation of \( \mathcal{L} \) may be slightly more involved and problem specific, but nevertheless amenable. In the above construction, the chosen family of summary statistics is non-differentiable due to the \( \arg\max \) operator, so gradient-based updates for the parameters cannot be computed. To work around this problem, a differentiable approximation \( \hat{s}(D; \phi) \) is considered. This function is defined by means of a \( \text{softmax} \) operator:

\[
\hat{s}_i(D; \phi) = \frac{e^{f_i(x; \phi)/\tau}}{\sum_{x \in D} e^{f_j(x; \phi)/\tau}}
\]

where the temperature hyper-parameter \( \tau \) will regulate the softness of the operator. In the limit of \( \tau \to 0^+ \), the probability of the largest component will tend to 1 while others to 0, and therefore \( \hat{s}(D; \phi) \to s(D; \phi) \). Similarly, let us denote by \( \hat{\mathcal{L}}(D; \theta, \phi) \) the differentiable approximation of the non-parametric likelihood obtained by substituting \( s(D; \phi) \) with \( \hat{s}(D; \phi) \). Instead of using the observed data \( D \), the value of \( \hat{\mathcal{L}} \) may be computed when the observation for each bin is equal to its corresponding expectation based on the simulated sample \( G_s \), which is commonly denoted as the Asimov likelihood \( \hat{\mathcal{L}}_A \):

\[
\hat{\mathcal{L}}_A(\theta; \phi) = \prod_{i=0}^{b} \text{Pois} \left( \frac{n}{g} \right) \hat{s}_i(G_s; \phi) \left| \left( \frac{n}{g} \right) \hat{s}_i(G_s; \phi) \right)
\]

for which it can be easily proven that \( \arg\max_{\theta \in \theta_0} (\hat{\mathcal{L}}_A(\theta; \phi)) = \theta_s \) \cite{8}, so the maximum likelihood estimator (MLE) for the Asimov likelihood is the parameter vector \( \theta_s \) used to generate the simulated dataset \( G_s \). In Bayesian terms, if the prior over the parameters is flat in the chosen metric, then \( \theta_s \) is also the maximum a posteriori (MAP) estimator. By taking the negative logarithm and expanding in \( \theta \) around \( \theta_s \), we can obtain the Fisher information matrix \( I(\theta) \) for the Asimov likelihood:

\[
I(\theta)_{ij} = \frac{\partial^2}{\partial \theta_i \partial \theta_j} \left( -\log \hat{\mathcal{L}}_A(\theta; \phi) \right)
\]

which can be computed via automatic differentiation if the simulation is differentiable and included in the computation graph or if the effect of varying \( \theta \) over the simulated dataset \( G_s \) can be effectively approximated. While this requirement does constrain the applicability of the proposed technique to a subset of inference problems, it is quite common for e.g. physical sciences that the effect of the parameters of interest and the main nuisance parameters over a sample can be approximated by the changes of mixture coefficients of mixture models, translations of a subset of features, or conditional density ratio re-weighting.

From the Fisher information, if \( \hat{\theta} \) is an unbiased estimator of the values of \( \theta \), the covariance matrix fulfils the Cramér-Rao lower bound \cite{10,11}:

\[
\text{cov}_{\theta} (\hat{\theta}) \geq I(\theta)^{-1}
\]

so the inverse of the Fisher information can be used as an estimator of the expected variance. If some of the parameters \( \theta \) are constrained by independent measurements characterised by their likelihoods \( \{ \mathcal{L}_{C_i}(\theta), ..., \mathcal{L}_{C_c}(\theta) \} \), those constraints can also be easily included in the covariance estimation, simply by considering the augmented likelihood \( \hat{\mathcal{L}}_A^c \) instead of \( \hat{\mathcal{L}}_A \) in Eq.8:

\[
\hat{\mathcal{L}}_A^c(\theta; \phi) = \hat{\mathcal{L}}_A(\theta; \phi) \prod_{i=1}^{c} \mathcal{L}_{C_i}(\theta).
\]

In Bayesian terminology, this approach is referred as the Laplace approximation \cite{12} where the log joint density (including the priors) is expanded around the MAP to a multi-dimensional normal approximation of the posterior density:

\[
p(\theta|D) \approx \text{Normal}(\theta; \hat{\theta}, I(\hat{\theta})^{-1})
\]

which has already been already approached by automatic differentiation in probabilistic programming frameworks \cite{13}. While a histogram has been used to construct a Poisson count sample likelihood, non-parametric density estimation techniques can be used in its place to construct a product of observation likelihoods based on the neural network output \( f(x; \phi) \) instead. For example, an
extension of this technique to use kernel density estimation (KDE) should be straightforward, given its intrinsic differentiability.

The loss function used for stochastic optimisation of the neural network parameters \( \phi \) can be any function of the inverse of the Fisher information matrix at \( \theta_s \), depending on the ultimate inference aim. The diagonal elements \( I_{ii}^{-1}(\theta_s) \) correspond to the expected variance of each of the \( \phi_i \) under the normal approximation mentioned before, so if the aim is efficient inference about one of the parameters \( \omega_0 = \theta_k \) a candidate loss function is:

\[
U = I_{kk}^{-1}(\theta_s)
\]

which corresponds to the expected width of the confidence interval for \( \omega_0 \) accounting also for the effect of the other nuisance parameters in \( \theta \). This approach can also be extended when the goal is inference over several parameters of interest \( \omega \subseteq \theta \) (e.g. when considering a weighted sum of the relevant variances). A simple version of the approach just described to learn a neural-network based summary statistic employing an inference-aware loss is summarised in Algorithm 1.

**Algorithm 1** Inference-Aware Neural Optimisation.

**Input 1:** differentiable simulator or variational approximation \( g(\theta) \).

**Input 2:** initial parameter values \( \theta_s \).

**Input 3:** parameter of interest \( \omega_0 = \theta_k \).

**Output:** learned summary statistic \( s(D; \phi) \).

1: for \( i = 1 \) to \( N \) do
2: Sample a representative mini-batch \( G_s \) from \( g(\theta_s) \).
3: Compute differentiable summary statistic \( \hat{s}(G_s; \phi) \).
4: Construct Asimov likelihood \( L_A(\theta, \phi) \).
5: Get information matrix inverse \( I(\theta)^{-1} = H_\theta^{-1}(\log L_A(\theta, \phi)) \).
6: Obtain loss \( U = I_{kk}^{-1}(\theta_s) \).
7: Update network parameters \( \phi \to \text{SGD}(\nabla_{\phi} U) \).
8: end for

### 4 Related Work

Classification or regression models have been implicitly used to construct summary statistics for inference in several scientific disciplines. For example, in experimental particle physics, the mixture model structure of the problem makes it amenable to supervised classification based on simulated datasets [14, 15]. While a classification objective can be used to learn powerful feature representations and increase the sensitivity of an analysis, it does not take into account the details of the inference procedure or the effect of nuisance parameters like the solution proposed in this work.

The first known effort to include the effect of nuisance parameters in classification and explain the relation between classification and the likelihood ratio was by Neal [16]. In the mentioned work, Neal proposes training of classifier including a function of nuisance parameter as additional input together with a per-observation regression model of the expectation value for inference. Cranmer et al. [3] improved on this concept by using a parametrised classifier to approximate the likelihood ratio which is then calibrated to perform statistical inference. At variance with the mentioned works, we do not consider a classification objective at all and the neural network is directly optimised based on an inference-loss. Additionally, once the summary statistic has been learnt the likelihood can be trivially constructed and used for classical or Bayesian inference without a dedicated calibration step. Furthermore, the approach presented in this work can also be extended, as done by Baldi et al. [17] by a subset of the inference parameters to obtain a parametrised family of summary statistics with a single model.

Recently, Brehmer et al. [18, 19, 20] further extended the approach of parametrised classifiers to better exploit the latent-space space structure of generative models from complex scientific simulators. Additionally they propose a family of approaches that include a direct regression of the likelihood ratio and/or likelihood score in the training losses. While extremely promising, the most performing solutions are designed for a subset inference problems at the LHC and require considerable changes.
in the way the inference is carried out. The aim of this work is different, as we try to learn sample summary statistics that may act as a plug-in replacement of classifier-based dimensionality reduction and can be applied to general likelihood-free problems where the effect of the parameters can be modelled or approximated.

Within the field of Approximate Bayesian Computation (ABC), there have been some attempts to use neural network as a dimensionality reduction step to generate summary statistics. For example, Jiang et al. \[21\] successfully employ a summary statistic by directly regressing the parameters of interest and therefore approximating the posterior mean given the data, which then can be used directly as a summary statistic.

A different path is taken by Louppe et al. \[22\], where the authors present a adversarial training procedure to enforce a pivotal property on a predictive model. The main concern of this approach is that a classifier which is pivotal with respect to nuisance parameters might not be optimal, neither for classification nor for statistical inference. Instead of aiming for being pivotal, the summary statistics learnt by our algorithm attempts to find a transformation that directly reduces the expected effect of nuisance parameters over the parameters of interest.

5 Experiments

In this section, we first study the effectiveness of the inference-aware optimisation in a synthetic mixture problem where the likelihood is known. We then compare the results with those obtained by standard classification-based summary statistics.

5.1 2D Mixture of Gaussians

In order to exemplify the usage of the proposed approach, evaluate its viability and test its performance by comparing to the use of a classification model proxy, a two-dimensional Gaussian mixture example with two components is considered. One component will be referred as background \( b(x|\lambda) \) and the other as signal \( s(x) \); their probability densities are taken to correspond respectively to:

\[
\begin{align*}
  f_b(x|\lambda) &= \mathcal{N}\left((2 + \lambda, 0), \begin{bmatrix} 5 & 0 \\ 0 & 9 \end{bmatrix}\right) \\
  f_s(x) &= \mathcal{N}\left((1, 1), \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\right)
\end{align*}
\]

where \( \lambda \), a nuisance parameter that shifts the mean of the background density, is unknown. Hence, the probability density function of observations has the following mixture structure:

\[
p(x|\mu, \lambda) = (1 - \mu)f_b(x|\lambda) + \mu f_s(x)
\]

where \( \mu \) is the parameter corresponding to the mixture weight for the signal and consequently \( (1 - \mu) \) is the mixture weight for the background.

Let us assume that we want to carry out inference based on \( n \) i.i.d. observations, such that \( E[n_s] = \mu n \) observations of signal and \( E[n_b] = (1 - \mu) n \) observations of background are expected, respectively. While the mixture model parametrisation shown in Eq. 15 is correct as is, the underlying model could also give information on the expected number of observations as a function of the model parameters. In this toy problem, we consider a case where the underlying model predicts that the total number of observations are Poisson distributed with a mean \( \nu s + b \), where \( s \) and \( b \) are the expected number of signal and background observations. Thus the following parametrisation will be more convenient for building sample-based likelihoods:

\[
p(x|\nu, \lambda) = \frac{b}{\nu s + b} f_b(x|\lambda) + \frac{\nu s}{\nu s + b} f_s(x)
\]

where \( \nu \) is the amount of signal corresponding to the model expectation. This parametrisation is common for physics analyses at the LHC, because theoretical calculations provide information about the expected number of observations. If the probability density is known, but the expectation for the number of observed events depends on the model parameters, the likelihood can be extended \[23\] with a Poisson count term as:

\[
L(\nu, \lambda) = \text{Pois}(n|\nu s + b) \prod^n p(x|\nu, \lambda)
\]
which will be used to provide an optimal inference baseline when benchmarking the different approaches. The analytical likelihood ratio per observation as a function of the value of \( x \) is shown in Fig. 2a when \( \nu = 0.04 \) and \( \lambda = 0 \), while the density ratio between the signal and background densities when \( \lambda = 0 \) is shown in Fig. 2b.

![Figure 2: Likelihood ratio contours](image)

While the synthetic nature of this example allows to rapidly generate training data on demand, a training dataset of 125,000 simulated observations has been considered, in order to study how the proposed method performs when training data is limited. Half of the simulated observations correspond to the signal component and half to the background component. The latter is generated with \( \lambda = 0 \). A validation holdout from the training dataset of 50,000 observations is only used for computing relevant metrics during training and to control over-fitting. The final figures of merit that allow to compare different approaches are computed using a larger dataset of 500,000 observations. For simplicity, mini-batches for each training step are balanced so the same number of events from each component is taken both when using standard classification or inference-aware losses.

The statistical model described above has two unknown parameters: the signal strength \( \nu \) and the background mean shift \( \lambda \). The former is the parameter of interest and its effect can be easily included in the computation graph by weighting the signal observations. This is equivalent to scaling the resulting vector of Poisson counts (or its differentiable approximation) if a non-parametric counting model as the one described in Sec. 3 is used. The latter, referred as \( \lambda \), is a nuisance parameter that causes a shift on the background along variable 1 with respect to the densities shown in Fig. 2b; its effect can accounted for in the computation graph by simply adding \( \lambda, 0 \) to each observation in the mini-batch. The effect of alternative transformations depending on parameters could also be accounted for as long as they are differentiable or substituted by a differentiable approximation.

The same basic network architecture is used both for cross-entropy and inference-aware training: two hidden layers of 10 nodes followed by ReLU activations. The number of layers on the output layer is two when classification proxies are used, matching the number of mixture classes in the problem considered. Instead, for inference-aware classification the number of output nodes can be arbitrary and will be denoted with \( b \), corresponding to the dimensionality of the sample summary statistic. The final layer is followed by a softmax activation function and a temperature \( \tau = 0.01 \) for inference-aware learning to ensure that the differentiable approximations are closer to the true expectations. Standard mini-batch stochastic gradient descent (SGD) is used for training and the optimal learning rate is fixed and decided by means of a simple scan; the best choice found is specified together with the results.

The considered toy problem can be posed as classification based on a simulated dataset. A supervised machine learning model such as a neural network can be trained to discriminate signal and background observations, considering a fixed \( \lambda \). The output of such a model consist on class probabilities \( c_s(x) \) and \( c_b(x) \) given an observation \( x \). The class probabilities can be used to approximate the \( f_s(x)/f_b(x) \) ratio as shown in Fig. 2c which can be compared with the true density ratio in Fig. 2b. The likelihood ratio (or directly the class probabilities) are powerful learned features; however their construction ignores the effect of the nuisance parameter \( \lambda \) on the background distribution. Furthermore, some kind non-parametric density estimation (e.g. a histogram) has to be considered in order to build a calibrated statistical model using the classification-based learned features, which will in turn smooth and reduce the information available for inference.
Dynamics and results of inference-aware optimisation: (a) inference-loss (i.e. approximated variance of the parameter of interest) as a function of the training step for 10 different random initialisations of the neural network parameters (b) profiled likelihood around the expectation value for the parameter of interest of 10 trained inference-aware models and 10 trained cross-entropy loss based models. The latter are constructed by building a binned likelihood by uniformly signal probability in 10 uniform intervals.

In Fig. 3, the dynamics of systematic-aware optimisation are shown by the validation loss, which corresponds to the approximate expected variance of parameter $\nu$, as a function of the training step. A total 10 random initialisations are used to study the convergence and variability of the resulting model. All inference-aware models were trained during 300 epochs with SGD using mini-batches of 1024 observations and a learning rate $\gamma = 0.0001$. All the model initialisations considered seem to converge successfully to an expected variance around 0.20.

To compare with alternative approaches and verify the validity of the results, the Asimov profile likelihoods obtained for each model are shown in Fig. 3. The expected uncertainty if the trained models are used for subsequent inference on the value of $\nu$ can be estimated from the profile width when $\Delta \mathcal{L} = 0.5$. Hence, the widths for the profile likelihood using inference-aware training $0.437 \pm 0.008$ can be compared with those obtained by uniformly binning the output of classification-based models in 10 bins $0.444 \pm 0.003$. The models based on cross-entropy loss were trained during 100 epochs using a mini-batch size of 256 and a fixed learning rate of $\gamma = 0.01$.

This simple example demonstrates that the direct optimisation of inference-aware losses as those described in the Sec. is viable. The summary statistics learnt accounting for the effect of nuisance parameters seem to compare favourably to those obtained by using a classification proxy to approximate the likelihood ratio. However, more experiments are needed to benchmark the usefulness of this technique for real-world inference problems as those found in High Energy Physics analyses at the LHC.

6 Conclusions

Classification-based summary statistics often suffer from the need of specifying a fixed model of the data, thus neglecting the effect of nuisance parameters in the learning process. The effect of nuisance parameters is only considered downstream of the learning phase, resulting in sub-optimal inference on the parameters of interest.

In this work we have described a new approach for building non-linear summary statistics for likelihood-free inference that directly minimise the expected variance of the parameters of interest. In this first version of the article we show the results of this strategy on a very simple toy problem, allowing to focus on the technical aspects of the procedure. A later version will include a discussion of examples more similar to the use cases of parameter estimation in High Energy Physics analyses, which the proposed technique is targeting.
Acknowledgments

Pablo de Castro would like to thank Daniel Whiteson, Peter Sadowski and the other attendants of the ML for HEP meeting at UCI for the initial feedback and support of the idea presented in this paper, as well as Edward Goul for his interest when the project was in early stages. The authors would also like to acknowledge Gilles Louppe and Joeri Hermans for some useful discussions directly related to this work.

This work is part of a more general effort to develop new statistical and machine learning techniques to use in High Energy Physics analyses within within the AMVA4NewPhysics project, which is supported by the European Union’s Horizon 2020 research and innovation programme under Grant Agreement number 675440. CloudVeneto is also acknowledged for the use of computing and storage facilities provided.
