It has been pointed out that the Berry phase\cite{1} associated with an adiabatic and cyclic change of a parameter in Hamiltonians can be adopted as a topological order parameter to characterize the quantum state for which the order parameters in the conventional sense do not exist.\cite{2}

In the recent study on an anisotropic magnet on the two-dimensional Kagome lattice\cite{3,4}, a new phase called the tripartite entangled plaquette state has been found\cite{4} by using large-scale Monte Carlo simulations when the average magnetization is 1/3 of the saturation magnetization. This new phase appears when anisotropy is introduced in the antiferromagnetic interactions between the z-components of the spins. It is different from the valence-bond solid phase and the ferromagnetic phase reported in the isotropic coupling\cite{3,4}, it restores all the symmetries of the Hamiltonian and is gapped. More interestingly, it is adiabatically connected\cite{4} to the product state of the tripartite entangled three-qubit W states\cite{12,13,14} in the limit of the strong anisotropy. This means that the ground state of the anisotropic Kagome magnet at the average magnetization of 1/3, is essentially a short-ranged entangled state, where the entanglement may be detected by the Berry phase\cite{4} Therefore, in the present paper, to characterize the tripartite entangled plaquette state of the anisotropic Kagome magnet, we examine the possibility of the Z3 Berry phase numerically.

We consider a spin-1/2 XXZ model on the Kagome lattice as shown in Fig. 1(a), where the unit cell is assumed to have three intra-spins forming the thick solid triangles (the up triangles). These intra-spins are coupled by thin lines to the spins in the neighboring unit cells, which form the down triangles. The Hamiltonian we adopt is described as\cite{4}

\[ H = \sum_{\langle i,j \rangle} J_{xy} (S_i^x S_j^x + S_i^y S_j^y) + J_z^2 S_i^z S_j^z, \quad a = u, d \]

where \( J_{xy} > 0 \) denotes the ferromagnetic coupling in the x-y plane and \( J_z^2 > 0 \) denotes the antiferromagnetic coupling between z-component of intra-sites (the up triangles) in the unit cell of the Kagome lattice, whereas \( J_z^2 > 0 \) denotes the coupling between inter sites represented by the thin solid lines (the down triangles). Here, the spin-1/2 operators at the lattice site \( i \) are denoted by \( S_i = (S_i^x, S_i^y, S_i^z) \). The summation is performed over the nearest-neighbor pairs \( \langle i, j \rangle \) of the Kagome lattice.

Different from the conventional definition of the Berry phase, here we consider the Berry phase for a cyclic change of local interactions in the lattice model\cite{4} We consider a two dimensional parameter \( \Theta = (\theta_1, \theta_2) \) for a set of three intra-spins in a certain unit cell (the up triangle)\cite{4} and modify the interactions among these three intra-spins as\cite{4}

\[
H(S_1, S_2, S_3) = \frac{J_{xy}}{2} \left\{ (e^{i\theta} S_1^+ S_2^- + e^{-i\theta} S_1^- S_2^+) \
+ (e^{i\theta} S_2^+ S_3^- + e^{-i\theta} S_2^- S_3^+) \
+ (e^{i(\theta_1+\theta_2)} S_1^+ S_3^- + e^{i(\theta_1+\theta_2)} S_1^- S_3^+) \right\} 
+ J_z^2 (S_1^z S_2^z + S_2^z S_3^z + S_3^z S_1^z),
\]

where these intra-spins are denoted by \( S_1, S_2, S_3 \) and \( S_k^+ = S_k^x + iS_k^y \) and \( S_k^- = S_k^x - iS_k^y \) with \( k = 1, 2, 3 \). We then define a Berry phase \( \gamma_\Theta(C) \)

\[
\gamma_\Theta(C) = \int_C \langle \psi(\Theta)|\nabla_\Theta|\psi(\Theta) \rangle \cdot d\Theta
\]

associated with the cyclic change of the parameter \( \Theta \) along the path \( C \) shown in Fig. 1(b). Here \( |\psi(\Theta)\rangle \) represents the ground-state wave function for the parameter \( \Theta \). As the path \( C \) is equivalent to paths \( C' \) and \( C'' \) because of the \( Z_3 \) symmetry of the Kagome lattice and \( C + C' + C'' = 0 \), we have \( \gamma_\Theta(C) = \gamma_\Theta(C') = \gamma_\Theta(C'') \) and \( \gamma_\Theta(C) + \gamma_\Theta(C') + \gamma_\Theta(C'') = 0 \) mod \( 2\pi \). The Berry phase defined above is thus expected to be quantized to \( \gamma_\Theta(C) = 2\pi m/3 \) with \( m = 0, 1, 2 \). The quantization of the present \( Z_3 \) Berry phase is thus protected by the \( Z_3 \) symmetry of the Kagome lattice. Hereafter, we denote \( \gamma_\Theta(C) \) as \( \gamma_\Theta \).

For the extreme case where the couplings between neighboring unit cells (thin lines in Fig. 1(a)) are negligibly small and the unit cells are decoupled from each other, the ground interactions among these three intra-spins as\cite{4} resulting in the anticipated numerical study of the Berry phase numerically.
state is given by the product of the ground states of the decoupled unit cells. In such a case, the above modification of interactions reduces to the rotations of spins $(S_i^+, S_i^-) \rightarrow (S_i^+ e^{i\theta}, S_i^- e^{-i\theta})$, which is a unitary transformation for the Hamiltonian in the space where the average magnetization is $1/3$. The ground state of the three spins in the unit cell is then given by

$$|\psi(\Theta)\rangle = \frac{1}{\sqrt{3}} (|\uparrow\uparrow\downarrow\rangle + |\downarrow\downarrow\uparrow\rangle + e^{-i\theta}|\downarrow\uparrow\uparrow\rangle),$$

with the energy $(-J_{xy} - J_z^0/4)\hbar^2$, which is independent of $\Theta$. Here, we assume that the magnitude of the average magnetization is $1/3$, which is the saturation magnetization in each unit cell. Subsequently, it is straightforward to see that the Berry phase defined above indeed becomes $\gamma_a = 2\pi/3$. This quantized value of the Berry phase is broadly expected in the phases adiabatically connected to such an extreme case as well, namely, the tripartite entangled plaquette W state.

For a system with non-zero couplings between unit cells (thin lines), we have performed exact diagonalization of Hamiltonians in infinite systems to obtain the ground state numerically. Using the ground states $|\psi(\Theta_a)\rangle$ for each value of the parameter $\Theta_a$ along the path $C$, the Berry phase can be evaluated as

$$\gamma_a = \text{arg} \left( \prod_{\alpha \in \mathcal{N}} \left( \psi(\Theta_{a\alpha} \Psi(\Theta_{a})) \right) \right),$$

where $\mathcal{N}$ denotes the number of mesh points along the path $C$. In practice, we set $\Theta_a = (2\pi/N)(n, n)$ for $0 \leq n \leq N/3$ and $\Theta_a = (2\pi/N)(N - n, N - n/2)$ for $N/3 < n \leq N$. Note that the Berry phase can be defined as long as the gap above the ground state does not close along the path $C$.

Adopting the Lanczos technique, we obtain the ground state of the spin-1/2 XXZ model on the Kagome lattice up to 27 spins with the periodic boundary condition in the sub-space where the average magnetization is $1/3$ of the saturation magnetization. We then find that the Berry phase is indeed quantized to an integer multiple of $2\pi/3$ and shows a transition from $\gamma_a = 0$ to $\gamma_a = 2\pi/3$ as the anisotropy $J_z^0/J_x^0$ is increased (Fig. 2). This clearly indicates the ground state in a strongly anisotropic regime is adiabatically connected to the decoupled three-qubit W state. It should be noted that even in a small system with 27 spins, the signature of the non-trivial topological state can be captured by evaluating the Berry phase. We estimate the phase boundary with $\gamma_a = 0$ and $\gamma_a = 2\pi/3$ as shown in Fig. 3. We also evaluate the Berry phase $\gamma_d$ for the down triangles. The Berry phase $\gamma_d$ is also shown to have a quantized value $2\pi/3$ when the coupling $J_z^0/J_x^0$ becomes larger than a critical value (Fig. 3). As expected from the symmetry, the phase with $\gamma_u = 2\pi/3$ and that with $\gamma_d = 2\pi/3$ appear symmetrically with respect to the isotropic line $J_z^0 = J_x^0$. The narrow region between these two phases with $\gamma_u = \gamma_d = 0$ may correspond to the ferromagnetic phase.

In summary, we have investigated the Berry phase in a spin 1/2 XXZ model on the Kagome lattice where the average magnetization is $1/3$ of the saturation magnetization. We have shown that the fractionally quantized Z$_3$ Berry phase becomes a quantized value $2\pi/3$ when the anisotropy is stronger than a critical value. This fact indicates the emergence of a topologically non-trivial phase and is consistent with the existence of the tripartite entangled plaquette phase in the anisotropic regime. Although the phase diagram shown in Fig. 3 is qualitatively similar to that obtained by a large-scale Monte Carlo analysis, the critical values of $J_z^0/J_x^0$ are smaller than those in Ref. 7. This may be attributed to the small size of the systems in the present study, suggesting that further studies are necessary in much larger systems by adopting a Monte Carlo technique to evaluate the Berry phase for quantitative study.
ies of topological phases in two dimensions.
