Quantum nonlocality provides an uniquely witness of nonlocal correlations, whose quantum nature can be revealed by the experimentally violation of Bell-type inequalities. In this Letter, we explore the quantum nonlocality as a witness to intrinsic correlation of non-Bunch-Davies (BD) vacua in de Sitter space. By the violation of CHSH inequality on localized state of two free falling Unruh-DeWitt detectors, we find that quantum nonlocality can be generated through Markovian evolution of system and overcome Gibbons-Hawking (GH) decoherence in de Sitter space. In particular, while CHSH bound monotonously degrades with growing GH temperature for BD-vacuum sector, we find that the amount of violation of CHSH inequality can drastically increase after certain turning points for non-BD vacua sectors, as a result of competition between GH decoherence and intrinsic correlation of α—vacua. Remarkably, we show that quantum nonlocality in some non-BD sectors can even survive at infinite GH temperature, contrasting sharply with previous results employing global field modes. To further illustrate our result, we calculate another quantum witness, i.e., entropic uncertainty bound, for non-BD vacua, and show certain residual quantum correlation can be utilized as a physical resource in practical quantum information process. Finally, a discussion on manifestation of invariant Planck-scale by quantum nonlocality is given.

I. INTRODUCTION

Local measurements performed by distant observers on spacelike-separated quantum systems may lead to nonlocal correlations, which Einstein famously called “spooky action at a distance.” This quantum nonlocality has been experimentally revealed by the violation of Bell-type inequalities [1, 2], e.g., CHSH inequality [3], which place an upper bound on the correlations compatible with classical local hidden-variable (LHV) theories. While quantum nonlocality completely characterizes the nature of entanglement for all pure states [4], they are inequivalent for mixed states [5]. For instance, it was shown [6] that entangled Werner states can admit classical LHV models. Therefore, quantum nonlocality provides an uniquely witness of quantum correlations [7].

Quantum nonlocality should play an important role in cosmology. In inflationary paradigm, quantum fluctuations would be stretched over to leave a signature as cosmic microwave background (CMB) anisotropies. As initial state of inflation is heavily squeezed [8], Bell inequality violating experiment was suggested [9] to performed on CMB to give compelling evidence for the quantum origin of primordial density fluctuations. Conventionally, quantum fluctuations are assumed to start in a Bunch-Davies (BD) vacuum at infinite past. However, since the field modes below the Planck-scale Λ are inaccessible, this simple picture has been seriously questioned [10]. With a short-distance cutoff at Planck-scale, inflation models with non-BD initial conditions have been extensively studied, in which the non-BD vacua are manifested in various approaches, e.g., general de Sitter invariant vacua [11], initial entanglement in scalar fields [12] or correlated bubble universes [13]. The related trans-Planckian frequencies are expected to red-shift down and leave observable imprint [14]. To reveal its quantum origin, Bell-type inequalities violating experiment on the trans-Planckian modification of CMB has been explored recently [15]. However, it is interesting to note that most of above schemes are constructed on global modes of quantum fluctuation, while the cutting-edge cosmic Bell test [16] can only access localized quantum states.

Recently, the significance of long-range quantum correlation in quantum gravity has also been appreciated. In general curved spacetime, the nonlocal properties of relativistic quantum fields can be indicated by various witnesses, e.g., entanglement entropy [17], negativity [18] and quantum discord [19]. In a local detector-field picture [20, 21], the dynamics of quantum correlation subjected to curved background has been explicitly studied. Within holographic context, an appealing connection between nonlocal EPR correlation and the emergence of macroscopic spacetime was suggested [22], and further summarized in “ER=EPR” duality [23] to resolve the firewall controversy of black hole information paradox [24]. Regarding these developments, it seems increasingly clear [25, 26] that we can hardly approach a complete quantum gravity theory until the exact nature of nonlocal correlation in gravity context has been adequately understood.

In this Letter, we explore the quantum nonlocality as a witness to quantum correlation of non-BD vacua in de Sitter space. In particular, we perform Bell-type inequalities violating test on the localized state of two Unruh-DeWitt detectors, which interact a scalar field in curved background and behave like an open quantum system,
II. DYNAMICS OF TWO UNRUH-DEWITT DETECTORS

To proceed Bell’s inequality test on Unruh-DeWitt detectors, we should first explore the full dynamics of bipartite detectors state in de Sitter background. We model each detector by a two-level atom, which interacts a bath of fluctuating quantum scalar field in de Sitter space. This indicates that the system of two detectors behaves like an open system, while the fluctuations of the quantum field are treated as environment decoherence and dissipation on the quantum state of system.

II.1. Master equation of detectors

Without loss of generality, the total Hamiltonian of the combined system (detectors + environment) is

\[ H_{tot} = \frac{\omega}{2} \sum_{i=1}^{3} n_i \Sigma_i + H_\Phi + H_I \]  

where \( \Sigma_i \equiv \sigma_i^A \otimes \mathbb{1}^B + \mathbb{1}^A \otimes \sigma_i^B \) are symmetrized two-system operators, and \( \omega \) is energy level spacing of the atoms. \( H_\Phi \) is the Hamiltonian of free massless scalar fields \( \Phi_\mu(x) \) satisfying Klein-Gordon equation in de Sitter space, and \( H_I = \eta \sum_{i=0}^{3} \{ (\sigma_i^A \otimes \mathbb{1}^B) \Phi(t, x_i) + (\mathbb{1}^A \otimes \sigma_i^B) \Phi(t, x_0) \} \) describes the interaction between atoms and bath, where \( \eta \) is a dimensionless coupling constant.

We study the dynamic evolution of detectors’ density matrix \( \rho_{AB}(t) = \text{Tr}_\Phi \rho_{tot}(t) \), where \( t \) is the proper time of detectors’ worldline. We assume that the initial density matrix of the total system is separable, i.e., \( \rho_{tot} = \rho_{AB}(0) \otimes |0\rangle \langle 0| \), where \( |0\rangle \) is the vacuum state of field \( \Phi(x) \), evolving according to von Neumann equation

\[ i\hbar \rho_{tot}(t) = [H_{tot}(t), \rho_{tot}(t)] \]  

In a weak coupling limit, the dynamics of two-atoms’ density matrix \( \rho_{AB}(t) \) can be induced from \( \rho_{tot}(t) \), therefore satisfies a master equation in Kossakowski-Lindblad form

\[ \frac{\partial \rho_{AB}(t)}{\partial \tau} = -i[H_{tot}, \rho_{AB}(t)] + \mathcal{L}[\rho_{AB}(t)] \]  

where

\[ \mathcal{L}[\rho_{AB}] = \sum_{i,j=1}^{3} \sum_{\alpha, \beta = A, B} \frac{C_{ij}}{2} \left\{ 2\sigma_i^{(\beta)} \rho_{AB} \sigma_j^{(\alpha)} - \{\sigma_j^{(\alpha)} \sigma_i^{(\beta)} \}, \rho_{AB} \right\} \]  

is a nonunitary evolution term produced by the coupling with the external fields. The Kossakowski matrix \( C_{ij} \) can be determined by Fourier transform \( G(\lambda) \) of the Wightman functions of scalar field \( G^+(x-y) = \langle 0|\Phi(x)\Phi(y)|0\rangle \), i.e.,

\[ G(\lambda) = \int_{-\infty}^{\infty} dx \ e^{i\lambda x} G^+(x) \]  

In particular, the Kossakowski coefficients \( C_{ij} \) can be written explicitly as

\[ C_{ij} = \Gamma_{+} \delta_{ij} - i \Gamma_{-} \epsilon_{ik} n_k + \Gamma_{0} n_in_j \]  

with

\[ \Gamma_{\pm} = \frac{1}{2} \left[ G(\omega) \pm G(-\omega) \right], \quad \Gamma_{0} = G(0) - \Gamma_{+} \]  

To resolve the master equation (2), we express the reduced density matrix of the two-atom system in a Bloch form as

\[ \rho_{AB}(t) = \frac{1}{4} \left( \mathbb{1}^A \otimes \mathbb{1}^B + \sum_{i=1}^{3} \rho_i \Sigma_i + \sum_{i,j=1}^{3} \rho_{ij} \sigma_i^A \otimes \sigma_j^B \right) \]  

Inserting it back into (2), straightforwardly calculation gives the final reduced density matrix at equilibrium as

\[ \rho_{i} = -\frac{R}{3 + R^2} (\tau + 3)n_i, \quad \rho_{ij} = \frac{1}{3 + R^2} [R^2(\tau + 3)n_i n_j + (\tau - R^2) \delta_{ij}] \]  

where \( R = \Gamma_{-} / \Gamma_{+} \) is the ratio of two constants appearing in the Kossakowski matrix, determined by the dynamics of the system. The final equilibrium state is also depend on the choice of initial state by \( \tau = \sum \rho_{ii}(0) \) which is a constant of motion and satisfies \( -3 \leq \tau \leq 1 \) to keep \( \rho_{AB}(0) \) positive.

II.2. Dynamics within general non-BD vacua

For simplicity, we consider free falling Unruh-DeWitt detectors in de Sitter space, which interact with a massless scalar field conformally coupling to background. Although no de Sitter-invariant vacuum can exist for a...
massless scalar field [11], we can ignore this subtlety by assuming a tiny but nonzero mass.

For an inertial detector in sector of BD vacuum \( |BD\rangle \), it ends up in thermal equilibrium at universal Gibbons-Hawking temperature \( T_H = 1/\beta = H/2\pi \) [34], as the correlation function \( G_{BD}^+(x,y) = \langle BD|\Phi(x)\Phi(y)|BD\rangle \) fulfills the KMS condition, i.e., \( G_{BD}^+(t) = G_{BD}^+(t+i\beta) \).

With Mottola-Allen (MA) transformation, each general \( \alpha \)-vacuum \( |\alpha\rangle \) can be interpreted as a squeezed state over \( |0\rangle_{BD} \), i.e., \( |\alpha\rangle = S|0\rangle_{BD} \) where \( Re \alpha < 0 \) and \( S|0\rangle \) denotes a squeezing operator in quantum optics [28]. In particular, we adopt CPT invariant \( \alpha \)-vacua, which means \( \alpha < 0 \) is real. Therefore, the Wightman function for the scalar field in \( \alpha \)-vacua can be expressed in terms of \( G_{BD}^+ \) as

\[
G_\alpha^+(x,y) = N^{-1}[G_{BD}^+(x,y) + e^{2\alpha}G_{BD}^+(y,x) + e^{\alpha}(G_{BD}^+(x,y_A) + G_{BD}^+(x_A,y))]
\]

where \( N \equiv 1 - e^{2\alpha} \) and \( x_A \) is the antipodal point of \( x \). One can easily find that, as \( \alpha \to -\infty \), \( G_\alpha^+(x,y) \) reduces to the Wightman function in BD vacuum \( G_{BD}^+(x,y) \), which uniquely extrapolates to the same short-distance behavior of two-point correlation function in the Minkowski vacuum, as the curvature of de Sitter vanishing.

Employing the relation [35]

\[
G^+(x,y_A) = G^+(x,y) = G^+(t-i\pi)
\]

we calculate the Fourier transformation of (8) as

\[
G_\alpha = \frac{\lambda(1 + e^{\alpha-\pi\omega})^2}{2\pi(1 - e^{-\beta\lambda})(1 - e^{2\alpha})}
\]

and the related Kossakowski coefficients are

\[
\Gamma_+ = \omega \left[ (1 + e^{\alpha-\pi\omega})^2 + e^{-\beta\lambda}(1 + e^{\alpha+\pi\omega})^2 \right] / 4\pi(1 - e^{2\alpha})(1 - e^{-\beta\lambda})
\]

\[
\Gamma_- = \omega \left[ (1 + e^{\alpha-\pi\omega})^2 - e^{-\beta\lambda}(1 + e^{\alpha+\pi\omega})^2 \right] / 4\pi(1 - e^{2\alpha})(1 - e^{-\beta\lambda})
\]

\[
R_\alpha = \frac{(1 + e^{\alpha-\pi\omega})^2 - e^{-\beta\lambda}(1 + e^{\alpha+\pi\omega})^2}{(1 + e^{\alpha-\pi\omega})^2 + e^{-\beta\lambda}(1 + e^{\alpha+\pi\omega})^2}
\]

For fixed energy level spacing of detectors, it is easy to find that \( R_\alpha \in [-1, +1] \) as \( \beta \) varying. Inserting (11) into (7), we obtain the final equilibrium state of two detectors respecting to \( \alpha \)-vacua. To be more concise, we consider an instructive case with unit vector chosen as \( \mathbf{n} = (0,0,1) \) and (7) becomes

\[
\rho_{AB} = \begin{pmatrix}
A_- & 0 & 0 & 0 \\
0 & B & C & 0 \\
0 & C & B & 0 \\
0 & 0 & 0 & A_+
\end{pmatrix}
\]

where

\[
A_\pm = \frac{(3 + \tau)(R_\alpha \pm 1)^2}{4(3 + R_\alpha^2)}, \quad B = \frac{3 - \tau - (\tau + 1)R_\alpha^2}{4(3 + R_\alpha^2)}, \quad C = \frac{\tau - R_\alpha^2}{2(3 + R_\alpha^2)}
\]

Before moving to the quantum nonlocality of our model, several remarks on \( \alpha \)-vacua should be addressed. Firstly, the squeezing nature of \( \alpha \)-vacua can heavily constrain the measurement uncertainty. This implies that certain intrinsic quantum correlation could be concealed in these non-BD states [17]. Secondly, \( \alpha \)-vacua are not thermal in character, following the fact that (8) does not fulfill the KMS condition unless it reduces to BD vacuum. Such deviation from thermalism has attracted many attempts [29] to take \( \alpha \)-vacua as alternative initial state of inflation. To match the anticipated correction in the primordial power spectrum of order \( \mathcal{O}(H/\Lambda)^2 \), the parameter \( \alpha \) can directly be connected to \( \Lambda \), some fundamental scales of new physics (e.g., the Planck scale or the stringy scale).

III. QUANTUM NONLOCALITY IN GENERAL DE SITTER VACUA

To explore the quantum nature of intrinsic correlation within non-BD vacua, we perform a Bell-type inequalities violating experiment on the bipartite state of Unruh-DeWitt detectors. From (12), we expect that the amount of violation should depend on the choice of initial state of detectors and different superselection sectors of \( \alpha \)-vacua.

III.1. Violation of Bell inequality in de Sitter invariant vacua

We would check that if the reduced density matrix (12) can violate a CHSH inequality [3], which is a suitable inequality for two qubits to test local-realistic theories. Any such theory must satisfy the bound

\[
|\langle B_{CHSH} \rangle_\rho| \leq 2
\]

where the CHSH expectation value for a given state \( \rho \) is defined as \( B_{CHSH} = a\sigma \otimes (b + b') \cdot \sigma + a' \cdot \sigma \otimes (b - b') \cdot \sigma \), and \( \sigma \) is the vector of Pauli matrices. Therefore, the nonlocal correlation of a quantum state \( \rho \) can be witnessed by the violation of (13) up to a value \( 2\sqrt{2} \), for some choices of unit vectors \( a, b, a' \) and \( b' \) in \( \mathbb{R}^3 \).

For general bipartite state, a criterion for the maximally possible violation of (13) has been proved in [36], which claims that the CHSH bound, i.e., the maximal possible value \( \langle B_{CHSH} \rangle_\rho \) can be determined by

\[
\langle B_{max} \rangle_\rho = 2 \sqrt{\nu_1 + \nu_2}
\]

Here \( \nu_1, \nu_2 \) are two largest eigenvalues of matrix \( T_\rho \), where the components of correlation matrix \( T \) are \( (i_{ij}) \) are given by \( i_{ij} = \text{Tr}[\rho \sigma_i \otimes \sigma_j] \).

In our case, we straightforwardly obtain a diagonal \( T_{\rho_{AB}} \) matrix from (12) with three eigenvalues

\[
\lambda_1 = \lambda_2 = \left( \frac{\tau - R_\alpha^2}{3 + R_\alpha^2} \right)^2, \quad \lambda_3 = \left( \frac{\tau + (\tau + 2)R_\alpha^2}{3 + R_\alpha^2} \right)^2
\]
which indicates that \( \langle B_{\text{max}} \rangle_{\rho AB} \) should depend on the initial state of detectors encoding by \( \tau \), and the superselection sectors of vacua labeling by \( \alpha \). According to different preparations of initial state \( \tau \), we come to three classes of the maximal amount of CHSH inequality violation:

(i) For the initial state prepared with \( \tau_0 = -(1 + 2/R_\alpha^2)^{-1} \), we have \( \lambda_1 = \lambda_2 = \lambda_3 \). The CHSH bound (14) is

\[
\langle B_{\text{max}} \rangle_{(i)} = 2\sqrt{2}\left|\tau_0\right| = \frac{2\sqrt{2}R_\alpha^2}{2 + R_\alpha^2} \leq \frac{2\sqrt{2}}{3} \tag{16}
\]

since \( R_\alpha \in [-1, +1] \). No violation of CHSH inequality for final equilibrium state can be found as the CHSH bound (16) is \( \sim 0.9428 \), which means that state (12) is local for any superselection sectors of non-BD vacua.

(ii) For the initial state prepared with \( \tau \in (\tau_0, 1] \), we have \( \lambda_1 = \lambda_2 > \lambda_3 \). The corresponding CHSH bound is

\[
\langle B_{\text{max}} \rangle_{(ii)} = 2\sqrt{\lambda_1 + \lambda_3} = \frac{2}{3 + R_\alpha^2} \sqrt{R_\alpha^2(\tau^2 + 4\tau + 5) + 2R_\alpha^2(\tau^2 + \tau) + 2\tau^2}
\]

As \( R_\alpha \in [-1, +1] \) for varying \( \beta \), we can evaluate (17) and find it cannot across the classical bound of 2, which indicates that no quantum nonlocality for final state (12) with such prepared initial state.

(iii) For the initial state preparing with \( \tau \in (-3, \tau_0) \), we have \( \lambda_1 = \lambda_2 > \lambda_3 \). Then the CHSH bound (14) becomes

\[
\langle B_{\text{max}} \rangle_{(iii)} = 2\sqrt{2\lambda_1} = 2\sqrt{2} \left|\frac{\tau - R_\alpha^2}{3 + R_\alpha^2}\right| \tag{18}
\]

It is easy to observe that for initial state prepared with \( \tau = -3 \), the CHSH inequality can be maximally violated for final equilibrium state up to \( 2\sqrt{2} \), i.e., so-called Tsirelson bound, the upper limit to quantum correlations between distant events. Such violation is independent on any choice of \( \alpha \)-vacua.

For general \( \tau \in (-3, \tau_0) \), things are complexed by the dependence on the infinite family of non-BD vacua. In particular, we want to show that for some initial states satisfying inequality (13), quantum nonlocality can be generated in final state (12) after Markovian evolution of the system, and be witnessed by violating CHSH inequality in de Sitter space.

To illustrate this, we consider two Unruh-DeWitt detectors initially prepared in a Bell-diagonal state in a free falling basis

\[
\rho_0 = \frac{1}{4} \left( 1^A \otimes 1^B + \sum_{i=1}^{3} c_i \sigma_i^A \otimes \sigma_i^B \right) \tag{19}
\]

with coefficients \( 0 \leq |c_i| \leq 1 \). These states are the convex combination of four Bell states and reduce to maximally entangled states (Bell-basis) if \( |c_1| = |c_2| = |c_3| = 1 \). The state (19) is a generalization of many important quantum states, e.g., Werner state [6], and has important applications in quantum information.

By performing a CHSH violating experiment on the initial states (19), we can determine the related CHSH bound. The matrix \( T_\rho^\alpha T_\rho^\beta \) is diagonal with three eigenvalues \( c_1^2, c_2^2, c_3^2 \). We consider an instructive example with \( c_1 = c_2 = c_3 = -2/3 \), which gives CHSH bound \( \langle B_{\text{max}} \rangle_0 = 2\sqrt{2}|c_1| \approx 1.8856 \), indicating that the bipartite detectors have no quantum nonlocality initially. As \( \tau \rightarrow -2 \) in the case, we employ CHSH bound (18) which gives

\[
\langle B_{\text{max}} \rangle_{\text{Bell-diag}} = \frac{1}{\sqrt{2}} \left( 3\gamma_+^2 + 3e^{-2\beta\omega}\gamma_-^2 + 2\gamma_+\gamma_-e^{-\beta\omega} \right) \tag{20}
\]

where \( \gamma_\pm \equiv (1 + e^{\alpha \pm \pi \omega})^2 \). We depict (20) in Fig.1 for various \( \alpha \), corresponding to different superselection sectors of de Sitter vacua.

We find that although the initial Bell-diagonal state is chosen without quantum nonlocality, the final state of detectors can violate the CHSH inequality, which indicates the quantum correlation has been generated through Markovian evolution of system and overcome Gibbons-Hawking decoherence in de Sitter space. With growing Gibbons-Hawking temperature (degrading \( \beta \)), for BD sector of \( \alpha \rightarrow -\infty \), the amount of CHSH bound monotonously degrades, consistent with the results of [20].

![FIG. 1. Violation of CHSH inequality. The initial state of detectors is chosen as Bell-diagonal state with \( c_1 = c_2 = c_3 = -2/3 \) (i.e., \( \tau = -2 \)), which satisfies CHSH inequality. With quantum correlation generated through Markovian evolution of the system, the inequality can be violated for the final state of detectors. For general \( \alpha \)-vacua, the amount of CHSH bound drastically increases after certain turning point \( \beta_* \). In particular, for vacua sectors with \( \alpha = -2, -2.5, -3 \), the residual quantum nonlocality can survive at infinite Gibbons-Hawking temperature. In the inset, the \( \alpha \) dependence of residual quantum nonlocality at \( \beta \rightarrow 0 \) is demonstrated, where the larger violation of CHSH inequality happens for larger deviation from BD superselection sector.](image-url)
when \( \beta \) across certain turning point, determined by 
\[ \partial_\beta \left( B_{\text{max}} \right)_{\text{Bell-diag}} = 0 \]

\[ \beta_c(\alpha) = \frac{1}{\omega} \ln \frac{\gamma_+}{\gamma_-} \tag{21} \]

With more deviation from BD superselection sector, we observe a larger amount of violation of CHSH inequality in the limit of infinite Gibbons-Hawking temperature \((\beta \to 0)\) can be achieved. In particular, starting with same initial state, for some \( \alpha \)-vacua, CHSH bound at \( \beta \to 0 \) can surpass the classical bound, which means that nonvanishing residual quantum nonlocality survives, as depicted in the inset of Fig.1. It is interesting to note that our result contrasts sharply the previous findings in [31], which claimed that no quantum nonlocality can exist in the limit of \( \beta \to 0 \), regardless of any vacuum sectors. Nevertheless, with in mind that our Bell violating experiment is performed on a local quantum system, we need not surprise on its difference to the Bell test in [31] which utilizes global field modes in non-BD sectors.

The increment of CHSH bound in Fig.1 can naturally be attributed to intrinsic quantum correlation of \( \alpha \)-vacua, since they are constructed by squeezing operator \( \hat{S}(\alpha) \sim \exp[\alpha(a^2 - \hat{a}^\dagger \hat{a})] \) on BD vacuum. For small squeezing parameter \( |\alpha| \), the quantum uncertainty of the state can be constrained so heavily, such that the intrinsic correlation grows faster than Gibbons-Hawking decoherence.

A more instructive explanation appeals to the connection between parameter \( \alpha \) and fundamental scale \( \Lambda \) of quantum gravity, e.g., \( e^\alpha \sim \Lambda \) implied by trans-Planckian physics in cosmology [29, 37]. The scale cutoff at \( \Lambda \) means that we can hardly distinguish the events in de Sitter space once across \( \Lambda \) to infinitesimal scales [38]. Inherited by local quantum state of detectors, such indistinguishability of states below scale \( \Lambda \) might be manifested in quantum nonlocality. Once we expect an universal relation between \( \Lambda \) and vacua selection should exist in de Sitter space, suggested as in trans-Planckian issue of inflation, the quantum nonlocality can be witnessed by an \( \alpha \)-dependent CHSH bound beyond classical limit. In this meaning, the increment of CHSH bound for general \( \alpha \) may imply a possible quantum gravity effect, potentially emerging at the scale determined from (21). Such interpretation of \( \beta_c \) as possible manifestation of quantum gravity may further be supported from the study on quantum communication between local events in de Sitter space [31], where the quantum capacity of Grassmann communication channel approaches zero at certain \( \alpha \)-dependent scale. In fact, more evidences can be found [39] in other spacetimes with horizon structure, where the presence of invariant Planck-scale may always be related to significant generation of quantum nonlocality below the cutoff scale.

### III.2. Other witnesses of quantum correlation

To further explore the quantum nature of non-BD vacua, we would like to concisely compare quantum nonlocality with other entanglement witnesses for \( \alpha \)-vacua.

Before proceeding, let us first clarify the difference between quantum nonlocality serving as a profound witness of quantum correlation and quantum entanglement itself. We employ quantum negativity as a measure of distillable entanglement for detectors’ final equilibrium state, defined [40] as \( \mathcal{N}(\rho) = \frac{1}{2} \sum_i |\lambda_i - \lambda_i| = -\sum_{\lambda_{\alpha} < 0} \lambda_i \), where \( \lambda_i \) are the negative eigenvalues of partial transposed density matrix of \( \rho \). The value of negativity ranges from 0, for separable states, to 0.5, for maximally entangled states. Form (12), we can straightforwardly obtain [41]

\[ \mathcal{N} = \frac{2\sqrt{R_{\alpha}^4 + R_{\beta}^2(9 + 4\tau + \tau^2 + \tau^2) - (3 + \tau)(1 + R_{\alpha}^2)} - 3)}{4(3 + R_{\alpha}^2)} \]

which reaches maximum 0.5 at \( \tau = -3 \) and becomes vanishing at \( \tau = (5R_{\alpha}^2 - 3)/(3 - R_{\beta}^2) \).

For different superselection sectors of vacua, we depict the related negativity in Fig.2. While entanglement exhibiting a similar dynamics w.r.t. \( \beta \) as the CHSH bound in Fig.1, residual entanglement can survive at infinite Gibbons-Hawking temperature for every superselection sector of vacua, including BD sector. However, as we showed before, except part of non-BD vacuum sectors (e.g., sectors with \( \alpha = -2, -2.5, -3 \) in Fig.1), the final state of detectors cannot violate CHSH inequality, which means that no quantum information tasks using these entanglement can outperform states with appropriate classical correlations. In this meaning, witnesses on quantum correlation such as quantum nonlocality just quantify the part of entanglement that can be utilized as a physical resource in practical quantum information process.

Regarding the squeezing nature of non-BD vacua, their intrinsic correlation can be recast by an entropic form of quantum uncertainty relation [42]. In particular, we consider an uncertainty game played by Alice (A) and Bob (B), free falling two-level atoms in de Sitter space. For incompatible measurements \( Q \) and \( R \) on quantum system A, with B serving as a memory, one arrives at quantum-memory-assisted entropic uncertainty relation (EUR) [43]

\[ S(Q|B) + S(R|B) \geq U_b \]

where \( U_b \equiv -\log_2 c + S(A|B) \) is the entropic uncertainty bound (EUR), and \( c = \max_{i,j} |\langle a_i | b_j \rangle|^2 \) quantifies the complementarity of the observables \( Q \) and \( R \) with eigenvectors \( |a_i \rangle \) and \( |b_j \rangle \). For disentangled A and B, the quantum conditional von Neumann entropy \( S(A|B) = S(\rho_{AB}) - S(\rho_B) \) satisfies \( S(A|B) \geq 0 \), which means that the lower \( U_b \) is at most the Heisenberg uncertainty bound \(-\log_2 c\). However, once A and B are entangled, \( S(A|B) \) may possible be negative, leading to a EUR
lower than Heisenberg bound. In the extreme case where $A$ and $B$ are maximally entangled, $U_b = 0$, enabling us to predict the outcomes precisely. Experimentally, EUB has served [44] as a novel witness of quantum entanglement between $A$ and $B$.

We would like to compare EUB for (12) with related quantum nonlocality discussed before. For simplicity, we assume that the qubit $A$ of Alice is measured by one of Pauli operators, which gives $c = \frac{1}{2}$ for any two observables $\sigma_j$ and $\sigma_k$ ($j \neq k = 1, 2, 3$). In our case, we apply the EUB of (23) for the final equilibrium state (12), which gives [41]

$$U_b = \frac{3 + \tau}{4} \left[ \log_2(3 + R_\alpha^2) - \sum_{\epsilon = \pm} \left( 1 + \frac{4\epsilon R_\alpha}{R_\alpha^2 + 3} \right) \log_2(1 + \epsilon R_\alpha) \right]$$

$$+ H_{\text{bin}} \left( \frac{1 - \tau}{4} \right) - H_{\text{bin}} \left[ \frac{1}{2} \left( 1 - \frac{3 + \tau}{1 + 3/R_\alpha} \right) \right] + 1$$

where the binary entropy $H_{\text{bin}}(p) \equiv -p \log_2 p - (1 - p) \log_2(1 - p)$ is defined, and $R_\alpha$ is given as (11). For specific initial state with $\tau$, we expect that the intrinsic correlation of superselection sectors of non-BD vacua can be witnessed by $U_b$ through its violation of Heisenberg uncertainty bound, i.e., $U_b \leq 1$ in our case.

We depict the dynamics of EUB (24) w.r.t. $\beta$ in Fig.3 for superselection sectors of non-BD vacua with $\alpha = -2, -2.5, -3, -4$, as well as BD vacuum sector with $\alpha \rightarrow -\infty$. Firstly, we observe that EUB of quantum measurement performed by detector can violate the Heisenberg bound $U_b = 1$ at large $\beta$, but growing with high Gibbons-Hawking temperature, which is not surprising as the thermality of de Sitter vacua should introduce classical noise in quantum measurement [45]. Nevertheless, for non-BD vacuum sectors, $U_b$ degrades once across certain turning point $\beta_c$, consistent with the behavior of CHSH bound in Fig.1. In particular, we find that in the limit of infinite Gibbons-Hawking temperature, residual quantum correlation for $\alpha = -2, -2.5$ can be utilized to surmount the Heisenberg bound through $U_b < 1$, compatible with the interpretation that only the entanglement recognized by quantum witnesses (e.g., violation of Bell inequality or EUB) can be employed in practical quantum information process. Moreover, since the residual entanglement at $\beta \rightarrow 0$ for $\alpha = -3$ can be recognized by the violation of CHSH inequality (20) but not the EUB (24), we should refer quantum nonlocality as a more profound quantum witness.

**FIG. 2.** Negativity as a measure of entanglement. The initial state of detectors is chosen as Bell-diagonal state with $c_1 = c_2 = c_3 = -2/3$ (i.e., $\tau = -2$). For general $\alpha$-vacua, negativity can drastically increase after turning point $\beta_c$. In the inset, the $\alpha$ dependence of residual quantum entanglement at infinite Gibbons-Hawking temperature is demonstrated, where the larger negativity happens for larger deviation from BD superselection sector.

**FIG. 3.** EUB as a witness of quantum entanglement. The initial state of detectors is chosen as Bell-diagonal state with $c_1 = c_2 = c_3 = -2/3$ (i.e., $\tau = -2$). For non-BD vacua sectors with $\alpha = -2, -2.5$, the Heisenberg uncertainty bound $U_b = 1$ can be violated at infinite Gibbons-Hawking temperature, witnessing the residual entanglement between detector and quantum memory. In the inset, the $\alpha$ dependence of EUB at $\beta \rightarrow 0$ is demonstrated.
a clear difference between BD vacuum and non-BD vacua in the violation of CHSH inequality or Heisenberg uncertainty bound, we may be able to find the nature of the initial state in inflationary cosmology [15]. The methodology of this Letter can be extended to other curved spacetime, where the geometry of background should affect the dynamics of quantum correlation witnessed by quantum nonlocality or EUB. In particular, it would be interesting to explore those quantum witnesses in the spacetime of black hole, where they exhibit a monogamy-like relation [24], thus may shed some new light on firewall paradox of black hole [26].

We explained the increment of quantum nonlocality in non-BD superselection sectors by a possible relation between parameter \( \alpha \) and the fundamental scale \( \Lambda \) where Planckian cutoff is introduced. Below the minimal scale \( \Lambda \), the indistinguishability of states can be manifested with nonvanishing quantum nonlocality. It is then natural to ask that, regardless of specific inflation model, if any invariant Planck scale cutoff in quantum gravity can be witnessed by the emergence of quantum nonlocality. Evidences shown that the delocalization caused by the minimal length [46] should lead to a deformed two-point correlation function [47], which modifies the spectrum of a detector in curved spacetime. By performing Bell-type inequalities violating experiment on the localized state of detector, the quantum nonlocality arose directly from minimal length is expected to be witnessed. We will report the related work elsewhere [39].
