In the regime of strong coupling between molecular excitons and confined optical modes, the intra-molecular degrees of freedom are profoundly affected, leading to a reduced vibrational dressing of polaritons compared to bare electronically excited states. However, existing models only describe a single vibrational mode in each molecule, while actual molecules possess a large number of vibrational degrees of freedom and additionally interact with a continuous bath of phononic modes in the host medium in typical experiments. In this work, we investigate a small ensemble of molecules with an arbitrary number of vibrational degrees of freedom under strong coupling to a microcavity mode. We demonstrate that reduced vibrational dressing is still present in this case, and show that the influence of the phononic environment on most electronic and photonic observables in the lowest excited state can be predicted from just two collective parameters of the vibrational modes. Besides, we explore vibrational features that can be addressed exclusively by our extended model and could be experimentally tested. Our findings indicate that vibronic coupling is more efficiently suppressed for environments characterised by low-frequency (sub-Ohmic) modes.

I. INTRODUCTION

When an ensemble of quantum emitters interacts with a confined electromagnetic field (EM) mode, the system can enter into the strong coupling regime, resulting in the formation of light-matter quasiparticles known as polaritons, which inherit properties from each constituent. In particular, organic molecules present favourable features to achieve large couplings to optical modes at room temperature, due to their tightly-bound Frenkel excitons1,2 with large dipole moments. These properties offer an optimal experimental platform for polariton lasing3,4, enhanced exciton conductivity5, light harvesting6 and suppression of photo-bleaching in J-aggregates7. The strong light-matter coupling regime can be attained experimentally in a variety of different setups, such as in microcavities filled with a large number of molecules8 or, more recently, in nanoscale plasmonic resonators coupled to just a few molecules9,10.

The influence of strong light-matter coupling on molecular properties has recently come into focus, with several works predicting a reduction of vibrational effects in exciton-polariton states compared to bare-molecule excited states. This reduced vibrational displacement (RVD) could have significant consequences for the chemical reactivity of such molecules, permitting polaronic-based catalysis of electron-transfer11 and photo-isomerisation12. Approaches typically rely on the Holstein-Tavis-Cummings (HTC) model, which describes a single EM mode coupled to a collection of molecules with a single vibrational mode each11,13–16.

Nevertheless, actual molecules possess a large number of nuclear oscillation modes and additionally, interact with a continuous bath of phononic modes in the host solvent17 or polymer matrix18 in typical experiments, which induces additional chemical changes19. In this case, the persistence of the RVD in polaritons is unknown.

In this work, we present a study of the lowest-energy polaronic state supported by a small ensemble of organic molecules under strong coupling to an optical micro-cavity mode, sketched in Fig. 1a. Under the assumption that the molecules are close to their mechanical equilibrium, we include the whole vibrational spectrum of nuclear and environmental modes in our analysis, specified by the spectral density \( J_\nu(\omega) \). The level of modelling of the molecules, therefore, goes beyond the HTC Hamiltonian, but still enables exploration of the full many-body wavefunction employing canonical bosonic operators and thus the toolbox from quantum optics. Due to its mixed threefold photonic-excitonic-phononic character, this eigenstate is dubbed the lower polaron-polariton (LPP), adopting the nomenclature in ref. 20. To treat phononic and photonic processes in the molecules in the same footing, and, at the same time, deal with an arbitrary number of vibrations, we exploit a Tensor Network (TN) representation of the system’s wavefunction that extends the widespread Matrix Product States (MPS) for one-dimensional quantum chains21. By this means, the LPP is retrieved by variational minimisation of the TN via the Variational Matrix Product State (VMPS) algorithm22, which filters out the most relevant components mixed in the state capturing their mutual entanglement.

Our results show the robustness of RVD in the LPP wavefunction beyond the HTC model, extending its validity to arbitrary structured phononic baths. Moreover, the trend for larger ensembles indicates the effective suppression of polaron formation in the thermodynamic limit. Intriguingly, we observe that excitonic and photonic com-
ponents are largely independent of specific molecular details, and can be reproduced by an effective HTC model determined by two single-molecule cumulative parameters. Specifically, these are the reorganisation energy $\Delta^{23}$, associated with the re-equilibration of the vibrational modes after electronic excitation, and the mean phononic oscillation frequency $\Omega_v$ that corresponds to a collective reaction coordinate. Conversely, the LPP vibrational properties are strongly molecule-dependent and thus shaped by $\Omega_v$.

The paper is organised as follows: in section II we first present the model and introduce the TN-based algorithm aimed to target the LPP wavefunction. Namely, we analyse in section III the LPP eigenfrequency and the excitonic and photonic states reduced populations as a function of the vibrational modes, including the vibration-free polaritonic components mixed into the state. In section IV focus on a particular realisation of organic polaritons (Rhodamine 800 molecule) in section V.

II. MODEL AND METHODS

Our model includes a collection of $N$ identical molecules, containing a single exciton with frequency $\omega_e$ and ladder operators $\hat{\sigma}_\pm^{(i)} (i = 1, \ldots, N)$, placed within the volume of a resonant EM mode (frequency $\omega_O = \omega_e$) and annihilation operator $\hat{a}$. The total Hamiltonian contains two different parts, as schematically depicted in Fig. 1b. First, the system $\mathcal{S}$ that accounts for the excitons within the molecules, the cavity EM mode and their mutual coupling, measured by the collective Rabi frequency $\Omega_R$ and treated within the rotating-wave approximation (setting $\hbar = 1$),

$$\hat{H}_S = \omega_O \hat{a} \hat{a}^\dagger + \sum_{i=1}^N \omega_v \hat{\sigma}_+^{(i)} \hat{\sigma}_-^{(i)} + \Omega_R \sum_{i=1}^N (\hat{a} \hat{\sigma}_-^{(i)} + \hat{a}^\dagger \hat{\sigma}_+^{(i)}).$$

We neglect inter-excitonic interactions, which we assume are screened out by the host environment. In the single-exciton subspace, $\hat{H}_S$ is exactly solvable. Its eigenstates are two polaritons, upper (UP) and lower (LP), $|\pm\rangle = (\hat{a}^\dagger |G\rangle \pm |B\rangle)/\sqrt{2}$, with frequencies $\omega_{\pm} = \omega_O \pm \Omega_R/2$, which result from the hybridisation of the collective excitonic bright state $|B\rangle = (\sum_{i=1}^N \hat{\sigma}_+^{(i)} |G\rangle)/\sqrt{N}$. In addition, there are $(N-1)$ so-called dark states (DS), $|d\rangle \in \mathcal{D}$, which are purely excitonic states of frequency $\omega_e$ that are orthogonal to $|B\rangle$.

The second part of the Hamiltonian describes the vibrational subspace $\mathcal{E}_v^{(i)}$ containing a large number $M_v$ of vibrational modes both inside the molecule and in the host environment, and their elastic coupling to the excitons. The $k$-th vibrational mode is approximated by a harmonic oscillator of frequency $\omega_k$ (valid close to the equilibrium position) with annihilation operator $\hat{b}_k^{(i)}$ and exciton-phonon coupling strength $\lambda_k^{(i)}$,

$$\hat{H}_V = \sum_{i=1}^N \sum_{k=1}^{M_v} \omega_k^{(i)} \hat{b}_k^{(i)} \hat{b}_k^{(i)} + \sum_{i=1}^N \sum_{k=1}^{M_v} \lambda_k^{(i)} (\hat{b}_k^{(i)} + \hat{b}_k^{(i)} \hat{\sigma}_+^{(i)} \hat{\sigma}_-^{(i)}).$$

The properties of these modes, $\{\omega_k^{(i)}, \lambda_k^{(i)}\}$, are encoded in the spectral density $J_v^{(i)}(\omega) = J_v(\omega) = \pi \sum_{k=1}^{M_v} \lambda_k^2 \delta(\omega - \omega_k)$. Here the exciton-phonon coupling does not lead to nonradiative decay$^{10}$. The coupling parameters $\lambda_k$ describe the relative shifts of electronic potential surfaces between ground and excited states. For the uncoupled molecules ($\Omega_R = 0$), the total Hamiltonian $\hat{H}_S + \hat{H}_V$ becomes a sum of exactly diagonalisable independent-boson-models$^{24}$. Namely, the eigen-extractions or Langer-Firsov polarons can be visualised as localised ‘phonon clouds’ surrounding the excitons at each molecule: $|\xi_k\rangle = e^{-S} |G\rangle$, with $S = \hat{\sigma}_\pm^{(i)} \hat{\sigma}_\pm^{(i)} \sum_{k=1}^{M_v} \lambda_k^{(i)} (\hat{b}_k^{(i)} - \hat{b}_k^{(i)})$.

For typical molecules, when $M_v$ becomes large (or even formally infinite when a continuum approximation for $J_v(\omega)$ is used), most standard approaches of quantum optics to calculate the eigenstates of the system fail, and even many approximate methods become prohibitively expensive. For instance, direct diagonalisation of the total Hamiltonian is unfeasible, even for $N = 1$. However, a VMPS algorithm permits to calculate the full wavefunction including all degrees of freedom of either the time-evolved wavefunction after excitation (analysed in 25) or the ground state within the single electronic excitation subspace. This is precisely the ‘lower polaron-polariton’$^{11,13,20}$ analysed in the so-called Holstein-Tavis-Cummings (HTC) model$^{11,13,16,20}$, which deals with a single vibrational mode with frequency $\omega_v$ and vibronic
coupling \( \lambda_v \), i.e., \( \mathcal{H}_{\text{HTC}}(\omega) = \pi \lambda_v^2 \delta(\omega - \omega_v) \). In particular, the Hamiltonian Eq. (2) extends the HTC to an arbitrary number \( M_v \) of vibrational modes.

Here we employ a Tensor Network State-based approach that is numerically exact as long as convergence is reached, permitting a nonperturbative exploration of the quantum effects arising in the LPP. It does not rely on any specific form of the spectral density, and in particular, can be used both for discrete and continuous \( \mathcal{H}_v(\omega) \). To apply this method, we perform an orthogonal mapping of the modes in the \( N \) vibrational (green in Fig. 1) environments \( (\mathcal{E}_v^{(i)}) \). We rely on the chain transformation introduced in\(^{30}\), which maps the molecular Hamiltonian Eq. (2) for an exciton coupled to many independent vibrations to an exciton coupled only to the first site in a chain of coupled oscillators, leading to the vibrational Hamiltonian

\[
\mathcal{H}_v' = \sum_{i=1}^{N} \mathcal{H}_v^{(i)}
\]

\[
\mathcal{H}_v^{(i)} = \Omega_v \hat{c}_i^{(i)} \hat{c}_i^{(i)^\dagger} + \bar{\eta} \hat{c}_i^{(i)} \hat{\sigma}_+^{(i)} \left( \hat{c}_i^{(i)^\dagger} + \hat{c}_i^{(i)} \right) + \sum_{l=1}^{M_v-1} \omega_l \hat{c}_l^{(i)^\dagger} \hat{c}_l^{(i)} + \sum_{l=0}^{M_v-2} t_l \left( \hat{c}_l^{(i)^\dagger} \hat{c}_{l+1}^{(i)} + \hat{c}_{l+1}^{(i)^\dagger} \hat{c}_l^{(i)} \right).
\]  

This transformation results in the star coupling structure for \( \mathcal{H}_v + \mathcal{H}_v' \) sketched in the right part of Fig. 1b. The modes are thus regrouped in chains with length \( L = M_v^{27} \), with only the first mode coupled to the exciton-photon subspace \( \mathcal{S} \) (red-blue). Namely, each exciton is coupled to a single collective reaction mode defined by \( \eta \hat{c}_0 = \sum_k \lambda_k \hat{b}_k^{28–31} \), with total amplitude

\[
\eta = \sqrt{\int_0^\infty \mathcal{J}_v(\omega) \, d\omega / \pi},
\]

which generalises the vibronic coupling in the HTC model (\( \eta = \lambda_v \) in this case), and average bath frequency

\[
\Omega_v = \frac{\int_0^\infty \omega \mathcal{J}_v(\omega) \, d\omega}{\int_0^\infty \mathcal{J}_v(\omega) \, d\omega},
\]

which similarly generalises \( \omega_v \). All other chain modes become connected through nearest-neighbor hopping interactions \( t_l \). The discussion below shows an important quantity to characterise the vibronic coupling in the system is the so-called reorganisation energy, given by

\[
\Delta = \frac{1}{\pi} \int_0^\infty \mathcal{J}_v(\omega) / \omega \, d\omega,
\]

and directly linked with the Stokes (frequency) shift between maxima of emission and absorption spectra in organic molecules, given by \( 2\Delta^{22,33} \).

The star Hamiltonian Eq. (3) permits direct implementation of the VMPS algorithm. To this end, the LPP wavefunction \( |\psi_{\text{LPP}}\rangle \) is represented by a tensor network with maximum bond dimensions \( D \), which directly mimics the coupling structure in the star Hamiltonian (Fig. 1b), making the representation numerically efficient. This procedure, coupled with a variational approach to calculate the LPP, leads to a multi-chain variant of the Density Matrix Renormalisation Group algorithm (DMRG) for 1D quantum lattices\(^{34}\). When continuous vibrational spectra are taken into account, the formally infinite phononic chains are truncated at length \( L \), which must be chosen large enough to reach convergence. A more detail discussion can be found in the Appendix, A 1 and A 2.

We present results for a maximum of \( N = 5 \) molecules. For large molecular ensembles, a severe memory bottleneck occurs if the system \( \mathcal{S} \) is stored in a single root tensor leading to exponential scaling in \( N \). However, as shown in\(^{35,36}\), it would be possible to restore the efficiency of the numerical method while maintaining precision, by further decomposing the root node into a tree TN, where each final branch represents an exciton or the cavity photon and is coupled to a single chain. Developing a suitably efficient tree model requires an explicit analysis of ‘entanglement topology’ of the state, an idea that has recently been implemented to allow the simulation of multi-environment linear vibronic models constructed from ab initio parametrisations of small molecules\(^{37}\).

This is precisely the approach followed to simulate time dynamics of this system in\(^{38}\). To further ameliorate memory issues for large chain mode occupations, we employ an optimal boson basis for the chain tensors\(^{38}\), which can be determined on the fly via VMPS\(^{39}\). A more detailed description of the theoretical approach can be found in\(^{39}\).

### A. The Holstein-Tavis-Cummings limit

In order to connect our study with the cases available in the literature, we start by briefly revisiting the HT model, first introduced by Kirton et al.\(^{13}\), which can be solved by various methods, including direct numerical di-
to the collective behaviour of the system, we analyse in the following a molecular dimer within the HTC model. In this case, the presence of one dark excitonic state \( |d\rangle = (\hat{\sigma}_z \hat{\sigma}_x^{-1})|G\rangle \) is also present in the vibration-free eigenstates displayed in the left panels of Fig. 3. Vibronic interaction results in a larger shift of dark states as compared to polaritons, as inferred from the right panels in Fig. 3. Eigenenergies present actual crossings in addition to anticrossings, leading to a much richer structure of eigenstates than for \( N = 1 \). Comparing the vibrational components in Fig. 3b with those of Fig. 2b above, a slight reduction of the vibrational dressing (RVD) in the LPP is noticed, close to the threshold at which reorganisation energy and Rabi frequency become comparable (i.e., when \( \Omega_R \approx \Delta \)).

In particular, numerical and variational solutions for larger \( N \) display scaling of this phenomenon as \( 1/N \).

In the thermodynamic limit, therefore, the LPP becomes closer to the bare LP, and polaron formation is suppressed. A key observation is that RVD is not observed for the whole ladder of eigenstates, resulting in strong vibronic effects arising in the excited states (for example in the dynamics triggered by a high-frequency pulsed excitation). One direct consequence of polaron decoupling is the eventual suppression of the reorganisation energy of excited electrons, which, as first pointed by, could be exploited to enhance electron transfer reaction rates.

### III. Excitonic and Photonic Features of the LPP

The spectral density in organic materials depends strongly on the molecules and the host matrix. In order to obtain general conclusions, we thus first study the effect of many-mode vibrational dressing on polaritons using a standard parametrisation of low-frequency vibrational modes, the Leggett-type spectral density

\[
J_\nu(\omega) = 2\pi \alpha \omega^{s-1} \Theta(\omega_\nu - \omega), \quad s > 0,
\]

where \( \omega_\nu \) corresponds to a cutoff energy, \( \alpha \) describes the overall strength of the exciton-phonon coupling and the exponent \( s \) determines the shape of the spectral density, with \( s = 1 \) giving a so-called ‘Ohmic’ spectral density, while \( s < 1 \) and \( s > 1 \) correspond to sub- or super-Ohmic densities, respectively. The cutoff \( \omega_\nu \) implies that fast modes \( \omega_n > \omega_\nu \) are reabsorbed in the coupling constants through the adiabatic approximation. It is interesting to note for the following discussion that, within the single molecule limit, a regime recently reported in plasmonic nanocavities, the Hamiltonian Eq. (2) can be mapped precisely to the well-known Spin-Boson Model (SBM) by a shift of the vibrational mode origin, as shown in section B of the Appendix.

In this section, we study the influence of vibrational dressing on the excitonic and photonic properties of the LPP. We focus on Leggett-type spectral densities, Eq. (7),
with $s = 0.5$, $s = 1$, and $s = 2$ (shown in Fig. 4a). For ease of reference, we will compare the results with those obtained from the HTC model. The cut-off frequency $\omega_c$ is tuned to maintain the reaction coordinate frequency constant and equal to that of the reference HTC model $\Omega_v = \omega_c(1 + s)/(2 + s) = \omega_v$ in the HTC). We consider an anthracene-like molecule having a vibrational spacing of $\Omega_v = 0.2$ eV, and unless otherwise stated, we assume an ensemble containing $N = 5$ molecules.

In order to investigate the interplay between exciton-photon and exciton-phonon interactions without dealing with the full many-body state, we trace out the vibrational modes to calculate the reduced density matrix, $\hat{\rho}_S = \text{Tr}_\Gamma [\hat{\psi}_- \hat{\psi}_+]$. As Fig. 4b shows, the LPP state becomes more excitonic as the coupling amplitude to the reaction coordinate $\eta$ Eq. (4) grows, with a more substantial photonic character in a given molecule if the Rabi frequency $\Omega_R$ is larger. Such behaviour signals the trade-off between vibrational and photonic coupling scales. Nevertheless, the different curves for different $J_v(\omega)$ clearly indicate that the vibrational influence on the system is not solely determined by the reaction coordinate in the organic molecules. Instead, the remaining ‘dark’ vibrational combinations produce changes that are not captured adequately by $\eta$.

These results motivate us to consider the reorganisation energy $\Delta$, defined by Eq. (6) and given by $\Delta = 2\alpha \omega_v/s$ for Leggett-type $J_v(\omega)$, as a measure of the global influence of the whole set of phononic modes on the system. We next proceed to include the LPP eigenfrequency $\omega_{\psi_-}$ in the discussion. In particular, the values of the shift $\omega_{\psi_-} - \omega_-$ (the bare LP frequency to disregard the linear energy shift by the Rabi frequency in the discussion) as a function of the reorganisation energy can be read from Fig. 5a. The LPP eigenenergy undergoes a monotonic red-shift as a result of the increased vibrational dressing in electronic and photonic components. Mirroring the results for the HTC model, the slope of the curves differs at either side of the crossover at $\Delta \approx \Omega_R/2$, being steeper at the large $\Delta$ region. Accompanying this trend, the total photonic (excitonic) fractions of the LPP, (diagonal elements in $\hat{\rho}_S$) are decreasing (increasing) very similar functions of the reorganisation energy (Fig. 5b). Additional insight into the LPP internal structure is gained by considering the weights of the vibration-free eigenstates ($\Delta = 0$) that are mixed into the LPP by the vibronic coupling. As expected, Fig. 5c reveals that $|\psi_-\rangle$ is constituted by major contributions from the bare LP ($|+\rangle$) and dark states ($|d\rangle \in D$), with some small fraction of the UP ($|-\rangle$). In particular, in the flatter region where $\Delta \ll \Omega_R/2$ the LPP is well approximated by the bare lower polaron with frequency $\omega_{\psi_-} \approx \omega_-$.

The results above suggest that in real space the limit at large Rabi frequencies corresponds to a LPP that is a spatially delocalised state over the ensemble, with nearly no molecular phonon excitation. In the opposite large Stokes-shift limit, the LPP becomes closer to spatially localised polarons, with a LPP-LP shift of $-\Delta$ (irrespective of $J_v(\omega)$), and no photonic component. The trade-off between the two effects leads to a relocation of the contribution $\rho_{++}$ into the dark excitonic states, $\rho_{D+,D-}$, with eventual crossover at the large Stokes shift limit, mirroring results for the HTC model in the previous section. To further corroborate the existence of the previous extremes we calculate the bipartite entanglement between $S$ and $E$, measured by the partial von Neumann entropy $S(\hat{\rho}_S) = -\text{Tr}(\hat{\rho}_S \log \hat{\rho}_S)$. As we observe in Fig. 5d, correlations in the LPP, absent at $\Delta = 0$, build up for increasing Stokes shift as vibrational states become more mixed with excitons (and indirectly the cavity photon). For large $\Delta$, the formation of polarons entails the saturation of the entanglement entropy at the value $S(\hat{\rho}_S) \approx \log N$ corresponding to $N$ excitons maximally mixed with the vibrational modes.

In the halfway of the polaritonic and polaronic limits, where neither $\Omega_R$ or $J_v(\omega)$ are negligible, state $|\psi_-\rangle$ possesses a threefold exciton-photonic-polaronic character. Even in this region, observables acting within the system $S$ present only quantitative changes depending on the vibrational spectrum of the molecules. A direct consequence is the emergence of an RVD effect when comparing the LPP with uncoupled excitons, arising from an increased Rabi frequency (lower panels in Fig. 5). In this way, shallower curves in Fig. 5a,b,c indicate a larger resemblance with the LP in frequency, populations
and light-matter coherences respectively, while the entanglement entropy $S(\hat{\rho}_S)$ diminishes in Fig. 5d as $\Omega_R$ is augmented due to decoupling from vibrations. In our simulations, we also observed similar effects for a fixed Rabi frequency and growing ensemble size $N$. The increasing suppression of the vibrational dressing could suggest the onset of polaron decoupling in the limit $N \gg 1$, similar to the one reported for a single mode as observed above\textsuperscript{11,16}. From the point of view of chemistry, similar results have been obtained without canonical quantisation of molecular vibrations, generalising our conclusions to arbitrary electronic potential energy surfaces far from equilibrium (e.g. in chemical reactions)\textsuperscript{12,45}. In this case, the so-called ‘collective protection’ (the extended version of the RVD) has been shown in the thermodynamic limit, by means of suppressed displacements in the polaritonic (nuclear-coordinate-resolved) surfaces. Lower polariton and ground state (vacuum) electronic surfaces thus become identical, with a critical impact on photoisomerisation reactions.

The results above reveal the robustness of the RVD, which does not rely on the fine molecular/host details encoded in $J_v(\omega)$. Instead, the LPP for molecules close to the equilibrium is accurately characterised by the coupling to a reaction coordinate with frequency $\Omega_v$ while the global effect of the vibrational modes enters through the full reorganisation energy $\Delta$. These features can therefore be understood within an effective HTC model, with phonon frequency chosen according to the experimental reaction coordinate frequency and Stokes shift.

The case of polaritons formed from molecules with large Stokes shift has been recently reported, showing that emission from the hybrid polaritons is suppressed and instead occurs from the bare molecules\textsuperscript{46}. In this limit, it is more energetically favourable for an exciton to form a polaron rather than hybridise with a photon, as shown by diagonalisation of $\hat{H}_S + \hat{H}_v$. Although TN-based approaches to target excited states have been devised\textsuperscript{147}, we exploit aforementioned similarities to further visualise the photonic properties of a simpler HTC model with

---

**FIG. 5.** (a) Energy shift with respect to the bare LP ($\Delta = 0$), (b) exciton/photon fractions (c), vibration-free components in the LPP and (d) Von-Neumann entropy of the photonic-excitonic and vibrational states bipartition, as a function of reorganisation energy. In these panels upper panels depict the case $\Omega_R = \Omega_v$ and $\Omega_R = 10\Omega_v = 2$ eV for the lower panels.
N = 2 (see Fig. 6). In this manner we observe that the quasi-particle weight of the vibration-free polariton $Z_{\psi_n} = \langle |\psi_n| |\psi_n\rangle \rangle^2$ indeed ‘climbs up’ to the excited states as $\Delta$ is increased, a fingerprint of polaritons at higher energies (see Fig. 6). This can be understood as a consequence of the fact that transitions within the Franck-Condon region (and thus with non-negligible dipole moment) occur to vibrationally excited states for large exciton-phonon coupling.

Finally, we noticed quantitative differences as molecular details were varied, which are particularly prominent in the region $\Delta \approx \frac{\Omega_R}{2}$, where maximum mixing between purely polaritonic and polaronic states is observed, and when the vibrational spectrum in the molecules is dominated by slow modes (sub-Ohmic $J_v(\omega)$). While exciton/photon properties have been shown to be universal, the impact of light-matter coupling on different molecular vibrations is averaged out in $\rho_S$. These non-trivial features motivate further analysis of the intrinsic vibrational properties in the LPP state, by first calculating a quasiparticle weight $Z_{\psi_n} = \langle |\psi_n| |\psi_n\rangle \rangle^2$ that indicates how close the LPP is to the vibration-free LP, shown in Fig. 7. Increased overlaps signal the RVD at large Rabi frequencies and exponents $s$. It should be noted that $Z_{\psi_n}$ includes only the overlap with the vibrational vacua $|0\rangle_{\psi_n}$, in contrast with the population $p_{-\omega}$, reduced over the whole environment. Therefore, when Fig. 5c and Fig. 7 are compared, a more polaronic character of the LPP is noticed with larger vibrational dressing for sub-Ohmic $J_v(\omega)$. However, as we show in Fig. 5a, the energy shifts associated with sub-Ohmic baths are actually weaker than in super-Ohmic and single mode environments, indicating that the RVD is strongest for sub-Ohmic baths. We shall elucidate the origin of this effect, related to the dominance of slow vibrational modes in sub-Ohmic environments, in the next section by further exploring the many-body vibrational properties of the LPP state.

**IV. VIBRATIONAL FEATURES OF THE LPP**

Our VMPS approach enables access to the full many-body vibrational component of the LPP wavefunction, which can be exploited to resolve phononic features in frequency space that are disregarded in the HTC model. In this section we show how vibrational observables are shaped by the specific shape of $J_v(\omega)$. To this end, we analyse the frequency-resolved vibrational displacement in the LPP state for the electronically excited molecule $i$. For further insight we split this observable into conditional displacement contributions arising from each system state $|n_S\rangle \in S$ mixed into the LPP,

$$X_{i,n_S}(\omega, \Delta) = \frac{|\langle \psi_{-\omega} | \widehat{P}_{n_S} (\hat{b}_k^{\dagger} + \hat{b}_k^{\dagger}) |\psi_{-\omega}\rangle|}{\rho_{n_S,n_S}},$$

which includes a projector over system states $\widehat{P}_{n_S}$. Here we normalised by the corresponding system state population, to discern situations where the state fraction is vanishingly small. In practice, the calculation of Eq. (8) requires reverting the chain mapping for the $\epsilon_{ij}^{(i)}$ modes. The displacement spectra in Fig. 8 explicitly show the RVD of electronically excited molecules in the LPP, with decreased vibrational displacement $X_{i,e}^{(i)}$ from the bare-molecule value $X_{i,e}(\omega, \Omega_R = 0) = \chi^2_{\omega} \Omega_R^{-1}$, when $\Omega_R$ is increased (see Fig. 8a) and a more substantial suppression at low frequencies and smaller $s$. The microcavity mode induces a ‘cross-talk’ between otherwise disconnected molecules (note that we neglected dipole-dipole interactions). This results in a finite contribution of phononic displacement in a given molecule, caused by electronically excited states residing in others, $X_{i,e}^{(i)}$ (see Fig. 8b), and also a ‘molecule-induced’ vibrational displacement in the cavity state measured by $X_{i,1}$. Although these contributions are suppressed for low frequencies at large $\Omega_R$, in a similar way to the ‘local’ quantity $X_{i,1}$, they slightly
Two distant power laws varying the ensemble size at large very similar trends, while the second is less sensitive to the cavity in strong coupling, vibrational dressing is collectively suppressed. At moderate Rabi frequency, the situation is different, and the reduction with $N$ depends non-analytically on $\Omega_R$ and $\Delta$. Although a full analysis is beyond the scope of this contribution, we note that the related SBM possesses a set of quantum phase transitions for Ohmic and sub-Ohmic baths in which strong polaronic dressing completely suppresses tunnelling dynamics. For sub-Ohmic baths, the critical coupling is a function of quantities related to $\Omega_R$ and $\Delta$ (see section B)\cite{44,48}, and the ground state contains complex superpositions of displaced oscillator states\cite{48}, which may be relevant for the physics of intermediate Rabi couplings.

As for the bare molecules, this observable is extremely sensitive to the molecular species supporting the LPP, even when the Stokes shift is kept constant. Additional
insight into the strength of the RVD effect for a given molecular ensemble is given by the ratio

$$R(\omega_k) = \frac{X_{1,e}(\omega_k, \Omega_R, \Delta)}{X_{1,e}(\omega_k, \Omega_R^*, \Delta)}$$

(9)

where \(\Omega_R > \Omega_R^*\) are two Rabi frequencies. Intriguingly, as shown in Fig. 9, the ratio \(R\) is mostly independent of the power law in \(J_v(\omega)\), unveiling another universal characteristic of the model. Therefore, although the LPP is more polaronic for lower \(s\), the suppression at low frequencies is increased in absolute terms in such a way that the relative suppression spectrum is molecule-independent.

Exploiting the similarities with the SBM for a single molecule, as discussed in Appendix B, the intrinsic frequency dependence of \(R\) follows from the variational polaron theory for the SBM \((N = 1)\) with ‘bias’ \(\delta = -\Delta\) (provided that \(\omega_s = \omega_D\)). For large \(\Omega_R\) and small \(\Delta\), bias effects caused by the vibrational reorganisation energy become irrelevant. The slow modes are anti-adiabatic from the perspective of the Rabi oscillations. Hence, they cannot readjust their displacements rapidly enough to track the formation of polaritons arising from light-matter coupling\(^{27}\), and are unable to maximise the vibrational dressing of the electronic states. Vibrational and phononic processes are hence ‘decoupled’ and \(R\) decreases monotonically with the frequency. This picture agrees with the smaller energy shifts for Ohmic and sub-Ohmic spin-boson models may develop over very long timescales when the system is biased and then prepared sub-Ohmic spin-boson model may develop over very long timescales when the system is biased and then prepared.

Up to now, we have considered smooth vibrational spectral densities. In the following, we show how these ideas can be tested in a molecule with highly structured vibrational features that reconfigures the conditions found in realistic organic microcavities.

**V. THE RHODAMINE 800 MOLECULE**

In typical organic molecules, besides simple power-law spectra at low frequencies, more complicated features may arise at high (typically mid-infrared) frequencies, as observed in, e.g., infrared and Raman spectroscopy where many sharp vibrational resonances are present. In the following, we consider the Rhodamine 800 perchlorate molecular compound (sketched in Fig. 10b), which constitutes a common choice for a laser gain media and strong coupling experiments\(^{31}\). In this case, the phononic information necessary to ‘feed’ \(J_v(\omega)\) is known from vibrational spectroscopy\(^{32}\). In particular, the data from three pulse photon echo peak shift (3PEPS) experiments at room temperature (in Fourier space) can be interpolated to give an accurate approximation for the low-frequency part \(J_v^H(\omega)\)\(^{33}\). Regarding the high-frequency modes, denoted as \(\Omega_k\), we consider that each oscillator is broadened by an amount of \(\Gamma \ll \Omega_k\) due to the interaction with a background Ohmic bath of vibrations for vibrational dephasing and decay\(^{28}\), by taking

$$J_v^H(\omega, \Omega_k, \gamma_k) = \frac{4\gamma_k \Omega_k^2 \eta^2}{(\Omega_k^2 - \omega^2)^2 + (2\pi\gamma_k \Omega_k \omega)^2},$$

(10)

where \(\gamma_k = \Gamma/(2\pi\Omega_k)\) is a dimensionless measure of the mode broadening. Firstly, we compared the \(S\) populations of a dimer of Rhod800, with spectral density \(J_{\text{Rhod800}}(\omega) = J_v^H(\omega) + \sum_{k \in \Delta} J_v^H(\omega, \Omega_k, \gamma_k)\), shown in Fig. 10a, with a HTC model with parameters \(\Omega_v^{\text{Rhod800}}, \Delta^{\text{Rhod800}}\) estimated from the experimental spectral density. Strikingly, despite the involved resonant structure of \(J_{\text{Rhod800}}(\omega)\), the energy shift and the reduced density matrix observables present a smooth behaviour as the Rabi frequency \(\Omega_R\) is varied (Fig. 10), which mimics the HTC model. This predicts that the probing of excitonic and phononic characteristics of the LPP supported by an ensemble of arbitrarily complex molecules, close to the mechanical equilibrium, only requires the experimental knowledge of few collective quantities.

However, in agreement with the conclusions drawn for the polynomial spectral densities in Eq. (7), the vibrational features cannot be described by the HTC model but are profoundly dominated by the vibrational structure of the molecule and the host medium, encoded in...
FIG. 10. Reduced observables for the LPP supported by a dimer of Rhod800 molecules. The total reorganisation energy for the modes that are considered is $\Delta = 0.112$ eV. The numerical first moment of the spectral density $J_{\text{Rhod800}}(\omega)$, depicted in panel (a) reveals a value of $\Omega_v = 0.154$ eV.

FIG. 11. (a) Displacement spectrum for the LPP supported by a dimer of Rhod800 molecules, projected on the electronically excited molecule. (b) Ratio between the displacement of the electronically excited molecule at $\Omega_R = 1.5$ eV and the cases depicted in (a). The remaining parameters are fixed according to Fig. 10 caption. Phononic displacements of the exciton component of the LPP in Fig. 11a, mirror the resonant structures in $J_{\text{Rhod800}}(\omega)$. Nevertheless, the relative suppression $R$ is surprisingly smooth see Fig. 11b. In agreement with our previous results, is controlled by just the reaction coordinate frequency $\Omega_v$ and the reorganisation energy $\Delta$ instead of details in $J_v(\omega)$.

VI. CONCLUSION

In this work, we have investigated a microscopic theory that goes beyond current models for the lower polaron polariton in organic microcavities, by introducing the whole phononic spectrum. In order to treat the problem numerically, we employed a quasi-exact VMPS algorithm, able to handle the full Hamiltonian including multimode and many molecule effects. We have demonstrated that the RVD of polaritons compared to bare electronic states is a universal feature of strongly-coupled organic microcavities.
that does not depend on the details of the vibrational structure. In this way, different distributions of intra- or extra-molecular vibrational modes lead to similar excitonic and photonic properties of the LPP wavefunction, where only the bath component is appreciably altered.

Our findings show unambiguously how, despite the involved phononic spectrum in organic molecules, a large extent of features in the LPP can still be emulated by the HTC model. The universal character of the results is not expected to be present in the time evolution of the exciton-photonic system, a problem that has attracted interest lately due to the experimental advances achieving exotic organic polariton dynamics and non-equilibrium BEC in the strong coupling regime. As we show in the non-equilibrium description of the bath modes is crucial to determine the time evolution route followed by the system arising from details in $J_0(\omega)$.

However, there is still a long way to go regarding experiments to obtain conclusive evidence of changes in chemical processes or electronic energy transfer in ESC. The model presented and explored here seeks to generalise the most simple descriptions of the problem, while future prospects along these lines would go towards extended approaches, that are able to introduce multi-dimensional features in the recent field of polaritonic chemistry.

Appendix A: Tensor-Network-based approach

In the following appendix, we outline the numerical approach to target the optimal LPP $|\psi_\ominus\rangle$. We state only what is necessary to understand this work, referring to the reader to complete reviews to the topic\textsuperscript{21,57}.

The numerical approach is based on the two following ideas: (i) Representation of $|\psi_\ominus\rangle$ as a multi-chain TN, mimicking the structure in the star Hamiltonian Fig. 1 that can be employed to implement the (ii) variational principle

$$|\psi_\ominus\rangle = \min_{|\psi\rangle \in M_{\text{TN}}} \frac{\langle \psi | \hat{H}_S + \hat{H}_E | \psi \rangle}{\langle \psi | \psi \rangle}, \quad (A1)$$

within the TN sub-manifold of the total Hilbert space ($M_{\text{TN}} \subset \mathcal{H}_S \otimes \mathcal{H}_E$) that leads to the star-DMRG algorithm employed in the work.

1. Star TN structure

The DMRG algorithm works especially well targeting ground states in one-dimensional systems. The orthogonal mapping of the vibrational modes, leading to the star Hamiltonian introduced in the main text, constitutes a convenient starting point for the application of this numerical method. We consider the expansion of the LPP in the single exciton-phonon subspace, which exploits the Fock states $|n_l(i)\rangle \in \mathcal{E}_l(i)$ for the $l$-th site at chain $i$, i.e.

$$|\psi_\ominus\rangle = \sum_{n_{S=1}}^N \sum_{n(i)}^N \sum_{n_S=1}^N \sum_{n_{L-2}}^N \Psi_{n_S,n(i)} |n_S\rangle \otimes |n(i)\rangle, \quad (A2)$$

where the array $n(i) = (n_0(i), \ldots, n_{L-2}(i))$ encompasses the Fock numbers at each of the chains. This statement admits a representation as an TN. In this case the complex $M_r + 1$-th order tensor $\Psi_{n_S,n(i),\ldots,n(N)}$ is decomposed into a product of rectangular matrices with site-dependent dimensions $q_l$ under the following setting: each of the excitations of a given bosonic site and chain $n_l(i)$ is assigned to a matrix $A_{d_{l-1}d_l}^{n_l(i)} \in \mathbb{C}^{D_{l-1} \times D_l}$, where each of the system degrees of freedom corresponds to $A_{d_L}^{n_{S}} \in \mathbb{C}^{1 \times D_{S}}$. Inherited from the star Hamiltonian depicted Fig. 1, the most natural TN representation of $|\psi_\ominus\rangle$ that enables to reduce the minimisation Eq. (A1) to a single site problem,
in the way described in section A 2 is given by
\[ |\psi_{-}\rangle = \sum_{n_{g}=1}^{N+1} A^{n_{g}} \sum_{i=1}^{N} A^{n_{g}(i)} \cdots A^{n_{g}(N)} |n_{g}\rangle \otimes |n^{(i)}\rangle. \] (A3)

The order in which the matrices occur in the product, sketched in Fig. 12a, mimics how the sites are connected in the Hamiltonian Eq. (3). Instead, here the system tensors (site 0) corresponding to the 0th site are contracted with the boson tensor at each of the 1st sites. To account for bosonic degrees of freedom, a decomposition of the bath modes in terms of an optimal boson basis (OBB) is considered. The auxiliary indexes that are contracted via the matrix product, \( d_{i} \in \{1, 2, \ldots, D_{l}\} \) are known as bond dimensions. They embody the entanglement content of the state; higher bond dimensions signify more entanglement, such that for sufficiently high \( D_{l} \) the form Eq. (A3) can represent any quantum state in the Hilbert space.

The major power of TN-based approaches relies on the efficient computer representation of the site tensors \( A \). In practice, this ‘compression’ is achieved by successive iterations of singular value decompositions and truncation of the states with small singular values, corresponding to the Schmidt coefficients. This protocol reduces the maximum bond dimensions, enabling to restrict the possible states to a sub-manifold \( \mathcal{M}_{\text{TN}} \subset \mathcal{H}_{S} \otimes \mathcal{H}_{E} \), that comprises the low-lying many-body states of the system.

### 2. Star DMRG algorithm

Employing the star TN representation Eq. (A3) in conjunction with the star Hamiltonian, the minimisation problem Eq. (A1), limited to the manifold \( \mathcal{M}_{\text{TN}} \) can be performed by a DMRG-sweeping procedure, which optimises one matrix at a time while keeping all others fixed, then optimising the neighbouring matrix, and so forth, until convergence is achieved. The basic steps of the algorithm employed, based on sequential 1D DMRG sweeps along the chain, are sketched in Fig. 12a.

To allow for fast contractions we keep the state in a mixed canonical form, enabling to benefit from orthogonality conditions as shown in. Such representation reduces each DMRG step as a linear eigenvalue (optimisation) problem for a single site tensor (either \( A_{l} \) or the OBB matrices) with the effective Hamiltonians shown in Fig. 12b. More details about the numerical implementation can be found in.

Finally, regarding the convergence of the DMRG algorithm for dense spectra where \( M_{l} \gg 1 \), it is important to notice that for gap-less finite-bandwidth \( J_{l}(\omega) \), it has been shown, that the chain becomes asymptotically homogeneous, such that \( \omega_{l>1} \rightarrow \omega_{c}/2 \) and \( \omega_{l>1} \rightarrow \omega_{c}/4 \) respectively. The translational-invariant slice of the chain can be diagonalised in ‘chain momentum’ space, giving rise to a cosine energy dispersion band \( \sim \omega_{c}(1 - \cos \pi q) \) with a minimum at zero energy. Thus there is no net contribution of these sites to the LPP energy, and the truncated chain approximation considered in this work is fulfilled.

### Appendix B: Single-molecule multimode limit

One interesting case of the Hamiltonian under study is the single-molecule limit. In particular, single-molecule strong coupling has been recently reported in plasmonic nanocavities. Within the single electronic/photonic excitation subspace, this case can be mapped exactly to the well-known Spin Boson Model (SBM) by a shift of the vibrational mode origin in the original Hamiltonian Eq. (1) before performing the chain transformation. After this shift, described by \( \hat{H}_{v}^{\text{shift}} = c^{\dagger} \hat{H}_{v} e^{-c} \) with \( c = \sum_{k} \lambda_{k}(\hat{b}_{k} - \hat{b}_{k}^{\dagger})/(2\omega_{k}) \), the light-matter coupling can be expressed through the dynamics of a quasispin \( \hat{S}_{-} = |e\rangle\langle 1| \) coupled to a bath of bosons, governed by the Hamiltonian \( \hat{H}_{\text{SBM}} = \hat{H}_{S} + \hat{H}_{v}^{\text{shift}} \).

\[ \hat{H}_{\text{SBM}} = \frac{\delta}{2} \hat{S}_{z} + \frac{g}{2} \hat{S}_{x} + \sum_{k} \left[ \omega_{k}\hat{n}_{k} + \frac{\lambda_{k}}{2} \hat{S}_{z}(\hat{b}_{k} + \hat{b}_{k}^{\dagger}) \right]. \] (B1)

Here, we have have introduced \(|e\rangle = \hat{\sigma}^{+}(G)\) and \(|1\rangle = \hat{a}^{\dagger}(G)\) as shortcuts for the excitonic and photonic states in the single-excitation subspace, respectively.

The SBM constitutes one of the minimal models to study quantum dissipation in solid-state and organic systems, e.g., decoherence of quantum oscillations in qubits, impurity moments coupled to bulk magnetic fluctuations, and electron transfer in biological molecules. Here, the detuning between the cavity and the zero-phonon line \( \delta = \omega_{c} - \Delta - \omega_{D} \) plays the role of a bias, where the reorganisation energy follows from Eq. (6).

The light-matter coupling \( g \) favours the mixing of the molecular exciton and the photon, similarly to the HTC model analysed in previous section, whereas the spin-bath interaction dresses them with vibrational modes, destroying light-matter coherence. In the unbiased case, i.e., when the cavity is resonant with the zero-phonon line, \( \omega_{D} = \omega_{c} - \Delta \), the Hamiltonian becomes parity symmetric under the exchange \( |e\rangle \leftrightarrow |1\rangle \). This symmetry is known to be spontaneously broken when the vibrational coupling becomes larger than a critical value for sub-Ohmic and Ohmic \( J_{\omega}(\omega) \), leading to a quantum phase transition in which the ground state is a fully polarised spin state. Translated to the present case, this would signify a novel vibrationally-driven localisation phenomenon in either excitonic or photonic states, precluding the formation of polaritons at the single molecule limit. However, it is questionable whether traces of this transition could be observed in nanocavity systems capable of significant light-matter coupling in the single-molecule case, especially considering that we are here neglecting the nonradiative and radiative losses associated with such systems. We thus have focused on the many-molecule case (\( N > 1 \))
FIG. 12. (a) Sketch of the star TN for the case $N = 3, M_v = 5$ that is used to represent the LPP. Here each of the squares signifies a tensor, that is contracted with the tensor to which its legs are connected. Arrows depict a possible order at which the tensors are optimised in the algorithm. The open legs represent the local Hilbert space at each of the sites, which is contracted with the Hamiltonian $\hat{H} = \hat{H}_S + \hat{H}_v$ to state the minimisation problem. To carry out this minimisation, it is instrumental to represent the state in mixed canonical form compute the contractions depicted in (b). Here we use a similar notation for the tensors as in the reference\textsuperscript{59}.

at zero detuning $\omega_e = \omega_O$, corresponding to the most common experimental setups, while using the analogy to the SBM to make connections to the existing literature.
