Helium-like and Lithium-like ions in non-relativistic QED:
Ground state energy

Abstract

Following detailed analysis of data the domain of applicability of Non-Relativistic QED (NRQED) with static nuclei is described for ground state energy of helium-like (and lithium-like) ions for \( Z \leq 20 \). It is demonstrated that finite nuclear mass effects do not change 4-5 significant digits (s.d.) and the leading relativistic and QED effects leave unchanged 3-4 s.d. for \( Z \leq 20 \) in ground state energy for both helium and lithium-like ions. It is shown that the non-relativistic ground state energy can be easily interpolated in full physics range of nuclear charge \( Z \) with accuracy of not less than 6 decimal digits (d.d.) (or 7-8 s.d.) for \( Z \leq 50 \) for helium-like ions and for \( Z \leq 20 \) for lithium-like ions using a meromorphic function in variable \( \lambda = \sqrt{Z - Z_B} \) (here \( Z_B \) is the 2nd critical charge [19]), which is well inside the domain of applicability of non-relativistic QED. In turn, it is found a fourth degree polynomial in \( \lambda \) which reproduces the ground state energy of the helium-like and lithium-like ions for \( Z \leq 20 \) in the domain of applicability of NRQED with static nuclei, thus, 3 s.d. It is noted that \( \sim 99.9\% \) of the ground state energy (and some expectation values) is given by the variational energy for properly optimized trial function of the form of (anti)-symmetrized product of three (six) Coulomb orbitals for two-(three) electron system with 3 (7) free parameters for \( Z \leq 20 \), respectively. It implies that these trial functions are, in fact, the exact wavefunctions for non-relativistic QED.

I. INTRODUCTION

In non-relativistic quantum electrodynamics (NRQED) the Coulomb system of the \( k \) electrons and infinitely-heavy, static, point-like charge \( Z \): \( (ke; Z) \) is described by a Hamiltonian

\[
\mathcal{H} = -\frac{1}{2m} \sum_{i=1}^{k} \Delta_i - \sum_{i=1}^{k} \frac{Z}{r_i} + \sum_{i>j=1}^{k} \frac{1}{r_{ij}},
\]

where \( r_i \) is the distance from charge \( Z \) to \( i \)th electron of mass \( m = 1 \) and electron charge \( e = -1 \), \( \Delta_i \) is three-dimensional Laplacian associated with \( i \)th electron, \( r_{ij} \) distance between the \( i \)th and \( j \)th electrons, \( \hbar = 1 \). Thus, energy is in atomic units (a.u.). It is widely known that there exists a certain critical charge \( Z_c \) above of which, \( Z > Z_c \), the system gets bound forming a \( k \) electron ion. It is also known that total energy of a bound state \( E(Z) \) as the function of integer charge \( Z = 1, 2, \ldots \) is very smooth, monotonously-decreasing negative function which, with the growth of \( Z \), is approaching to the sum of the energies of \( k \) Hydrogenic ions, see for illustration Fig.1 at \( k = 1, 2, 3 \). Domain of applicability of NRQED with static charge \( Z \) is limited due to finite-mass effects, as well as relativistic and QED effects, and many other effects. The first three effects are dominant and define the domain of applicability. For large \( Z \) the relativistic effects become large and the Schroedinger equation should be replaced by the Dirac equation. Therefore we limit our consideration by \( Z \leq 20 \).

In many applications, especially, in astrophysics and plasma physics we do not need high accuracies, it might well be inside of a domain of applicability of NRQED with static charges where relativistic, QED and mass effects can be neglected. Hence, it is natural to find such a domain of applicability of NRQED with static charge. It may depend on the quantity we study. As the first step we will consider the ground state energy for 2-3 electron systems.

(A) For two-electron case, \( k = 2 \) (\( H^- \), He, Li\(^+ \) etc) with infinitely heavy charge \( Z \) (we will call the static approximation) the spectra of low-lying states was a subject of intense, sometimes controversial, numerical studies (usually, each next calculation had found that the previous one exaggerated its accuracy). This program had run almost since the inception of quantum mechanics \([1]\) and had culminated at 2007 \([2]\) where the problem was solved for \( Z = 1 - 10 \) for the ground state with overwhelmingly/excessively high accuracy (\( \sim 35 \) s.d.) from physical point of view and it still continues. Recently, it was checked that the energies found in \([2]\) are compatible with \( 1/Z \)-expansion up to 12 d.d. for \( Z > 1 \) and 10 d.d. for \( Z = 1 \), see \([3]\). A time ago Nakashima-Nakatsuji made the impressive calculation
FIG. 1: Ground state energy vs Z for one-, two-, three-electron atoms in NRQED in static approximation. Critical charges marked by filled squares.

of the ground state energy of the 3-body problem (2e, Z) with finite mass of nuclei [4]. It was explicitly seen that taking into account the finiteness of the nuclear mass changes in the energy (taken in a.u.) the 4th significant digit for Z = 1, 2 and the 5th one for Z = 3 – 10 . In present paper using the Lagrange mesh method [5] we checked and confirmed correctness of the 12 s.d. in both cases of infinite and finite nuclear masses for Z = 1 – 10 obtained in [2, 4]; we also calculated the ground state energies in both cases of infinite and finite nuclear masses for larger Z = 11, 12, 20, 30, 40, 50 with accuracy of not less than 10 d.d. [30].

(B) For three-electron case k = 3 (Li, Be + etc) accurate calculations of the ground state energy for Z = 3 – 20 were carried out in [7] for both infinite and finite nuclear masses. We believe that, at least, 10 s.d. obtained in these calculations are confident. The effect of finiteness of the nuclear mass changes 4th - 3rd decimal digit in the energy (in a.u.) when moving from small to large Z. For Z = 15 – 20 (and for infinite nuclear mass) the check of compatibility of obtained results with 1/Z-expansion was also made: it was found that 5-6 d.d. in energy coincide [7]. This coincidence provides us the confidence in the correctness
of a certain number of decimal digits (not less than six) which is sufficient for our purposes. Note that finite mass effects were found perturbatively, taking into account one-two terms in the expansion in electron-nuclei mass ratio. We are unaware about any calculations of the ground state energy of the four-body problem \((3e, Z)\) in full geometry even for small \(Z\).

Aim of the present paper is three-fold: (i) To localize the domain of applicability of non-relativistic QED with static nucleus, (ii) to construct a simple interpolating function for the ground state energy in full physics range of \(Z \leq 20\) for \(k = 2, 3\) which would reproduce the ground state energy with not less than six d.d. exactly. Such a number of exact d.d. is definitely inside of domain of applicability of non-relativistic QED with static nucleus; (iii) to present a simple trial function for which the variational energy describes the exact ground state energy in the domain of applicability non-relativistic QED with static nucleus with accuracy 99.9\%, thus, it is the exact ground state NRQED wavefunction.

The paper is organized in the following way: Section II contains the analysis of theoretical data defining the domain of applicability of NRQED, in Section III the Puiseux expansion for small \(Z\) and the Taylor expansion for large \(Z\) are presented, two-point interpolations are introduced in Section IV, Section V presents the ”exact” functions of the ground state in NRQED approximation.

All energies are given in atomic units (a.u.).

II. DOMAIN OF APPLICABILITY

As the first step we have to collect data for the ground state energies available in literature for the cases of both infinite nuclear masses and finite nuclear masses (taking the masses of the most stable nuclei, see \([9]\)) for two- and three-electron systems, see Table I, II, respectively. In particular, this step is necessary to evaluate the effects of finite nuclear mass to the ground state energy: what leading significant (decimal) digit in energy is influenced by mass effects.

(A) For \(k = 2\) (two-electron ions) we collected in Table I data available in literature. The energies for \(Z = 11, 12, 20, 30, 40, 50\) were calculated for the first time employing the Lagrange mesh method \([5]\) and using the concrete computer code designed for three-body studies \([10, 11]\), where it can be consulted. In the past this method provided systematically the accuracy of 13-14 s.d. for the ground state energy of various 3-body problems, see
e.g. [11]. As for \( Z = 1 - 10 \) the results (rounded to 10 d.d.) obtained in [2, 4] are also presented. All these energies were recalculated in the Lagrange mesh method and confirmed in all displayed digits at Table I. Taking into account the relativistic and QED effects obtained in [12] for \( Z = 2 - 12 \) (and collected in Table I) and polynomially-extrapolating them to \( Z = 1 \) and \( Z = 20 \) [31] one can see that these effects leave unchanged the first 3-4 s.d. in the ground state energy. It defines the domain of applicability of non-relativistic QED with static nuclei for \( Z = 1 - 12 \) as 3-4 s.d. in the ground state energy.

(B) For \( k = 3 \) (three-electron ions) for infinite nuclear mass the results by Yan et al., [7] are presented in Table II. Recently, for \( Z = 3, 4 \) these results were recalculated by Puchalski et al., [8] using the alternative method. This recalculation confirmed 9 d.d. in energies obtained in [7], but explicitly disagreed in 10-11th d.d. Since the results [8] give lower energies than [7] we consider them as more accurate. As for finite nuclear mass case for \( Z = 3 - 8 \) the six d.d. only can be considered as established, except for \( Z = 8 \), see [7, 8, 13]. In [8] it was shown that for \( Z = 3, 4 \) the sum of the leading relativistic (\( E_{rel} \)) and QED (\( E_{QED} \)) corrections is of the same order of magnitude as mass polarization. In particular, for \( Z = 3 \) the sum of the leading corrections \( E_{rel} + E_{QED} = -4.31 \times 10^{-4} \) a.u. while the mass correction \( E_{mass} = 6.08 \times 10^{-4} \) a.u., being of opposite sign, see below Table II. For \( Z = 4 \) the sum of \( E_{rel} + E_{QED} = -19.76 \times 10^{-4} \) a.u. being more than four times larger of one at \( Z = 3 \), while the mass correction \( E_{mass} = 8.99 \times 10^{-4} \) a.u. increasing in about 50\% and being also of the opposite sign, see below Table II. Overall correction to ground state energy gives contribution to 5th s.d. in the ground state energy for \( Z = 3, 4 \), see below, Table II.

We are unaware about the analysis of both QED and relativistic corrections for other values of \( Z \) of the same quality as in [8] (and [12] for \( k = 2 \)). Thus, we can assume that for \( Z = 3 - 20 \) these relativistic and QED corrections leave unchanged 5-4-3 s.d. with growth of \( Z \) up to \( Z = 20 \) in the ground state energy in static approximation (similarly to the two-electron case) [32]. It defines the domain of applicability of non-relativistic QED of three electron atomic systems with static nuclei.
III. EXPANSIONS

It is well known since Hylleraas [1] that at large \( Z \) the energy of \( k \)-electron ion in static approximation admits the celebrated \( 1/Z \) expansion,

\[
E(Z) = -B_0 Z^2 + B_1 Z + B_2 + O\left(\frac{1}{Z}\right),
\]

where \( B_0 \) is the sum of energies of \( k \) Hydrogenic atoms, \( B_1 \) is the so-called electronic interaction energy, which usually, can be calculated analytically. In atomic units \( B_{0,1} \) are rational numbers. In particular, for the ground state at \( k = 2 \) [15],

\[
B_0^{(2e)} = 1, \quad B_1^{(2e)} = \frac{5}{8}, \quad B_2^{(2e)} = -0.15766642946915,
\]

and \( k = 3 \) [17],

\[
B_0^{(3e)} = \frac{9}{8}, \quad B_1^{(3e)} = \frac{5965}{5832}, \quad B_2^{(3e)} = -0.40816616526115,
\]

respectively, where \( B_2 \) is the so-called electronic correlation energy. The expansion (2) for \( k = 2 \) has a finite radius of convergence, see e.g. [16].

In turn, at small \( Z \), following the qualitative prediction by Stillinger and Stillinger [17] and further quantitative studies performed in [18], [19], there exists a certain value \( Z_B > 0 \) for which the NRQED ground state energy with static nuclei is given by the Puiseux expansion in a certain fractional degrees

\[
E(Z) = E_B + \sum p_j (Z - Z_B)^j + \sum q_j (Z - Z_B)^{j/2} + \ldots,
\]

(3)

where \( E_B = E(Z_B) \). This expansion was derived numerically using highly accurate values of ground state energy in close vicinity of \( Z > Z_B \) obtained variationally. Three results should be mentioned in this respect for \( k = 2,3 \): (i) \( Z_B \) is not equal to the critical charge, \( Z_B \neq Z_c \), (ii) the square-root term \( (Z - Z_B)^{1/2} \) is absent, hence \( E(Z) \) at \( Z_B \) has square-root branch point with exponent 3/2 and it may define the radius of convergence of \( 1/Z \) expansion (2), and, (iii) seemingly the expansion (3) is convergent. In particular, for the ground state at \( k = 2 \) [19] the first coefficients in (3) are,

\[
Z_B^{(2e)} = 0.904854, \quad E_B^{(2e)} = -0.407924, \quad p_1^{(2e)} = -1.123470,
\]

\[
q_3^{(2e)} = -0.197785, \quad p_2^{(2e)} = -0.752842,
\]

(4)
while for $k = 3$ [19, 20],

$$Z_B^{(3e)} = 2.0090, \quad E_B^{(3e)} = -2.934281, \quad p_1^{(3e)} = -3.390348,$$

$$q_3^{(3e)} = -0.115425, \quad p_2^{(3e)} = -1.101372,$$

respectively.

IV. INTERPOLATION

Let us introduce a new variable,

$$\lambda^2 = Z - Z_B .$$

(6)

It can be easily verified that in $\lambda$ the expansion of $E_B^{(3e)}$ becomes the Taylor expansion while the expansion of $E_B^{(2e)}$ is the Laurent expansion with the fourth order pole at $\lambda = \infty$. The simplest interpolation matching these two expansion is given by a meromorphic function

$$- E_{N,4}(\lambda(Z)) = \frac{P_{N+4}(\lambda)}{Q_N(\lambda)} \equiv \text{gPade}(N + 4/N)_{n_0,n_\infty}(\lambda) ,$$

(7)

which we call the generalized Pade approximant. Here $P, Q$ are polynomials of degrees $N+4$ and $N$ respectively

$$P_{N+4} = \sum_{0}^{N+4} a_k \lambda^k, \quad Q_N = \sum_{0}^{N} b_k \lambda^k ,$$

with normalization $Q(0) = 1$, thus, $b_0 = 1$, the total number of free parameters in (7) is $(2N + 5)$. It is clear that $P(0) = E_B$, thus $a_0 = E_B$. The interpolation is made in two steps: (i) similarly to the Pade approximation theory some coefficients in (7) are found by reproducing exactly a certain number of terms ($n_0$) in the expansion at small $\lambda$ and also a number of terms ($n_\infty$) at large $\lambda$-expansion, (ii) remaining undefined coefficients are found by fitting the numerical data, which we consider as reliable, requiring the smallest $\chi^2$. It is a state-of-the-art to choose ($n_0$) and ($n_\infty$).

For both cases $k = 2, 3$ in (7) we choose $N = 4$, which is in a way a minimal number leading to six correct d.d. in fit of exact ground state energy. It is assumed to reproduce exactly the first four terms in the Laurent expansion $E_B^{(2e)}, n_\infty = 4,$ and the first three terms in the Puiseux expansion $E_B^{(3e)}, n_0 = 3.$ Thus, it leads us to the generalized Pade approximant 

$$\text{gPade}(8/4)(\lambda(Z))_{3,4} .$$

The remaining six free parameters in Approximant

$$\text{gPade}(8/4)(\lambda)_{3,4} = \frac{E_B + a_1 \lambda + a_2 \lambda^2 + a_3 \lambda^3 + a_4 \lambda^4 + a_5 \lambda^5 + a_6 \lambda^6 + a_7 \lambda^7 + a_8 \lambda^8}{1 + b_1 \lambda + b_2 \lambda^2 + b_3 \lambda^3 + b_4 \lambda^4} ,$$

(8)
are found making fit. As for \( k = 2 \), data from Table I, obtained by Nakashima-Nakatsuji [2] and via the Lagrange mesh method [11], are fitted. While for \( k = 3 \) data from Table II obtained by Yan et al [7] are used. In practice, in order to construct the Approximant \( g_{\text{Pade}}(\frac{8}{4})(\lambda)_{3,4} \), we need to know the energies for six values of \( Z \) only. In Table III the optimal parameters in \( g_{\text{Pade}}(\frac{8}{4})(\lambda)_{3,4} \) for \( k = 2, 3 \) are presented. Let us emphasize that in both cases roots of denominator in \( g_{\text{Pade}}(\frac{8}{4})(\lambda)_{3,4} \) form complex-conjugated pairs with negative (or almost negative) real parts!

It is interesting to find from \( g_{\text{Pade}}(\frac{8}{4})(\lambda(Z))_{3,4} \) the coefficient in front of \( \lambda^3 \) in the expansion [3],

\[
q_{3,\text{fit}}^{(2e)} = -0.192510, \quad q_{3,\text{fit}}^{(3e)} = -0.09126923.
\]

They are quite close to accurate ones in [4], [5]. In general, expanding the function \( g_{\text{Pade}}(\frac{8}{4})(\lambda(Z)) \) with optimal parameters, see Table III, around \( Z = Z_B \) we get

\[
E^{(2e)}(Z) \simeq -0.40792398 - 1.1234699(Z - Z_B) - 0.1925102(Z - Z_B)^{3/2} - 0.8442238(Z - Z_B)^2 + 0.5063843(Z - Z_B)^{5/2} + \ldots,
\]

\[
E^{(3e)}(Z) \simeq -2.93428064 - 3.3903478(Z - Z_B) - 0.0912692(Z - Z_B)^{3/2} - 1.2546454(Z - Z_B)^2 + 0.2957621(Z - Z_B)^{5/2} \ldots,
\]

and compare with (4)-(5).

In Table I and II the results of interpolations for \( k = 2 \) and \( k = 3 \) are presented, respectively. In general, difference in energy occurs systematically in seventh or, sometimes, in eighth decimal for all range of \( Z \) studied. However, at \( k = 3 \) and \( Z > 14 \) the difference occurs (non-systematically) at one-two portions in sixth decimal. We do not have an explanation of this phenomenon. It might be an indication to an inconsistency of the variational energies and \( 1/Z \)-expansion found in [7]. From other side, not less than 7-8 significant digits in energies are reproduced exactly in the whole range of physically relevant \( Z \) presented in Tables I,II.

The analysis of relativistic and QED corrections for two-electron system performed for \( Z = 2-12 \) in [6, 12], see Table I, shows that they are small or comparable with respect to the mass polarization effects for \( Z = 1, 2, 3 \) and then become larger (and dominant) for \( Z > 3 \). Note that in general the relativistic and QED corrections systematically are of opposite sign.
TABLE I: Helium-like ions, the 1s$^2$ 1S state energy (ground state): for $Z = 1 \ldots 10$ (note: for infinite nuclear mass case it coincides with $1/Z$ expansion, see 3, in all displayed digits) and 4 (note: for finite nuclear mass case it coincides with Lagrange mesh results in all displayed digits, see text); for $Z = 11, 12$ 3 (for infinite mass) and Lagrange mesh results (present calculation, for finite nuclear mass); for $Z = 20, 30, 40, 50$ the Lagrange mesh results presented for both infinite and finite nuclear mass cases (present calculation); for infinite nuclear mass case it is compared with fit 7 (6th column; for parameters see Table III). For infinite mass case (2nd column), underlined digits remain unchanged due to finite-mass effects (after its rounding), digits given by bold reproduced by fit (7) (after rounding); in column 5 the sum of leading relativistic and QED corrections from 12 given, † the estimate 14, ( )* the result of polynomial extrapolation from $Z \in [2 - 12]$, see text. Last column represents the variational energies obtained with Ansatz 10 (see text)

Similar analysis of relativistic and QED corrections of three-electron system, performed for $Z = 3, 4$ in [8], shows that they contribute to the 1st significant digit in the energy difference between infinite and finite mass cases. For both cases of 2- and 3-electron systems the question about the order of relativistic and QED effects for large $Z$ needs to be investigated. We can only guess that for both systems the domain of applicability of static approximation for any $Z$ is limited by 3 s.d. in the ground state energy.

Interestingly, the simplest interpolation gPade$(4/0)_{2,1}$ ($\lambda(Z)$) (which is in fact the termi-
nated Puiseux expansion) with two fitted parameters,

\[ g_{\text{Pade}}(4/0)(\lambda)_{2,1} = E_B + a_2\lambda^2 + a_3\lambda^3 + a_4\lambda^4, \quad (9) \]

can reproduce 3-4 s.d. in ground state energy in static approximation for both systems in physics range of \( Z \leq 20 \), see Tables I,II with parameters taken from Table IV. These digits remain unchanged if finite-mass effects are taken into account. It implies the exact reproduction the domain of applicability of non-relativistic QED in static approximation for the ground state energy!

V. VARIATIONAL ENERGIES VS EXACT ONES

In 1929 E Hylleraas in his celebrated paper [1] had proposed to use for Helium type system \((2e; Z)\) the exponentially correlated trial function in the form of symmetrized product of three (modified by screening) Coulomb Orbitals,

\[ \Psi_0 = (1 + P_{12}) e^{-\alpha_1 Z r_1 - \alpha_2 Z r_2 + \beta r_{12}}, \quad (10) \]

with three variational parameters \( \alpha_{1,2}, \beta \), here \( P_{12} \) is permutation operator \( 1 \leftrightarrow 2 \). Many years after, Calais-Löwdin [22] demonstrated that all integrals involved to the variational calculations are intrinsically 3-dimensional in \( r_1, r_2, r_{12} \) variables (for discussion see [23]) and they can be evaluated analytically. Eventually, the variational energy is the rational function of parameters \( \alpha_{1,2}, \beta \). Hence, the procedure of minimization of the variational energy is essentially algebraic and can be easily performed. On Fig.2 the optimal parameters vs the nuclear charge \( Z \) are presented - they are smooth, slow-changing functions. At \( Z \) tends to infinity the \( \alpha \)-parameters approach slowly to one, \( \alpha_{1,2} \to 1 \), and \( \beta \to 1/2 \), while asymptotically, at \( Z \to \infty \) the function \( (10) \) (in appropriate variables) becomes the product of two ground state Coulomb orbitals. Making concrete calculations for different values of \( Z \) one can see that the variational energy coincides systematically with exact non-relativistic QED energies in 4-3 s.d. while at \( Z = 2 - 12 \), in fact, it differs in the 3rd d.d.! Thus, the simple trial function \( (10) \) describes the energy in the domain of applicability of non-relativistic QED in static approximation. Overall quality of the trial function \( (10) \) can be "measured" by how accurate it reproduces the (normalized) cusp parameters (the residues in Coulomb singularities) by \( (\alpha_1 + \alpha_2)/2 \) and \( \beta/2 \), respectively, see Fig.2. If at small \( Z \) the difference is of order 10%, then it reduces to 0.01% at \( Z = 12 \) and tends to zero at large \( Z \).
FIG. 2: Variational Parameters vs the nuclear charge $Z$ for the two-electron system using the trial function $\psi = (e^{-\alpha_1 Z r_1 - \alpha_2 Z r_2} + e^{-\alpha_2 Z r_1 - \alpha_1 Z r_2}) e^{\beta r_{12}}$, see (10), assuming $\alpha_1 \geq \alpha_2$.

Taking $\Psi_0$ with optimal parameters as the zero approximation in Non-Linearization Procedure, where $V_0 = \frac{\Delta \Psi_0}{\Psi_0}$, one can develop the convergent perturbation theory w.r.t. difference with original potential $V$, see (11), and $V_0$, see for review [24]. The sum of the first two terms $(E_0 + E_1)$ coincides with the variational energy with trial function $\Psi_0$ as entry. It is evident that the next correction $E_2$ changes the 3rd decimal digit in the variational energy. In principle, this procedure allows us to calculate quantal corrections to non-relativistic QED with static nuclei. These corrections, of course, can be calculated using variational method taking more complicated trial functions than (10), in particular, their linear superpositions, see [25].

For Lithium-type system (3e; $Z$) let us take a variational trial function (for the total spin $1/2$) in the form

$$\psi(\vec{r}_1, \vec{r}_2, \vec{r}_3; \chi) = \mathcal{A} [\phi(\vec{r}_1, \vec{r}_2, \vec{r}_3) \chi] ,$$

(11)

where $\chi$ is the spin eigenfunction, $\mathcal{A}$ is the three-particle antisymmetrizer

$$\mathcal{A} = 1 - P_{12} - P_{13} - P_{23} + P_{231} + P_{312} ,$$

(12)

and $\phi(\vec{r}_1, \vec{r}_2, \vec{r}_3)$ is the explicitly correlated orbital function

$$\phi(\vec{r}_1, \vec{r}_2, \vec{r}_3; \alpha_i, \alpha_{ij}) = e^{-\alpha_1 Z r_1 - \alpha_2 Z r_2 - \alpha_3 Z r_3} e^{\beta_{12} r_{12} + \beta_{13} r_{13} + \beta_{23} r_{23}} ,$$

(13)
FIG. 3: (Normalized) variational cusp parameters (the residues at Coulomb singularities in (11)): electron-nucleus cusp($r_1$) = cusp($r_2$) and electron-electron cusp($r_{12}$) vs the nuclear charge $Z$ for the two-electron system using the trial function (10); their exact values are 1 and 1/4, respectively.

see e.g. [26], where $\alpha_i$ and $\beta_{ij}$ are non-linear variational parameters. Here, $P_{ij}$ represents the permutation $i \leftrightarrow j$, and $P_{ijk}$ stands for the permutation of (123) into ($ijk$). In total, (11) contains six all-non-linear variational parameters. The function (11) is a properly anti-symmetrized product of (1s) (modified by screening) Coulomb orbitals and the exponential correlation factors $\sim \exp (\beta_{ij} r_{ij})$.

There are two linearly independent spin 1/2 functions of mixed symmetry:

$$\chi_1 = \frac{1}{\sqrt{2}} [\alpha(1)\beta(2) - \beta(1)\alpha(2)]\alpha(3)$$  \hspace{2cm} (14)

and

$$\chi_2 = \frac{1}{\sqrt{6}} [2\alpha(1)\alpha(2)\beta(3) - \beta(1)\alpha(2)\alpha(3) - \alpha(1)\beta(2)\alpha(3)] ,$$ \hspace{2cm} (15)

where $\alpha(i)$, $\beta(i)$ are spin up, spin down eigenfunctions of $i$-th electron, respectively. For simplicity, the spin function $\chi$ in (11) is chosen as

$$\chi = \chi_1 + c\chi_2 ,$$ \hspace{2cm} (16)

(see [26]), where $c$ is a variational parameter. It implies that the coordinate (orbital) functions in front of $\chi_{1,2}$ are the same. Eventually, the trial function is a linear superposition of twelve terms, it contains 7 free parameters.
In variational integrals the integrations over three dimensions describing overall orientation are easily performed, and we end up with six-dimensional integrals over the relative coordinates \((r_1, r_2, r_3, r_{12}, r_{13}, r_{23})\) (for discussion see [23]). Although it is in principle possible to reduce these integrals analytically to one-dimensional integration: to expressions involving dilogarithm functions, as first shown by Fromm and Hill [27], the analytic properties of the resulting expressions were found to be unreasonably complicated (see Harris [28]). For that reason, the primary method we used was direct six-dimensional numerical integration.

The results of variational calculations are shown in Table II last column for \(Z = 3 - 14\). Variational parameters \(vs\ Z\) are presented in Fig. 4; they are smooth, slow-changing functions. Parameter \(c\) being small at \(Z = 3, 4, \ldots\) grows with \(Z\) reaching sufficiently large value 0.536 at \(Z = 14\). It indicates the importance of the contribution emerging from the second spin function \(\chi_2\) \([15]\) for large \(Z\). It might be considered as the indication that the condition \([16]\) should be relaxed and the orbital functions should be different,

\[
\phi \chi = \phi(\vec{r}_1, \vec{r}_2, \vec{r}_3; \alpha^{(1)}_i, \alpha^{(1)}_{ij}) \chi_1 + c \phi(\vec{r}_1, \vec{r}_2, \vec{r}_3; \alpha^{(2)}_i, \alpha^{(2)}_{ij}) \chi_2 ,
\]

see \([11]\), where \(\phi\)'s are given by \([13]\). This trial function depends on 13 free parameters. Immediate calculation shows a significant improvement in variational energy even for \(Z = 3\):

\(-7.471\) a.u. vs \(-7.455\) a.u., see Table II [29].

It is easy to check variational energies reproduce not less than 99.9\% of the exact non-relativistic energies, hence, the non-relativistic QED energies in static approximation. Relaxing condition \([16]\), thus, assuming that the orbital functions are different but both of the type \([13]\) should increase accuracy. Note that the overall quality of the trial function \([11]\)-\([16]\) is reflected in accurate reproduction of electron-nuclear cusp parameter 2.953 [26] at \(Z = 3\) while the exact one is equal to 3.
FIG. 4: Variational Parameters vs the nuclear charge $Z$ for the three-electron system using the trial function (11)-(13): $\alpha_{1,2,3}$ (a), $\alpha_{12,23,13}$ (b) and $c$ (c).
Conclusions

Concluding we state that a straightforward interpolation between small and large $Z$ in a suitable variable $\lambda\left(\frac{\sqrt{Z}}{Z} - \frac{Z}{Z_B}\right)$ based on meromorphic function $\text{gPade}(8/4)_{3,4}(\lambda(Z))$ leads to accurate description of 7-8 s.d. of the ground state energy of the Helium-like and Lithium-like ions in non-relativistic QED in static approximation, in $1s^2\,1S$ and $1s^2\,2s\,2S$ states, respectively, for $Z \leq 20$. It seems natural to assume that the similar interpolations have to provide reasonable accuracies for the energies of excited states of above systems and even for other many-electron atomic systems. It will be presented elsewhere [20].

Note that similar interpolation works extremely well for simple diatomic molecules $\text{H}_2^+$, $\text{H}_2$ and HeH matching perturbation theory at small internuclear distances and multipole expansion with instanton-type, exponentially-small contributions at large distances (as for the first two systems). It provides 4-5-6 s.d. at potential curves at all internuclear distances and 6 s.d. for energies of rovibrational states [21].

Making detailed analysis of mass corrections, QED and relativistic effects for the ground state energy of 2- and 3-electron ions for $Z \leq 20$ we are able to localize the domain of applicability of non-relativistic QED in static approximation. This domain is limited by 3-4 s.d. in the ground state energy. Surprisingly, this domain is described by the 4th degree polynomial in variable $\lambda = \sqrt{Z - Z_B}$, where $Z_B$ is the 2nd critical charge [19].

Interestingly, making a generalization of the Slater determinant method by including inter-electronic correlations in exponential form, thus, taking a trial function in the form of (anti)-symmetrized product of three (six) modified-by-screening Coulomb orbitals for two-(three-) electron system, respectively, allows us to reproduce $\sim 99.9\%$ of the ground state energy from small $Z$ up to $Z = 20$. Of course, it requires a careful minimization with respect to screening parameters. In other words, the variational energy, in fact, coincides with exact energy in domain of applicability of non-relativistic QED with infinitely-heavy nuclei. This observation hints that such a generalized Slater determinant method might be successful for other atomic and molecular systems. It will be checked elsewhere.

[30] Note that for \(Z = 2\) the ground state energy difference for infinite and finite nuclear mass (full geometry) cases, see below Table I, coincides with the sum of the first three orders in mass corrections in 11 d.d. found in \[6\]

[31] Since we were unable to find in literature the direct calculation of relativistic and QED corrections for \(Z = 1\), we used polynomial interpolation \(a_0 + a_1Z + a_2Z^2 + a_3Z^3 + a_4Z^4\)

[32] When this work was completed following our request the SPb University group (A.V. Malyshhev, I.I. Tupitsyn, and V.M. Shabaev) \[14\] made estimates of both QED and relativistic corrections for 3-electron ions, see Table II. They turned to be consistent with ones found in \[8\] for \(Z = 3, 4.\)
