Successive Convex Approximation Algorithms for Sparse Signal Estimation with Nonconvex Regularizations
Yang Yang, Marius Pesavento, Symeon Chatzinotas and Björn Ottersten

Abstract—In this paper, we propose a successive convex approximation framework for sparse optimization where the nonsmooth regularization function in the objective function is nonconvex and it can be written as the difference of two convex functions. The proposed framework is based on a nontrivial combination of the majorization-minimization framework and the successive convex approximation framework proposed in literature for a convex regularization function. The proposed framework has several attractive features, namely, i) flexibility, as different choices of the approximate function lead to different type of algorithms; ii) fast convergence, as the problem structure can be better exploited by a proper choice of the approximate function and the stepsize is calculated by the line search; iii) low complexity, as the approximate function is convex and the line search scheme is carried out over a differentiable function; iv) guaranteed convergence to a stationary point. We demonstrate these features by two example applications in subspace clustering, namely, the network anomaly detection problem and the sparse subspace clustering problem. Customizing the proposed framework by adopting the best-response type approximation, we obtain soft-thresholding with exact line search algorithms for which all elements of the unknown parameter are updated in parallel according to closed-form expressions. The attractive features of the proposed algorithms are illustrated numerically.

Index Terms—Big Data, Line Search, Majorization Minimization, Nonconvex Regularization, Successive Convex Approximation

I. INTRODUCTION

In this paper, we consider the following optimization problem

\[ \min_x h(x) \triangleq f(x) + g(x). \]  \hspace{1cm} (1)

where \( f \) is a smooth function and \( g \) is a nonsmooth function. Such a formulation plays a fundamental role in parameter estimation, and typically \( f \) models the estimate error while \( g \) is a regularization (penalty) function promoting in the solution a certain structure known a priori such as sparsity \[1\]. Among others, the linear regression problem is arguably one of the most extensively studied problems and it is a special case of (1) by setting \( f(x) = \frac{1}{2} \|Ax - y\|_2^2 \) and \( g(x) = \|x\|_1 \) where \( A \in \mathbb{R}^{N \times K} \) is a known dictionary and \( y \in \mathbb{R}^N \) is the available noisy measurement. Many algorithms have been proposed for the linear regression problem, for example, the fast iterative soft-thresholding algorithm (FISTA) \[2\], the block coordinate descent (BCD) algorithm \[3\], the alternating direction method of multiplier (ADMM) \[4\], proximal algorithm \[5\] and the parallel best-response with exact line search algorithm \[6\].

In linear regression, the function \( f(x) = \frac{1}{2} \|Ax - y\|_2^2 \) is convex in \( x \). This is generally desirable in the design of numerical algorithms solving problem (1) iteratively. However, this desirable property is not available in many other applications where we have to deal with a nonconvex \( f \). Consider for example the linear regression model where we assume that the dictionary \( A \) is unknown and treated as a variable.

In this case, the objective function \( f(A, x) = \frac{1}{2} \|Ax - y\|_2^2 \) is a nonconvex function in \( (A, x) \) and the problem is known as Dictionary Learning. In nonlinear regression problems \[7\], \( f(x) \) is in general a nonconvex function, for example, \( f(x) = \frac{1}{2} \|\sigma(Ax) - b\|_2^2 \) and \( \sigma \) is a given function specifying the nonlinear regression model, e.g., the cosine or sigmoid function.

When the function \( f \) is nonconvex, the above mentioned algorithms must be re-examined. For example, the FISTA algorithm no longer converges, and the generalized iterative soft-thresholding algorithm (GIST) has been proposed instead. However, as a proximal type algorithm, the GIST algorithm suffers from slow convergence \[2\]. The block coordinate descent (BCD) algorithm usually exhibits a faster convergence because the variable update is based on the so-called nonlinear best-response \[8\]: the variable \( x \) is partitioned into multiple block variables \( x = (x_k)_{k=1}^K \), and in each iteration of the BCD algorithm, one block variable, say \( x_k \), is updated by its best-response \( x_k^{(t+1)} = \arg\min_{x_k} h(x_k^{(t)} + \sigma_k(x_k^{(t)}, x_{k-1}, x_{k+1}, \ldots, x_K^{(t)})) \) (i.e., the optimal point that minimizes \( h(x) \) with respect to \( x_k \)) the variable \( x_k \) only while the remaining variables are fixed to their values of the preceding iteration) while all block variables are updated sequentially. Its convergence is guaranteed under some sufficient conditions on \( f \) and \( g \) \[9\] \[10\] \[11\] and due to its simplicity, this method and its variants have been successfully adopted to many practical problems including the network anomaly detection problem in \[12\]. Nevertheless, a major drawback of the sequential update is that it may incur a large delay because the \((k + 1)\)-th block variable \( x_{k+1} \) cannot be updated until the \( k\)-th block variable \( x_k \) is updated and the delay may be very large when \( K \) is large, which is a norm rather than an exception in big data analytics \[13\].

A parallel variable update based on the best-response (also known as the parallel block coordinate descent algorithm \[14\]) seems attractive as a mean to speed up the updating procedure, however, sufficient conditions guaranteeing the convergence of a parallel best-response algorithm are known for smooth problems only (that is, \( g(x) = 0 \) and they are rather restrictive, for example, \( f \) is convex and satisfies the diagonal dominance condition \[15\]). However, it has been shown in some recent works \[14\] \[15\] \[16\] that if a stepsize is large, which is a norm rather than an exception in big data analytics \[13\].

A parallel variable update based on the best-response (also known as the parallel block coordinate descent algorithm \[14\]) seems attractive as a mean to speed up the updating procedure, however, sufficient conditions guaranteeing the convergence of a parallel best-response algorithm are known for smooth problems only (that is, \( g(x) = 0 \) and they are rather restrictive, for example, \( f \) is convex and satisfies the diagonal dominance condition \[15\]). However, it has been shown in some recent works \[14\] \[15\] \[16\] that if a stepsize is large, which is a norm rather than an exception in big data analytics \[13\].

When the function \( f \) is nonconvex, the above mentioned algorithms must be re-examined. For example, the FISTA algorithm no longer converges, and the generalized iterative soft-thresholding algorithm (GIST) has been proposed instead. However, as a proximal type algorithm, the GIST algorithm suffers from slow convergence \[2\]. The block coordinate descent (BCD) algorithm usually exhibits a faster convergence because the variable update is based on the so-called nonlinear best-response \[8\]: the variable \( x \) is partitioned into multiple block variables \( x = (x_k)_{k=1}^K \), and in each iteration of the BCD algorithm, one block variable, say \( x_k \), is updated by its best-response \( x_k^{(t+1)} = \arg\min_{x_k} h(x_k^{(t)} + \sigma_k(x_k^{(t)}, x_{k-1}, x_{k+1}, \ldots, x_K^{(t)})) \) (i.e., the optimal point that minimizes \( h(x) \) with respect to \( x_k \)) the variable \( x_k \) only while the remaining variables are fixed to their values of the preceding iteration) while all block variables are updated sequentially. Its convergence is guaranteed under some sufficient conditions on \( f \) and \( g \) \[9\] \[10\] \[11\] and due to its simplicity, this method and its variants have been successfully adopted to many practical problems including the network anomaly detection problem in \[12\]. Nevertheless, a major drawback of the sequential update is that it may incur a large delay because the \((k + 1)\)-th block variable \( x_{k+1} \) cannot be updated until the \( k\)-th block variable \( x_k \) is updated and the delay may be very large when \( K \) is large, which is a norm rather than an exception in big data analytics \[13\].

A parallel variable update based on the best-response (also known as the parallel block coordinate descent algorithm \[14\]) seems attractive as a mean to speed up the updating procedure, however, sufficient conditions guaranteeing the convergence of a parallel best-response algorithm are known for smooth problems only (that is, \( g(x) = 0 \) and they are rather restrictive, for example, \( f \) is convex and satisfies the diagonal dominance condition \[15\]). However, it has been shown in some recent works \[14\] \[15\] \[16\] that if a stepsize is large, which is a norm rather than an exception in big data analytics \[13\].
iteration \[16\]. Remark 4], which might be computationally expensive for some \(g\) such as the nuclear norm \[17\]. Diminishing stepizes has the lowest complexity, but sometimes they are difficult to deploy in practice because the convergence behavior is sensitive to the decay rate \[6\]. As a matter of fact, the applicability of SCA algorithms in big data analytics is severely limited by the meticulous choice of stepizes \[13\].

To reduce the complexity of the traditional line search schemes and avoid the parameter tuning of the diminishing stepize rules, a new line search scheme is proposed in \[6\]: the exact line search is carried out over a properly constructed differentiable function; in the successive line search, the approximate function only needs to be optimized once. The line search schemes in \[6\] are much easier to implement, and closed-form expressions even exist for many applications. Besides this, the assumption on the strong or strict convexity of the approximate functions made in \[15, 16\] is also relaxed to convexity in \[6\].

Another popular algorithm for problem \[1\] in big data analytics is the alternating direction method of multipliers (ADMM) \[4\], but it does not have a guaranteed convergence to a stationary point if the optimization problem \[1\] is nonconvex \[13\]. There is some recent development in ADMM for nonconvex problems, see \[19, 20\] and the references therein. Nevertheless, the algorithms proposed therein are for specific problems and not applicable in a broader setup. For example, the ADMM algorithm proposed in \[19\] is designed for nonconvex sharing/consensus problems, and the ADMM algorithm proposed in \[20\] converges only when the dictionary matrix has full row rank, which is generally not satisfied for the network anomaly detection problem \[12\].

So far we have assumed that the regularization function \(g\) in \(1\) is convex, for example, the \(\ell_1\)-norm function, as it has been used as a standard regularization function to promote sparse solutions \[21\]. However, it was pointed out in \[22, 23\] that the \(\ell_1\)-norm is a loose approximation of the \(\ell_0\)-norm and it tends to produce biased estimates when the sparse signal has large coefficients. A more desirable regularization function is singular at the origin while flat elsewhere. Along this direction, several nonconvex regularization functions have been proposed, for example, the smoothly clipped absolute deviation \[22\], the capped \(\ell_1\)-norm \[24\], and the logarithm function \[25\]; we refer the interested reader to \[26\] for a more comprehensive review.

The nonconvexity of the regularization function \(g\) renders many of the above discussed algorithms inapplicable, including the SCA framework \[6\], because the nonsmooth function \(g\) is assumed to be convex. It is shown in \[26\] that if the smooth function \(f\) is convex and the nonconvex regularization function \(g\) can be written as the sum of a convex and a concave function, the classic majorization-minimization (MM) method can be applied to find a stationary point of \(1\) firstly in the majorization step, an upper bound function is obtained by linearizing the concave regularization function, and then the upper bound function is minimized in the minimization step; see \[27\] for a recent overview article on the MM algorithms. Nevertheless, the minimum of the upper bound cannot be expressed by a closed-form expression and must be found iteratively. The MM method is thus a two-layer algorithm that involves iterating within iterations and has a high complexity: a new instance of the upper bound function is minimized by iterative algorithms at each iteration of the MM method while minimizing the upper bound functions repeatedly is not a trivial task, even with a warm start that sets the optimal point of the previous instance as the initial point of the new instance.

To reduce the complexity of the classic MM method, an upper bound function based on the proximal type approximation is designed in \[28\] and it is much easier to optimize (see \[29\] for a more general setup). Although the algorithm converges to a stationary point, it suffers from two limitations. Firstly, the convergence speed with the proximal type upper bound functions is usually slower than some other approximations, for example, the best-response approximation \[6\]. Secondly, the proximal type upper bound function minimized in each iteration is nonconvex, and it may not be easy to optimize except in the few cases discussed in \[23\].

In this paper, we propose a SCA framework for problem \(1\) where the smooth function \(f\) is nonconvex and the nonsmooth nonconvex regularization function \(g\) is the difference of two convex functions \[7\]. The proposed SCA framework is based on a nontrivial combination of the SCA framework for a convex \(g\) proposed in \[6\] and standard MM framework \[27\]. In particular, in each iteration, we first construct a (possibly nonconvex) upper bound of the original function \(h\) by the standard MM method, and then minimize a convex approximation of the upper bound which can be constructed by the standard SCA framework \[6\]. On the one hand, this is a beneficial combination because the approximate function is typically much easier to minimize than the original upper bound function and the proposed algorithm is thus a single layer algorithm if we choose an approximate function such that its minimum has a closed-form expression. On the other hand, this is a challenging combination because the convergence of the proposed algorithms can no longer be proved by existing techniques. To further speed up the convergence, we design a line search scheme to calculate the stepsize by generalizing the line search schemes proposed in \[6\] for a convex \(g\). The proposed framework has several attractive features, namely,

- **flexibility**, as the approximate function does not have to be a global upper bound of the original objective function and different choices of the approximate functions lead to different types of algorithms, for example, proximal type approximation and best-response type approximation;
- **fast convergence**, as the problem structure can be better exploited by a proper choice of the approximate function, and the stepsize is calculated by the line search;
- **low complexity**, as the approximate function is convex and easy to optimize, and the proposed line search scheme over a properly constructed differentiable function is easier to implement than traditional schemes which are directly applied to the original nonconvex nonsmooth objective function;
- **guaranteed convergence to a stationary point**, as long as the approximate function is convex and satisfies some other mild assumptions on gradient consistency and continuity.

We then illustrate the above attractive features by customizing the proposed framework for two example applications in subspace learning, namely, the network anomaly detection problem and the sparse subspace clustering problem, where both the optimal point of the (best-response type) approximate functions and the stepsize obtained from the exact line search have closed-form expressions.

The rest of the paper is organized as follows. In Sec. \[II\] we introduce the problem formulation and the example applications. The novel SCA framework is proposed and its convergence is analyzed in Sec. \[III\]. In Sec. \[IV\] and Sec. \[V\] two example applications, the network anomaly detection problem through sparsity regularized rank minimization and the subspace clustering problem through capped \(\ell_1\)-norm minimization, are discussed, both theoretically and numerically. The paper is concluded in Sec. \[VI\].

**Notation:** We use \(x, x, \text{ and } X\) to denote a scalar, vector and matrix, respectively. We use \(X_{jk}\) to denote the \((j,k)\)-th element of \(X\); \(x_k\) is the \(k\)-th element of \(x\) where \(x = (x_k)_{k=1}^{K}\), and \(x_{-k}\) denotes all elements of \(x\) except \(x_k\); \(x_{-k} = (x_j)_{j=1,j\neq k}^{K}\). We denote \(x^{-1}\) as the element-wise inverse of \(x\), i.e., \((x^{-1})_k = 1/x_k\). Notation \(x \circ y\)

\[1\] Some preliminary results of this paper have been presented at [30] [31].
and $X \otimes Y$ denotes the Hadamard product between $x$ and $y$, and the Kronecker product between $X$ and $Y$, respectively. The operator $[x]_a^b$ returns the element-wise projection of $x$ onto $[a, b]$. The condition $\max(\min(x, b), a)$.

We denote $d(X)$ as the vector that consists of the diagonal elements of $X$ and diag$(x)$ is a diagonal matrix whose diagonal elements are as same as those of $x$. We use 1 to denote a vector with all elements equal to 1. The sign function $\text{sign}(x) = 1$ if $x > 0$, 0 if $x = 0$, and $-1$ if $x < 0$, and $\text{sign}(x) = (\text{sign}(x_k))_k$.

II. Problem Formulation

In this section, we formally introduce the problem that will be tackled in the rest of the paper. In particular, we assume $g(x)$ in (1) can be written as the difference of two convex functions, and consider from now on the following problem:

$$ \min_{x \in \mathcal{X}} h(x) = f(x) + g^+(x) - g^-(x), $$

(2)

where

- $f$ is a proper and differentiable function with a continuous gradient,
- $g^+$ and $g^-$ are convex functions, and
- $\mathcal{X}$ is a closed and convex set.

Note that $f(x)$ is not necessarily convex, and $g^+(x)$ and $g^-(x)$ are not necessarily differentiable.

We aim at developing efficient iterative algorithms that converge to a stationary point $x^*$ of problem (2) that satisfies the first order optimality condition:

$$(x - x^*)^T(\nabla f(x^*) + \nabla g^+(x^*) - \nabla g^-(x^*)) \geq 0, \forall x \in \mathcal{X},$$

where $\nabla g^+$ and $\nabla g^-$ are a subgradient of $g^+(x)$ and $g^-(x)$, respectively. Note that a convex function always has a subgradient.

A. Example Application: Network Anomaly Detection Through Sparsity Regularized Rank Minimization

Consider the problem of estimating a low rank matrix $X \in \mathbb{R}^{N \times K}$ and a sparse matrix $S \in \mathbb{R}^{I \times K}$ from the noisy measurement $Y \in \mathbb{R}^{N \times K}$ which is the output of a linear system:

$$ Y = X + DS + V, $$

where $D \in \mathbb{R}^{N \times I}$ is known and $V \in \mathbb{R}^{N \times K}$ is the unknown noise.

The rank of $X$ is much smaller than $N$ and $K$, i.e., $\text{rank}(X) \ll \min(N, K)$, and the support size of $S$ is much smaller than $IK$, i.e., $\|S\|_0 \ll IK$. A natural measure for the estimation error is the least square loss function augmented by regularization functions to promote the sparsity of $X$ and support sparsity of $S$:

$$ \min_{X,S} \frac{1}{2} \|X + DS - Y\|_F^2 + \lambda \|X\|_n + \mu \|S\|_1, $$

(3)

where $\|X\|_n$ is the nuclear norm of $X$. Problem (3) plays a fundamental role in the analysis of traffic anomalies in large-scale backbone networks [12]. In this application, $D$ is a given binary routing matrix, $X = RZ$ where $Z$ is the unknown traffic flows over the time horizon of interest, and $S$ is the traffic volume anomalies. The matrix $X$ inherits the rank sparsity from $Z$ because common temporal patterns among the traffic flows in addition to their periodic behavior render most rows/columns of $Z$ linearly dependent and thus low rank, and $S$ is assumed to be sparse because traffic anomalies are expected to happen sporadically and last shortly relative to the measurement interval, which is represented by the number of columns $K$.

Problem (3) is convex and it can be solved by the SCA algorithm proposed in [17], which is a parallel best-response with exact line search algorithm. Although it presents a much lower complexity than standard methods such as proximal type algorithms and BCD algorithms, it may eventually become inefficient due to the use of complex models: computing the nuclear norm $\|X\|_n$ has a cubic complexity and is unaffordable when the problem dimension is large. Furthermore, problem (3) is not suitable for the design of distributed and/or parallel algorithms because the nuclear norm $\|X\|_n$ is neither differentiable nor decomposable among the blocks of $X$ (unless $X$ is Hermitian).

It follows from the identity [33] $\|X\|_n = \min_{(P, Q)} \frac{1}{2} \|P\|_F^2 + \|Q\|_F^2$, s.t. $PQ = X$

that the low rank matrix $X$ can be written according to the above matrix factorization as the product of two low rank matrices $P \in \mathbb{R}^{N \times \rho}$ and $Q \in \mathbb{R}^{\rho \times K}$ for a $ho$ that is larger than the rank of $X$ but usually much smaller than $N$ and $K$: rank$(X) \leq \rho \ll \min(N, K)$. It may be useful to consider the following optimization problem where the nuclear norm $\|X\|_n$ is replaced by $\|P\|_F^2 + \|Q\|_F^2$, which is differentiable and separable among its blocks:

$$ \min_{P, Q, S} \frac{1}{2} \|PQ + DS - Y\|_F^2 + \frac{\lambda}{2} \|P\|_F^2 + \|Q\|_F^2 + \mu \|S\|_1. $$

(4)

This optimization problem is a special case of $\min (P, Q, S)$ obtained by setting $f(P, Q, S) \triangleq \frac{1}{2} \|PQ + DS - Y\|_F^2 + \frac{\lambda}{2} \|P\|_F^2 + \|Q\|_F^2$.

Although problem (3) is nonconvex, every stationary point of (3) is an optimal solution of (2) under some mild conditions [18 Prop. 1]. In Sec. IV we will customize the proposed SCA framework to design an iterative soft-thresholding with exact line search algorithm for problem (3), which is essentially a parallel best-response algorithm.

B. Example Application: Sparse Subspace Clustering Through Capped $\ell_1$-Norm Minimization

Consider the linear regression model

$$ y = Ax + v, $$

where the dictionary $A \in \mathbb{R}^{N \times K}$ is known and $y \in \mathbb{R}^{N \times 1}$ is the noisy measurement. To estimate $x$ which is known to be sparse a priori, we minimize the quadratic estimation error function augmented by some regularization function to promote the sparsity of $x$. A common routine is to use the $\ell_1$-norm, which has however been shown to yield biased estimates for large coefficients [24]. Alternatives include for example the capped $\ell_1$-norm function [24, 26, 28], and the resulting optimization problem is as follows:

$$ \min_{x} \frac{1}{2} \|Ax - y\|_2^2 + \mu \sum_{k=1}^{K} \min(|x_k|, \theta), $$

(5)

This optimization problem is a special case of (2) obtained by setting $f(x) \triangleq \frac{1}{2} \|Ax - b\|_2^2$,

$$ g^+(x) \triangleq \mu \sum_{k=1}^{K} |x_k|, \text{ and } g^-(x) \triangleq \mu \sum_{k=1}^{K} |x_k| - \min(|x_k|, \theta), $$

where $g^+$ is a convex but nonsmooth function. A graphical illustration of the functions $g, g^+$ and $g^-$ is provided in Fig. 1 and interested readers are referred to [26 Fig. 2] for more examples.

When $\theta$ is sufficiently large, problem (5) reduces to the standard LASSO problem, which plays a fundamental role in sparse subspace clustering problems [33] and can be solved efficiently by the SCA algorithm proposed in [6]. In Problem [5], we take one step further
by considering the capped $\ell_1$-norm and then in Sec. IV we customize the proposed SCA framework to design an iterative soft-thresholding algorithm with exact line search algorithm for problem (9), which is essentially a parallel best-response algorithm.

III. THE PROPOSED SUCCESSIVE CONVEX APPROXIMATION ALGORITHMS

In this section, we formally introduce the proposed SCA framework for problem (9), where $h$ is in general a nonconvex function since $f$ is not necessarily convex and $g^-$ is convex, and $h$ is in general a nonsmooth function since both $g^+$ and $g^-$ are assumed to be nonsmooth.

At any arbitrary but given point $x^0$, assume the subgradient of $g^-(x)$ is $\xi^-(x^0)$. Since $g^-$ is convex, it follows from Jensen’s inequality that

$$g^-(x) \geq g^-(x^0) + (x - x^0)^T \xi^-(x^0), \forall x \in \mathcal{X}. \tag{6}$$

Define $\tilde{h}(x; x^0)$ as

$$\tilde{h}(x; x^0) \triangleq \frac{f(x) - g^-(x^0) - (x - x^0)^T \xi^-(x^0) + g^+(x)}{h(x; x^0)}. \tag{7}$$

We can readily infer from (6) that $\tilde{h}(x; x^0)$ is a global upper bound of $h(x)$ which is tight at $x = x^0$:

$$\tilde{h}(x; x^0) \geq h(x), \quad \text{and} \quad \tilde{h}(x^0; x^0) = h(x^0), \forall x \in \mathcal{X}. \tag{8}$$

In the standard MM method for problem (9) proposed in [26], a sequence of points $\{x^t\}$ is generated by minimizing the upper bound function $\tilde{h}(x; x^t)$:

$$x^{t+1} = \arg \min_{x \in \mathcal{X}} \tilde{h}(x; x^t). \tag{9}$$

This and (9) imply that $\{h(x^t)\}$ is a decreasing sequence as

$$h(x^{t+1}) \leq \tilde{h}(x^{t+1}; x^t) \leq \tilde{h}(x^t; x^t) = h(x^t). \tag{10}$$

However, the optimization problem (10) is not necessarily easy to solve due to two possible reasons: $\tilde{h}(x; x^0)$ may be nonconvex, and $x^{t+1}$ may not have a closed-form expression and must be found iteratively.

The proposed algorithm consists of minimizing a sequence of successively refined approximate functions. Given $x^t$ at iteration $t$, we propose to minimize a properly designed approximate function of the upper bound function $\tilde{h}(x; x^t)$, denoted as $h(x; x^t)$:

$$h(x; x^t) = \tilde{f}(x; x^t) - (x - x^t)^T \xi^-(x^0) + g^+(x), \tag{11}$$

where $\tilde{f}(x; x^t)$ is an approximate function of $f(x)$ at $x^t$ that satisfies several technical conditions that are in the same essence as those specified in [6], namely,

(A1) The approximate function $\tilde{f}(x; x^t)$ is convex in $x$ for any given $x^t \in \mathcal{X}$;

(A2) The approximate function $\tilde{f}(x; x^t)$ is continuously differentiable in $x$ for any given $x^t \in \mathcal{X}$ and continuous in $x$ for any $x \in \mathcal{X}$;

(A3) The gradient of $\tilde{f}(x; x^t)$ and the gradient of $f(x)$ are identical at $x = x^t$ for any $x^t \in \mathcal{X}$, i.e., $\nabla_x f(x^t; x^t) = \nabla_x f(x^t)$.

Comparing $\tilde{h}(x; x^t)$ in (7) with $h(x; x^t)$ in (10), we see that replacing $f(x)$ in $\tilde{h}(x; x^t)$ by its approximate function $\tilde{f}(x; x^t)$ leads to the proposed approximate function $h(x; x^t)$. Note that $h(x; x^t)$ is not necessarily a global upper bound of $\tilde{h}(x; x^t)$ (or the original function $h(x)$), because according to Assumptions (A1)-(A3), $\tilde{f}(x; x^t)$ does not have to be a global upper bound of $f(x)$.

At iteration $t$, the approximate problem consists of minimizing the approximate function $h(x; x^t)$ over the same constraint set $\mathcal{X}$:

$$\min_{x \in \mathcal{X}} \tilde{f}(x; x^t) - (x - x^t)^T \xi^-(x^0) + g^+(x). \tag{11}$$

Since $\tilde{f}(x; x^t)$ is convex by assumption (A1), (11) is a convex optimization problem. We denote as $\mathbb{B}x^t$ an (globally) optimal solution of (11) and as $\tilde{S}(x^t)$ the set of (globally) optimal solutions:

$$\mathbb{B}x^t \in S(x^t) = \left\{ x^t : x^t \in \arg \min_{x \in \mathcal{X}} h(x; x^t) \right\}. \tag{12}$$

Based on (12), we define the mapping $\mathbb{B}x$ that is used to generate the sequence of points in the proposed algorithm:

$$\mathcal{X} \ni x \mapsto \mathbb{B}x \in \mathcal{X}. \tag{13}$$

Given the mapping $\mathbb{B}x$, the following properties hold.

**Proposition 1** (Stationary point and descent direction). Provided that Assumptions (A1)-(A3) are satisfied: (i) A point $x^t$ is a stationary point of (9) if and only if $x^t \in \tilde{S}(x^t)$ defined in (12); (ii) If $x^t$ is not a stationary point of (12), then $\mathbb{B}x^t - x^t$ is a descent direction of $\tilde{h}(x; x^t)$ at $x = x^t$ in the sense that

$$(\mathbb{B}x^t - x^t)^T (\nabla f(x^t; x^t) - \xi^-(x^t)) + g^+(\mathbb{B}x^t) - g^+(x^t) < 0. \tag{14}$$

**Proof:** See Appendix A.

If $\mathbb{B}x^t - x^t$ is a descent direction of $\tilde{h}(x; x^t)$ at $x = x^t$, there exists a scalar $\gamma^t \in (0, 1]$ such that

$$\tilde{h}(x^t + \gamma^t (\mathbb{B}x^t - x^t)) < \tilde{h}(x^t),$$

for which a formal proof is provided shortly in Proposition 2. This motivates us to update the variable as follows

$$x^{t+1} = x^t + \gamma^t (\mathbb{B}x^t - x^t). \tag{15}$$

The function value $h(x^t)$ is monotonically decreasing because

$$h(x^{t+1}) \leq \tilde{h}(x^{t+1}; x^t) \leq \tilde{h}(x^t; x^t) \leq h(x^t). \tag{16}$$

where $(a)$ and $(b)$ in (16) follow from (8).

There are several commonly used stepsize rules, for example, the constant/decreasing stepsize rules and the line search. In this paper, we restrict the discussion to the line search schemes because they lead to a fast convergence speed as shown in [6]. On the one hand, the traditional exact line search aims at finding the optimal stepsize,
\[ f(x') + \beta^m(Bx' - x') \leq (x' + \beta^m(Bx' - x'))^2 \xi^-(x') + g^+(x') + \beta^m(g^+(Bx') - g^+(x')) \]

\[ f(x') + \beta^m(Bx' - x') - \beta^m(Bx' - x')^2 \xi^-(x') + \beta^m(g^+(Bx') - g^+(x')) \]

\[ f(x') + \alpha \beta^m((Bx' - x')^2 \xi^-(x')) + g^+(Bx' - x')^2 \xi^-(x') \]

\[ f(x') + \alpha \beta^m((Bx' - x')^2 (\nabla f(x') - \xi^-(x')) + g^+(Bx') - g^+(x')) \]

Although it is a scalar problem, it is not theoretically easy to solve because it is not convex (even when \( f(x) \) is convex) and nondifferentiable. On the other hand, as \( Bx' - x' \) is also a descent direction of \( h(x; x') \) according to Proposition 1, it is possible to perform the exact line search over the upper bound function \( h(x; x') \) along the direction \( Bx' - x' \):

\[ \gamma_{ub} \triangleq \arg \min_{0 \leq \gamma \leq 1} h(x' + \gamma(Bx' - x')) \]

\[ \gamma_{ub} = \arg \min_{0 \leq \gamma \leq 1} \begin{cases} f(x' + \gamma(Bx' - x')) \\ + g^+(x' + \gamma(Bx' - x')) \\ - g^-(x' + \gamma(Bx' - x')) \end{cases} \]

\[ \gamma = \frac{1}{\gamma_{ub}} \left( \frac{\nabla f(x') + g^+(Bx') - g^+(x')}{\nabla f(x') - \xi^-(x')} \right) \]

\[ \gamma = \arg \min_{0 \leq \gamma \leq 1} \begin{cases} f(x' + \gamma(Bx' - x')) \\ + g^+(x' + \gamma(Bx' - x')) - g^-(x' + \gamma(Bx' - x')) \end{cases} \]

\[ \gamma = \frac{1}{\gamma_{ub}} \left( \frac{\nabla f(x') + g^+(Bx') - g^+(x')}{\nabla f(x') - \xi^-(x')} \right) \]

\[ f(x' + \gamma(Bx' - x')) - h(x') \]

\[ \leq \alpha \beta^m((Bx' - x')^2 (\nabla f(x') - \xi^-(x')) + g^+(Bx') - g^+(x')) = m \]

\[ \alpha \beta^m((Bx' - x')^2 (\nabla f(x') - \xi^-(x')) + g^+(Bx') - g^+(x')) \]

\[ \frac{1}{\gamma_{ub}} \begin{cases} f(x' + \gamma(Bx' - x')) \\ + g^+(x' + \gamma(Bx' - x')) - g^-(x' + \gamma(Bx' - x')) \end{cases} \]

\[ \gamma = \frac{1}{\gamma_{ub}} \left( \frac{\nabla f(x') + g^+(Bx') - g^+(x')}{\nabla f(x') - \xi^-(x')} \right) \]

Proposition 2 (Existence of a nontrivial stepsize). If \( Bx' - x' \) is a descent direction of \( h(x; x') \) at the point \( x = x' \) in the sense of (17), then the stepsize \( \gamma \) obtained by the proposed exact line search scheme (19) or the proposed successive line search (21) is nonzero, i.e., \( \gamma \in (0, 1] \).
Algorithm 1 The proposed successive convex approximation framework for problem (2).

Data: $t = 0$, $x^t$ (arbitrary but fixed, e.g., $x^0 = 0$), stop criterion $\delta$.
S1: Compute $Bx^t$ according to (12).
S2: Determine the stepsize $\gamma^t$ by the exact line search (19) or the successive line search (21).
S3: Update $x^{t+1}$ according to (15).
S4: If $|\langle Bx^t - x^t \rangle^T (\nabla f(x^t) - \xi^t(x^t)) + g^+(Bx^t) - g^+(x^t)| \leq \delta$, STOP; otherwise $t \leftarrow t + 1$ and go to S1.

Proof: See Appendix A.

The proposed SCA framework is summarized in Algorithm 1 and its convergence properties are given in the following theorem.

Theorem 3 (Convergence to a stationary point). Consider the sequence $\{x^t\}$ generated by Algorithm 1. Provided that Assumptions (A1)-(A3) as well as the following assumptions are satisfied:

(A4) The solution set $S(x^t)$ is nonempty for $t = 1, 2, \ldots$.
(A5) Given any convergent subsequence $\{x^t\}_{t \in T}$ where $T \subseteq \{1, 2, \ldots\}$, the sequence $\{Bx^t\}_{t \in T}$ is bounded.

Then any limit point of $\{x^t\}$ is a stationary point of $f$. (Proof: See Appendix B.)

Sufficient conditions for Assumptions (A4)-(A5) are that either the upper bound function in (19) is bounded or the approximate function in (11) is strongly convex [50]. We will show that these assumptions are satisfied by the example application in the next section.

If, in addition, $f(x^t; x^t)$ in the approximate function (10) is a global upper bound of $f(x)$, then the proposed Algorithm 1 converges (in the sense specified by Theorem 3) under a constant unit stepsize $\gamma^t = 1$. We omit the details due to the page limit.

In what follows, we draw some comments on the proposed algorithm’s features and connections to existing algorithms.

On the choice of approximate function. Note that different choices of $f(x; x^t)$ lead to different algorithms. We mention for the self-containment of this paper two commonly used approximate functions, and assume for now that the constraint set $X$ has a Cartesian product structure and $g^+$ is separable, i.e., $g^+(x) = \sum_{k=1}^K g^+(x_k)$. We refer the interested readers to [6, Sec. III-B] for a more comprehensive discussion.

Proximal type approximation. The proximal type approximate function $h(x; x^t)$ has the following form [50, Sec. 4.2]:

$$ f(x^t; x^t) = \frac{1}{2} ||x - x^t||^2 - (x - x^t)^T \xi^t(x^t) + g(x) $$

where $c^t > 0$. Since the approximate function is separable among the decision variables and the constraint set has a Cartesian structure, minimizing the approximate function to obtain $Bx^t$ is equivalent to set $Bx^t = (Bx^t_k)_{k=1}^K$, where $x = (x_k)_{k=1}^K$ and

$$ Bx^t_k = \arg\min_{x_k \in X_k} \left\{ \nabla_k f(x^t_k)(x_k - x_k^t) + \frac{c^t}{2} ||x_k - x_k^t||^2 - (x_k - x_k^t)^T \xi_k^t(x_k^t) + g(x_k) \right\}, $$

for all $k = 1, \ldots, K$. According to Theorem 3 and the discussion that immediately follows, the proposed algorithm converges under a constant unit stepsize if $\tilde{f}(x; x^t)$ in (23a) is a global upper bound of $f(x)$, which is indeed the case when $c^t \geq L_{\nabla f}$ ($L_{\nabla f}$ is the Lipschitz constant of $\nabla f$) in view of the descent lemma [33, Prop. A.24].

Best-response type approximation. In problem (3), if $f(x)$ is convex in each $x_k$ where $k = 1, \ldots, K$ but not necessarily jointly convex in $(x_1, \ldots, x_K)$, the best-response type approximate function is defined as

$$ \tilde{f}(x; x^t) = \sum_{k=1}^K f(x_k, x_k^t), $$

and the approximate problem is

$$ Bx^t_k = \arg\min_{x_k \in X_k} \left\{ f(x_k, x_k^t) - (x_k - x_k^t)^T \xi_k^t(x_k^t) + g(x_k) \right\}. $$

for all $k = 1, \ldots, K$. Comparing (24a) with (24b), we see that the function $f$ is not linearized in (24b). The best-response type algorithm typically converges faster than the proximal type algorithm because the desirable property such as convexity is preserved in the best-response type approximation while it is lost when $f(x)$ is being linearized in the proximal type approximation.

On the proposed line search schemes. Since the objective function in the proposed exact line search scheme (19) is an upper bound of the objective function in (17b) (see the discussion after (19)), the obtained decrease by the proposed line search $\gamma^t$ in (19) is generally smaller than that of $\gamma^t_{opt}$ in (17b). The line search over the upper bound function $h(x; x^t)$, which is further more smaller than that of $\gamma^t_{opt}$ in (17a), the line search over the original function $h(x)$:

$$ h(x^t + \gamma^t(Bx^t - x^t)) \leq h(x^t + \gamma^t_{opt}(Bx^t - x^t)) \leq h(x^t + \gamma^t(Bx^t - x^t)) < h(x^t). $$

Nevertheless, the order of complexity is reversed. To see this, assume $f(x)$ is convex. Then the optimization problem in (17a), (17b) and (19) is nonconvex and nondifferentiable, convex but nondifferentiable, and convex and differentiable, respectively. We will illustrate later by several example applications that the proposed line search scheme achieves a good tradeoff between efficiency and complexity.

On the convergence speed of the proposed algorithm. The proposed algorithm presents a fast convergence behavior because we could choose the approximate function so that the problem structure is exploited to a larger extent, for example, the partial convexity in the best-response type approximation. Furthermore, the line search leads to a much faster convergence than predetermined stepsizes such as constant stepsizes and decreasing stepsizes.

On the complexity of the proposed algorithm. The Algorithm 1 has a low complexity due to the use of an approximate function and the line search scheme over a differentiable function. The benefits of employing the approximate function $f(x; x^t)$ are twofold. On the one hand, it is a convex function by Assumption (A1), so the approximate problem (11) is convex, which is presumably easier to solve than (9) which is nonconvex if $f(x)$ is nonconvex. On the other hand, it can be tailored according to the structure of the problem at hand so that the approximate problem (11) is even easier to solve. For example, if $g^+(x)$ is separable among the scalar elements of $x$ (as in, e.g., $\ell^1$-norm $||x||_1 = \sum_{k=1}^K |x_k|$), we can choose $f(x; x^t)$ to be separable as well, so that the problem (11) can be decomposed into independent subproblems which are then solved in parallel. Furthermore, the proposed line search scheme (19) is carried out over a differentiable function, which is presumably much easier to implement than traditional schemes [17] over nonsmooth functions.

On the connection to the classic MM method [26]. Assume $f$ is convex. The proposed algorithm includes as a special case the MM method proposed in [26] by setting $\tilde{f}(x; x^t) = f(x)$, i.e., no approximation is employed. For this particular choice of approximate function, it can be verified that the assumptions (A1)-(A3) are satisfied. Interpreting the MM method as a special case

3 This is an assumption made in [26].
of the proposed algorithm consolidates once more that choosing an approximate function that is easier to optimize may notably reduce the algorithm's complexity.

On the connection to the SCA framework for a convex function \( g \).

The proposed framework includes as a special case the SCA framework proposed in [6] for a convex function; assume \( g'(x) = 0 \), and the approximate function in (19) reduces to \( h(x; x') = f(x; x') + g'(x) \).

On the connection to the GIST algorithm [37]. Assume \( g'(x) = 0 \) in the GIST algorithm [37]. The variable is updated as follows:

\[
x^{t+1} = \arg\min_{x} (x - x')^{T} \nabla f(x') + \frac{c}{2} \| x - x' \|^2 + g'(x).
\]

This is a special case of the proximal type algorithm by choosing \( c' \geq L_{\nabla f} \) and \( \gamma' = 1 \). When the value of \( L_{\nabla f} \) is unknown, \( c' \) is estimated iteratively: for a constant \( \beta \in (0, 1) \), define \( x^*(\beta^m) \) as

\[
x^*(\beta^m) \equiv \arg\min_{x} (x - x')^{T} \nabla f(x') + \frac{1}{2\beta^m} \| x - x' \|^2 + g'(x).
\]

Then \( c' = 1/\beta^m \) and \( x^{t+1} = x^*(\beta^m) \) while \( m_t \) is the smallest nonnegative integer such that the following inequality is satisfied for some \( \alpha \in (0, 1) \):

\[
f(x^*(\eta^m)) + g(x^*(\eta^m)) < f(x') + g(x) - \frac{\alpha}{2\beta^m} \| x^*(\eta^m) - x' \|^2.
\]

This implies that, in the GIST algorithm, \( x^*(\beta^m) \) and \( g(x^*(\beta^m)) \) are evaluated for \( m_t + 1 \) times, namely, \( m_t = 0, 1, \ldots, m_t \). This is however not necessary in the proposed successive line search [21], because \( \nabla x^k \) given by (13) does not depend on any unknown parameters and both \( \nabla x^k \) and \( g^k \) only need to be computed once. Therefore, the algorithmic complexity could be notably reduced by employing a convex approximate function that is not necessarily an upper bound of the original function \( h(x) \).

IV. NETWORK ANOMALY DETECTION THROUGH SPARSITY REGULARIZED RANK MINIMIZATION

In this section, we propose an iterative algorithm by customizing Algorithm 1 to solve the network anomaly detection problem introduced in Sec. III A. For the simplicity of cross reference, we duplicate the problem formulation here

\[
\min_{P, Q, S} \frac{1}{2} \| PQ + DS - Y \|^2_F + \frac{\lambda}{2} \left( \| P \|^2_F + \| Q \|^2_F \right) + \mu \| S \|_1,
\]

and remark again that problem \( \ref{eq:5} \) is a special case of \( \ref{eq:4} \) by setting

\[
f(P, Q, S) \equiv \frac{1}{2} \| PQ + DS - Y \|^2_F + \frac{\lambda}{2} \left( \| P \|^2_F + \| Q \|^2_F \right) + \mu \| S \|_1,
\]

\[
g(S) \equiv \mu \| S \|_1,
\]

where \( g(S) \) is convex. To simplify the notation, we use \( Z \) as a compact notation for \( (P, Q, S) \): \( Z \equiv (P, Q, S) \); in the rest of this section, \( Z \) and \( (P, Q, S) \) are used interchangeably.

Related work. We first briefly describe the BCD algorithm adopted in [12] to find a stationary point of the nonconvex problem \( \ref{eq:5} \), where the variables are updated sequentially according to their best-response. For example, when \( P \) (or \( Q \)) is updated, the variables \( (Q, S) \) (or \( (P, S) \)) are fixed. When \( (P, Q) \) is fixed for example, the optimization problem w.r.t. \( S \) decouples among its columns:

\[
\frac{1}{2} \| PQ_k + DS_k - y_k \|^2_F - \mu \| S_k \|_1
\]

where \( q_k, s_k \) and \( y_k \) is the \( k \)-th column of \( Q, S \) and \( Y \), respectively. However, the optimization problem w.r.t. \( S_k \) does not have a closed-form solution and is not easily to solve. To reduce the complexity, the elements of \( S \) are updated row-wise, as the optimization problem w.r.t. \( S_k \) is of the following form:

\[
\minimize_{S_k} \sum_{i=1}^{K} \left( \frac{1}{2} \| Pq_{ik} - d_i s_{ik} - \sum_{j \neq i} (d_j s_{jk} - y_{ik}) \|^2_2 \right) + \mu \| S_k \|_1.
\]

This is an assumption made in [27].
and similarly \( \nabla_{\mathbf{Q}} \tilde{f}(\mathbf{Z}; \mathbf{Z}') = \nabla_{\mathbf{Q}} f(\mathbf{P}, \mathbf{Q}, \mathbf{S})|_{\mathbf{Z} = \mathbf{Z}'} \). Furthermore, \( \nabla_{\mathbf{S}} \tilde{f}(\mathbf{Z}; \mathbf{Z}') = (\nabla_{s_{i,k}} \tilde{f}(\mathbf{Z}; \mathbf{Z}'))_{i,k} \) while

\[
\nabla_{s_{i,k}} \tilde{f}(\mathbf{Z}; \mathbf{Z}') = \nabla_{s_{i,k}} \tilde{f}_S(\mathbf{S}; \mathbf{Z}') = \nabla_{s_{i,k}} f(P^1, Q^1, s_{i,k}, s_{i-k}, s_{i+k}) = \nabla_{s_{i,k}} f(\mathbf{P}, \mathbf{Q}, \mathbf{S})|_{\mathbf{Z} = \mathbf{Z}'}.
\]

Therefore Assumptions (A1)-(A3) are satisfied.

In iteration \( t \), the approximate problem consists of minimizing the approximate function:

\[
\min_{\mathbf{Z} \in \{\mathbf{P}, \mathbf{Q}, \mathbf{S}\}} \frac{1}{2} \| \mathbf{f}_P(\mathbf{P}; \mathbf{Z}') + \mathbf{f}_Q(\mathbf{Q}; \mathbf{Z}') + \mathbf{f}_S(\mathbf{S}; \mathbf{Z}') + g(\mathbf{S}) \|_F^2.
\]

Since \( \tilde{f}(\mathbf{Z}; \mathbf{Z}') \) is strongly convex in \( \mathbf{Z} \) and \( g(\mathbf{S}) \) is a convex function w.r.t. \( \mathbf{S} \), the approximate problem (30) is strongly convex and it has a unique globally optimal solution, which is denoted as \( \mathbb{B}\mathbf{Z}' = (\mathbb{B}\mathbf{P}\mathbf{Z}', \mathbb{B}\mathbf{Q}\mathbf{Z}', \mathbb{B}\mathbf{S}\mathbf{Z}') \). As the approximate problem (30) is separable among the optimization variables \( \mathbf{P}, \mathbf{Q}, \) and \( \mathbf{S} \), it naturally decomposes into several smaller problems which can be solved in parallel:

\[
\mathbb{B}\mathbf{P}\mathbf{Z}' = \arg \min_{\mathbf{P}_n} \frac{1}{2} \| \mathbf{f}_P(\mathbf{P}; \mathbf{Z}') \|_F^2 = ((\mathbf{Y} - \mathbf{D}\mathbf{S}')^T(\mathbf{Q}'^T(\mathbf{Q}'^T + \lambda I)^{-1})^T, \quad (31a)
\]

\[
\mathbb{B}\mathbf{Q}\mathbf{Z}' = \arg \min_{\mathbf{Q}} \frac{1}{2} \| \mathbf{f}_Q(\mathbf{Q}; \mathbf{Z}') \|_F^2 = ((\mathbf{P}')^T\mathbf{P} + \lambda I)^{-1}(\mathbf{Y} - \mathbf{D}\mathbf{S}')^T, \quad (31b)
\]

\[
\mathbb{B}\mathbf{S}\mathbf{Z}' = \arg \min_{\mathbf{S}} \frac{1}{2} \| \mathbf{f}_S(\mathbf{S}; \mathbf{Z}') + g(\mathbf{S}) \|_F^2 = \text{d}(\mathbf{D}'^T\mathbf{D})^{-1}. S_n \left( \text{d}(\mathbf{D}'^T\mathbf{D})\mathbf{S}' - \mathbf{D}'^T(\mathbf{D}'\mathbf{S}' - \mathbf{Y} + \mathbf{P}'\mathbf{Q}'^T) \right), \quad (31c)
\]

where \( S_n(\mathbf{X}) \) is an element-wise soft-thresholding operator: the \((i,j)\)-th element of \( S_n(\mathbf{X}) \) is \( |X_{ij} - \lambda|_+^{\lambda} - \lambda |X_{ij} - \lambda|_+ \). As we can readily see from (31), the approximate problems can be solved efficiently because the optimal solutions are provided in an analytical expression.

Since \( \tilde{f}(\mathbf{Z}; \mathbf{Z}') \) is convex in \( \mathbf{Z} \) and differentiable in both \( \mathbf{Z} \) and \( \mathbf{Z}' \), and has the same gradient as \( f(\mathbf{Z}) \) at \( \mathbf{Z} = \mathbf{Z}' \), it follows from Proposition 1 that \( \mathbb{B}\mathbf{Z}' = \mathbf{Z}' \) is a descent direction of the original objective function \( f(\mathbf{Z}) + g(\mathbf{S}) \) at \( \mathbf{Z} = \mathbf{Z}' \). The variable update in the \( t \)-th iteration is thus defined as follows:

\[
P^t + 1 = P^t + \gamma(\mathbb{B}\mathbf{P}\mathbf{Z}' - P^t), \quad (32a)
\]

\[
Q^t + 1 = Q^t + \gamma(\mathbb{B}\mathbf{Q}\mathbf{Z}' - Q^t), \quad (32b)
\]

\[
S^t + 1 = S^t + \gamma(\mathbb{B}\mathbf{S}\mathbf{Z}' - S^t), \quad (32c)
\]

where \( \gamma \in [0, 1] \) is the stepsize that should be properly selected.

We determine the stepsize \( \gamma \) by the proposed exact line search scheme (19):

\[
f(\mathbf{Z}' + \gamma(\mathbb{B}\mathbf{Z}' - \mathbf{Z}')) + g(\mathbf{S}') + \gamma g(\mathbb{B}\mathbf{S}\mathbf{Z}' - g(\mathbf{S}')). \quad (33)
\]

After substituting the expressions of \( f(\mathbf{Z}) \) and \( g(\mathbf{S}) \) into (33), the exact line search consists in minimizing a fourth order polynomial over the interval \([0, 1] \):

\[
\gamma^t = \arg \min_{0 \leq \gamma \leq 1} \{ f(\mathbf{Z}' + \gamma(\mathbb{B}\mathbf{Z}' - \mathbf{Z}')) + g(\mathbb{B}\mathbf{S}\mathbf{X}' - g(\mathbf{S}')) \} = \arg \min_{0 \leq \gamma \leq 1} \left\{ \frac{1}{4} \alpha \gamma^4 + \frac{1}{3} \beta \gamma^3 + \frac{1}{2} \gamma c^2 + d \gamma \right\}. \quad (34)
\]

\[\text{Algorithm 2 STELA:} \text{ The proposed parallel best-response with exact line search algorithm for the sparsity regularized rank minimization problem} \]
A. Parallel Decomposition and Implementation of the Proposed Algorithm STELA

The proposed algorithm STELA can be further decomposed to enable the parallel processing over a number of $L$ nodes in a distributed network. To see this, we first decompose the system model across the nodes:

$$Y_l = X_l + D_lS + V_l, l = 1, \ldots, L,$$

where $Y_l \in \mathbb{R}^{N_l \times K}$, $X_l \in \mathbb{R}^{N_l \times K}$, $D_l \in \mathbb{R}^{N_l \times I}$ and $V_l \in \mathbb{R}^{N_l \times K}$ consists of $N_l$ rows of $Y$, $X$, $D$ and $V$, respectively:

$$Y = \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_L \end{bmatrix}, \quad X = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_L \end{bmatrix}, \quad D = \begin{bmatrix} D_1 \\ D_2 \\ \vdots \\ D_L \end{bmatrix}, \quad V = \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_L \end{bmatrix}.$$

Since the variables of interest for the node $l$ are $X_k$ and $S$, we decompose $P$ into multiple blocks $(P_l)_{l=1}^L$ with $P_l \in \mathbb{R}^{N_l \times P}$:

$$P = \begin{bmatrix} P_1 \\ P_2 \\ \vdots \\ P_L \end{bmatrix}.$$

All nodes should have access to the variable $Q$ so that $X_l$ can be estimated locally by $X_l = P_lQ$.

The computation of $B^T Z'$ in (32a) can be decomposed as $B^T Z'_l = \langle B^T, Z'_l \rangle_{t=1}$:

$$B^T Z'_l = (Y_l - D_lS_l)'(Q_l)'(Q_l)' + \lambda_l)^{-1}, l = 1, \ldots, L.$$

Accordingly, the computation of $B^T Z'$ and $B^T S'$ in (32b) and (32c) can be rewritten as

$$B^T Z'_l = \left( \sum_{i=1}^L (P_i)'(P_i) + \lambda_l \right)^{-1} \left( \sum_{i=1}^L (P_i)'(Y_l - D_lS_l) \right),$$

$$B^T S'_l = (d S_l)'(d)' S_l - \left( \sum_{i=1}^L (D_i)'(D_i)' S_l - Y_l + P_lQ_l \right)'.$$

Before determining the stepsize, the computation of a in (35) can also be decomposed among the nodes as $a = \sum_{i=1}^L a_i$, where

$$a_i \hat{=} 2 \| \Delta P_i \Delta Q_i \|^2_F.$$

The decomposition of $b, c,$ and $d$ is similar to that of $a$, where

$$b_l \hat{=} 3 \mathrm{tr}(\Delta P_l \Delta Q_l (P_l)'(P_l)' + \Delta P_l(Q_l)'D_lS_l)' + \lambda \| \Delta P_l \|^2_F + \lambda \| \Delta Q_l \|^2_F,$$

$$c_l \hat{=} 2 \mathrm{tr}(\Delta P_l \Delta Q_l (P_l)'(Q_l)' + D_lS_l)' + \lambda \| \Delta P_l \|^2_F + \lambda \| \Delta Q_l \|^2_F,$$

$$d_l \hat{=} \mathrm{tr}(\Delta P_l \Delta Q_l (P_l)'(Q_l)' + D_lS_l)'(P_l)'(Q_l)' + D_lS_l)' + \lambda \| \Delta P_l \|^2_F + \lambda \| \Delta Q_l \|^2_F.$$
algorithms, namely, STELA, BCD and ADMM. In Fig. 2(b), the error is defined as $(f(Z^*) + g(S^*) - f(Z^*) - g(S^*))/f(Z^*) + g(S^*)$, where $Z^*$ is obtained by running the proposed algorithm STELA for a sufficiently large number of iterations. As we see from Fig. 2(a), the ADMM does not converge, as the optimization problem (26) and (27) is nonconvex. We also observe that the behavior of the ADMM is very sensitive to the value of $c$: in some instances, the ADMM may converge if $c$ is large enough, but it is a difficult task on its own to choose an appropriate value of $c$ to achieve a good performance.

We run the BCD algorithm for 10 iterations, each represented by a circle. In each iteration, all rows of $S$ are updated once in a sequential order, and it incurs a large delay. In particular, we see from Fig. 2(a) that each iteration of the BCD algorithm takes about 35 minutes, and a reasonably good solution is obtained after two iterations (70 minutes). By contrast, all variables are updated simultaneously in STELA and the CPU time needed for each iteration is very small. We see from Fig. 2(b) that STELA converges to a stationary point with a precision of $10^{-5}$ in less than 1 minute, while it takes the BCD algorithm about 330 minutes (5.5 hours) to find a solution that has the same precision. This marks a notable improvement which is important in real time anomaly detection in large networks.

V. SPARSE SUBSPACE CLUSTERING THROUGH CAPPED $\ell_1$-NORM MINIMIZATION

In this section, we consider the sparse subspace clustering problem through the capped $\ell_1$-norm minimization introduced in Sec. II-B:

$$\min_x \frac{1}{2} \|Ax - b\|^2 + \mu \sum_{k=1}^K \min(|x_k|, \theta),$$

or more compactly,

$$\min_x \frac{1}{2} \|Ax - b\|^2 + \mu \min(\|x\|_1, \theta),$$

(37)

It is shown in [26] that problem (37) is a special case of [2] by setting

$$f(x) \triangleq \frac{1}{2} \|Ax - b\|^2, \quad g^+(x) \triangleq \mu \|x\|_1, \quad g^-(x) \triangleq \mu \min(\|x\|_1, \theta).$$

(38a)-(38c)

Since $f$ is convex, we adopt the best-response type approximate function: the approximate function consists of $K$ component functions, and in the $k$-th component function, only the $k$-th element of $x$, of $x$ is treated as a variable while other elements $x_{-k} \triangleq (x_j)_{j \neq k}$ are fixed,

$$\tilde{f}(x; x^i) \triangleq \frac{1}{2} \sum_{k=1}^K f(x_k, x^i_k) = \frac{1}{2} \sum_{k=1}^K \|a_k x_k + \sum_{j \neq k} a_j x_j^i - b\|^2.$$  

(39)

To obtain the update direction, we solve the approximate problem

$$Bx^i = \arg \min_{x \in X} \{\tilde{f}(x; x^i) - (x - x^i)\xi^-(x^i) + g^+(x)\} = d(A^T A)^{-1} S_\delta(x^i, \xi^-(x^i)),$$  

where

$$r(x^i, \xi^-(x^i)) \triangleq d(\|A^T x^i\|_2^2 - \|A^T x - \xi^-(x^i)\|_2^2 - \nabla f(x^i)) = d(A^T A)^{-1} x^i \xi^-(x^i) - A^T (Ax^i - b),$$

and $d(X)$ is the diagonal operator of $X$, $S_\delta(b) \triangleq [b - a]^+ - [b - a]^-$ is the soft-thresholding operator, and the subgradient of $g^-(x)$ defined in (29) is $\xi^-(x) = (\xi_k^-(x_k))_{k=1}^K$ with

$$\xi_k^-(x_k) = \begin{cases} \mu, & \text{if } x_k \geq \theta, \\ -\mu, & \text{if } x_k \leq -\theta, \\ 0, & \text{otherwise}, \end{cases}$$

Algorithm 3 STELA: The proposed parallel best-response with exact line search algorithm for the capped $\ell_1$-norm minimization problem (37).

Data: $t=0$, $x^0$ (arbitrary but fixed, e.g., $x^0 = 0$), stop criterion $\delta$.

S1: Compute $Bx^i$ according to (12).

S2: Determine the stepsize $\gamma^t$ by the exact line search (19).

S3: Update $x^{i+1}$ according to (15).

S4: If $\|Bx^i - x^i\|^2 \leq \|Bx^i - x^i\|^2 - g^+(Bx^i) - g^+(x^i) \leq \delta$, STOP; otherwise $t \leftarrow t + 1$ and go to S1.

or more compactly,

$$\xi^-(x) = \frac{1}{2} \mu (\text{sign}(x - \theta) - \text{sign}(-x - \theta)).$$

Given the update direction $Bx^i - x^i$, we calculate the stepsize $\gamma^t$ according to the proposed exact line search (19), which can be performed in a simple closed-form expression:

$$\gamma^t = \arg \min_{0 < \gamma \leq 1} \left\{ f(x^i + \gamma(Bx^i - x^i)) + \gamma g(Bx^i - x^i)^T \xi^-(x^i) \right\} = \left\langle (\xi^-(x^i) - A^T (Ax^i - b))^T (Bx^i - x^i) \right\rangle_{\theta \rightarrow 0}.$$  

(41)

The proposed update (40)-(41) or (29) are summarized in Algorithm 3 and we name it as Soft-Thresholiding with Exact Line search Algorithm (STELA). It has several attractive features:

- **i)** low complexity, as the approximate function is chosen such that its minimum can be obtained in closed-form expressions and the proposed algorithm thus has a single layer. Besides this, the stepsize can also be computed by closed-form expressions;
- **ii)** fast convergence, as all elements are updated in parallel, the approximate function is of a best-response type, and the stepsize is based on the exact line search;
- **iii)** guaranteed convergence, as $f(x; x^i)$ in (39) is strongly convex and Assumptions (A4)-(A5) are satisfied.

Compared with state-of-the-art algorithms proposed for problem (37), we remark that

- feature i) is an advantage over the traditional MM method [26];
- feature ii) is an advantage over the algorithms [28, 29] with a proximal type approximation;
- feature iii) is an advantage over the standard SCA framework for convex regularization functions [6, 15, 16].

On the comparison with the proximal MM method [28]. The proximal type algorithm proposed in [28] is essentially a MM method, because the variable is updated by

$$x^{i+1} = \arg \min_{x \in X} \left\{ f(x^i) + \nabla f(x^i)^T (x - x^i) + \frac{\mu}{2} \|x - x^i\|^2 + g^+(x^i - x^i) \right\},$$  

(42)

with $c^i > L_{\nabla f}$, while the objective function in (42) is a global upper bound of $h(x)$ in view of the descent lemma (13) Prop. A.24. When the value of $L_{\nabla f}$ is not known, $c^i$ is estimated iteratively: for some constants $0 < \alpha < 1$ and $0 < \beta < 1$, set $x^{i+1} = x^i(\beta^m)$, where $x^i(\beta^m)$ is defined as

$$x^i(\beta^m) \triangleq \arg \min_{x \in X} \left\{ f(x^i) + \nabla f(x^i)^T (x - x^i) + \frac{1}{2\beta^m} \|x - x^i\|^2 \right\},$$  

(43)

and $m_i$ is the smallest nonnegative integer such that $h(x^i(\beta^m)) < h(x^i) \leq -\alpha/2\beta^m \|x^i(\beta^m) - x^i\|^2$. As a result, $x^i(\beta^m)$ must be
evaluated repeatedly for $m_t$ times, namely, $m = 0, 1, \ldots, m_t$. This is however not necessary in the proposed algorithm STELA, because computing the descent direction and the stepsize according to (40) does not depend on any unknown parameters. Furthermore, computing the descent direction and the stepsize according to (40) is however not necessary in the proposed algorithm STELA, because all of its elements are generated randomly by the normal distribution $\mathcal{N}(0, 1)$, and (41) does not depend on any unknown parameters. Furthermore, (43) may not be easy to solve for a general $g^*(x)$ except for some specific choices studied in [28].

A. Numerical Simulations

In our numerical simulations the dimension of $A$ is $10000 \times 50000$: all of its elements are generated randomly by the normal distribution $\mathcal{N}(0, 1)$, and the rows of $A$ are normalized to have a unit $\ell_2$-norm. The density (the proportion of nonzero elements) of the sparse vector $x_{true}$ is $0.1$. The vector $b$ is generated as $b = Ax_{true} + e$ where $e$ is drawn from an i.i.d. Gaussian distribution with mean $0$ and variance $10^{-4}$. The regularization parameter $\mu$ is set to $\mu = 0.1 \|A^Tb\|_\infty$, which allows $x_{true}$ to be recovered to a high accuracy [35], and the parameter $\theta$ in the capped $\ell_1$-norm is set to $1$. We compare the proposed algorithm STELA with the classic MM method [28] and the proximal MM algorithm [28]. The comparison is made in terms of CPU time that is required until the maximum number of iterations (100 for STELA and the proximal MM algorithm and 10 for the classic MM method) is reached. The running time consists of both the initialization stage required for preprocessing (represented by a flat curve) and the formal stage in which the iterations are carried out. For example, in STELA, $d(A^TA)$ is computed in the initialization stage since it is required in the iterative variable update in the formal stage, cf. [28]. The upper bound function in the classic MM method, cf. [28], is minimized by STELA for $\ell_1$-norm (with a warm start that sets the optimal point of the previous iteration as the initial point of the current iteration [28 Sec. II-D]), which was presented in [6 Sec. IV-H]. All algorithms have the same initial point, $x^0 = 0$. The simulation results are averaged over 20 instances.

The achieved function value $h(x^t)$ and error $h(x^{t-1}) - h(x^t)$ versus the CPU time (in seconds) is plotted in Fig. 3 (a) and 3 (b), respectively. We see from Fig. 3 (a) that all algorithms converge to the same value. Furthermore, the initialization stage of STELA is much longer than that of the proximal MM algorithm, because computing $d(A^TA)$, the diagonal vector of $A^TA$, is computationally expensive, especially when the dimension of $A$ is large.

Nevertheless, in the formal stage, the convergence speed of STELA is much faster than the proximal MM algorithm, and this is mainly due to the use of the best-response type approximate function (39), and more specifically, the use of $d(A^TA)$, cf. [40], which represents partial second order information of the function $f$ in (37) (note that $\nabla^2 f(x) = A^TA$). We see from Fig. 3 (b) that the long initialization stage is compensated by the fast convergence speed in the formal stage. We mention for the paper’s completeness that $d(A^TA)$ can be calculated analytically in some applications, e.g., when $A$ is a Vandermonde or constant modulus matrix.

We see from Fig. 3 (a) that the major complexity of the classic MM method lies in the first few iterations, as the complexity of late iterations are notably reduced by a good initialization thanks to the warm start. The most notable difference between the MM method and the STELA is that the upper bound function is only approximately minimized in the STELA, and this leads to a significant reduction in the computational complexity. Using the approximate function is also beneficial when the upper bound function $\tilde{f}(x; x^t)$ is not easy to minimize, e.g., $f(x)$ is nonconvex.

VI. CONCLUDING REMARKS

In this paper, we have proposed a successive convex approximation framework for sparse signal estimation where the nonsmooth nonconvex regularization function is nonconvex and can be written as the difference of two convex functions. The proposed procedure is to apply the standard successive convex approximation for convex regularization functions to an upper bound of the original objective function that can be obtained following the standard MM method. This procedure also facilitates the design of low-complexity line search schemes which are carried out over a differentiable function. The proposed framework is flexible and it leads to algorithms that exploit the problem structure and have a low complexity. Customizing the general framework for the example applications in network anomaly detection and sparse subspace clustering, the proposed algorithm STELA is a best-response type algorithm with exact line search and has several attractive features, illustrated both theoretically and numerically: i) fast convergence due to the best-response type approximation and the line search for stepsize calculation; ii) low complexity as both the optimal point of the approximate function and the exact line search have closed-form expressions; and iii) guaranteed convergence to a stationary point.

APPENDIX A

Proof of Proposition [1] Since the approximate problem [11] is convex, $\exists x^* \in X$ is a globally optimal point of (11) and

$$\tilde{h}(\exists x^*; x^t) = \min_{x \in X} \hat{h}(x; x^t) \leq \tilde{h}(x^*; x^t).$$

We discuss the two possibilities separately, namely,

i) $\hat{h}(\exists x^*; x^t) = \hat{h}(x^*; x^t)$, (44)

or

ii) $\tilde{h}(\exists x^*; x^t) < \hat{h}(x^*; x^t)$.

(45)

i) If $\hat{h}(\exists x^*; x^t) = \hat{h}(x^*; x^t)$, then $x^* \in S(x^t)$

and must satisfy the first-order optimality condition: for some $\xi^+(x^t), \xi^-(x^t) \geq 0, \forall x$,
Since problem (11) is convex, the above condition implies that on the gradient consistency. Therefore, 
the existence of a decreasing sequence and it thus converges. Besides, for any two (possibly different) convergent subsequences \( \{x^i\}_{i \in T_1} \) and \( \{x^j\}_{j \in T_2} \), the following holds:

\[
\lim_{i \to \infty} h(x^i) = \lim_{j \to \infty} h(x^j) = \lim_{i \to j \to \infty} h(x^i) = h(x^*) .
\]
Since $h(x)$ is a continuous function, we infer from the preceding equation that
\[
    h \left( \lim_{t \to \infty} x^t \right) = \lim_{t \to \infty} h \left( x^t \right).
\]

Now consider any convergent subsequence $\{x^t\}_{t \in T}$ with limit point $y$, i.e., $\lim_{t \to \infty} x^t = y$. To show that $y$ is a stationary point, we first assume the contrary: $y$ is not a stationary point. Since $h(x; x')$ is continuous in both $x$ and $x'$ by Assumption (A2) and $\{B x \}_{t \in T}$ is bounded by Assumption (A5), there exists a sequence $\{\phi_t\}_{t \in T}$ with $T \subseteq T$ such that it converges and it follows from the Maximum Theorem in [40, Ch. VI.3] that $\lim_{t \to \infty} \phi_t \in S(y)$. Since both $f(x)$ and $\nabla f(x)$ are continuous, applying the Maximum Theorem again implies there is a $T'$ such that $T' \subseteq T \subseteq T$ and $\{x^t\}_{t \in T'}$ converges to $y$ defined as $y = y + \rho (\nabla y - y)$, where $\rho$ is the stepsize when either the exact or successive line search is applied to $f(y)$ along the direction $\nabla y - y$. Since $y$ is not a stationary point, it follows from (50) that $h(y') < h(y)$, but this would contradict (51). Therefore $y$ is a stationary point, and the proof is completed.
