A new type of quadrature is developed. The Gauss quadrature, for a given measure, finds optimal values of a function’s argument (nodes) and the corresponding weights. In contrast, the Lebesgue quadrature developed in this paper, finds optimal values of function (value–nodes) and the corresponding weights. The Gauss quadrature groups sums by function argument; it can be viewed as a \( n \)–point discrete measure, producing the Riemann integral. The Lebesgue quadrature groups sums by function value; it can be viewed as a \( n \)–point discrete distribution, producing the Lebesgue integral. Mathematically, the problem is reduced to a generalized eigenvalue problem: Lebesgue quadrature value–nodes are the eigenvalues and the corresponding weights are the square of the averaged eigenvectors. A numerical estimation of an integral as the Lebesgue integral is especially advantageous when analyzing irregular and stochastic processes. The approach separates the outcome (value–nodes) and the probability of the outcome (weight). For this reason, it is especially well–suited for the study of non–Gaussian processes. The software implementing the theory is available from the authors.
I. INTRODUCTION

The Gauss quadrature is typically considered as “an integral calculation tool”. However, the quadrature itself can be considered as a discrete measure\(^\text{[1]}\). The major practical drawback of Gauss–type quadratures is that they, like Riemann integral, are based on finding nodes in function argument space. A very attractive idea is to build a quadrature with the nodes in function value space, Lebesgue quadrature. As with the Lebesgue integral, such a quadrature can be applied to integration of irregular functions and interpolating sampled measure by the discrete Lebesgue integral. When implemented numerically such an approach can give a completely new look toward relaxation type process analysis. This is the goal of this paper.

II. MEASURE

Consider a measure \(d\mu\), a basis \(Q_k(x)\), and a function to integrate \(f(x)\). An example of the measure can be: Chebyshev with \([-1:1]\) support \(d\mu = dx/\sqrt{1-x^2}\), Laguerre with \([0:\infty]\) support \(d\mu = dx \exp(-x)\), experimental data sample \((f_l, x_l)\) of \(l = 1 \ldots M\) points (discrete \(M\)-point measure), etc. In this paper \(Q_k(x)\) basis is a polynomial of degree \(k\), e.g. \(x^k\) or some orthogonal polynomials basis, the results are invariant with respect to basis choice, \(Q_k(x) = x^k\) and \(Q_k = T_k(x)\) give identical results, but numerical stability can be drastically different\(\text{[2, 3]}\). Introduce Paul Dirac quantum mechanic bra–ket notation\(\text{[4]}\): \(\langle \mid \) and \(| \rangle\):  

\[
\langle Q_k f \rangle = \int d\mu Q_k(x) f(t) \tag{1}
\]
\[
\langle Q_j \mid f \mid Q_k \rangle = \int d\mu Q_j(x) Q_k(x) f(t) \tag{2}
\]

The problem we study in this paper is to estimate Lebesgue integral\(\text{[5]}\) by optimal \(n\)-point discrete measure.  

\[
\langle f \rangle = \int f d\mu \tag{3}
\]

We are going to apply the technique originally developed in Refs. \(\text{[3, 6, 7]}\), the main idea is to consider not a traditional interpolation of observable \(f\) as a linear superposition of basis
functions:

$$f \approx \sum_{k=0}^{n-1} \beta_k Q_k(x)$$  \hspace{1cm} (4)

but instead to introduce a wavefunction $\psi(x)$ as a linear superposition of basis functions, then to average $f(x)$ with $\psi^2(x)d\mu$ weight:

$$\psi(x) = \sum_{j=0}^{n-1} \alpha_j Q_j(x)$$  \hspace{1cm} (5)

$$f \psi = \langle \psi \mid f \mid \psi \rangle = \frac{\sum_{j,k=0}^{n-1} \alpha_j \langle Q_j \mid f \mid Q_k \rangle \alpha_k}{\sum_{j,k=0}^{n-1} \alpha_j \langle Q_j \mid Q_k \rangle \alpha_k}$$  \hspace{1cm} (6)

With positively defined matrix $\langle Q_j \mid Q_k \rangle$ generalized eigenvalue problem:

$$\sum_{k=0}^{n-1} \langle Q_j \mid f \mid Q_k \rangle \alpha_k^{[i]} = \lambda^{[i]} \sum_{k=0}^{n-1} \langle Q_j \mid Q_k \rangle \alpha_k^{[i]}$$  \hspace{1cm} (7)

$$\psi^{[i]}(x) = \sum_{k=0}^{n-1} \alpha_k^{[i]} Q_k(x)$$  \hspace{1cm} (8)

has a unique solution. Found eigenfunctions to be normalized as $\langle \psi^{[i]} \mid \psi^{[j]} \rangle = \delta_{ij}$. Then $\langle \psi^{[i]} \mid f \mid \psi^{[j]} \rangle = \lambda^{[i]} \delta_{ij}$; $\sum_{l,m=0}^{n-1} \alpha_l^{[i]} \langle Q_l \mid Q_m \rangle \alpha_m^{[j]} = \delta_{ij}$; and $\lambda^{[i]} = \left\langle \left( \psi^{[i]} \right)^2 f \right\rangle / \left\langle \left( \psi^{[i]} \right)^2 \right\rangle$.

A. The Gauss quadrature

The $n$-point Gauss quadrature $(x_i, w_i); i = 0 \ldots n - 1$:

$$\int f(x)d\mu = \langle f \rangle \approx \sum_{i=0}^{n-1} f(x_i)w_i$$  \hspace{1cm} (9)

on the measure $d\mu$ is integration formula [9] that is exact if $f(x)$ is a polynomial of degree $2n - 1$ or less, in other cases it can be considered as an approximation of the measure $d\mu$ by discrete $n$–point measure $(x_i, w_i)$. A question about an efficient numerical approach to $(x_i, w_i)$ calculation is a subject of extensive work [1, 8]. In our recent work [3] we established, that the most practical approach to obtain $(x_i, w_i)$ for arbitrary measure (often available only through data sample) is to put $f = x$ in Eq. [7] and solve generalized eigenvalue
problem:
\[
\sum_{k=0}^{n-1} \langle Q_j \mid x \mid Q_k \rangle \alpha_k^{[i]} = \lambda^{[i]} \sum_{k=0}^{n-1} \langle Q_j \mid Q_k \rangle \alpha_k^{[i]} \quad (10)
\]
\[
x_i = \lambda^{[i]} \quad (11)
\]
\[
w_i = \frac{1}{(\psi^{[i]}(x_i))^2} \quad (12)
\]

The \(n\)-th order orthogonal polynomial relatively the measure \(d\mu\) is equal to the \(\pi_n(x) = \text{const} \cdot (x - x_i)\psi^{[i]}(x) = \text{const} \prod_{j=0}^{n-1}(x - x_j)\). The Gauss quadrature nodes \(x_i\) are \(\text{eigenvalues}, \) the weights are equal to inverse square of the eigenfunction at \(x = x_i \) (the eigenfunctions are normalized as \(\langle \psi^{[i]} \mid \psi^{[i]} \rangle = \sum_{j,k=0}^{n-1} \alpha_j^{[i]} \langle Q_j \mid Q_k \rangle \alpha_k^{[i]} = 1\)). The \(\text{(10)}\) is exactly threediagonal Jacobi matrix eigenvalue problem (see Ref. [9] and references therein for a review), but written in the basis of \(Q_k(x)\), not in the basis of \(\pi_k(x)\), as typically studied. Particularly, this make it easy to obtain numerically three term recurrence coefficients \(a_k\) and \(b_k\) \((x\pi_k = a_{k+1}\pi_{k+1} + b_k\pi_k + a_k\pi_{k-1})\) from sampled data using the moments \(\langle Q_m \rangle ; m = 0 \ldots 2n - 1\): obtain (in \(Q_k(x)\) basis) orthogonal polynomials \(\pi_k \); \(k = 0 \ldots n\), then calculate \(a_k\) and \(b_k\), see the method \text{getAB()}\) of provided software. An ability to use Chebyshev or Legendre basis as \(Q_k(x)\) allows to calculate \(a_k\) and \(b_k\) to a very high order (hundreds).

The Gauss quadrature \(\text{(9)}\) can be considered as a Riemann integral formula, its nodes \(x_i\) select optimal positions of function arguments, they are \(\|x\|\) operator eigenvalues \(\text{(10)}\), this integration formula assumes that \(f(x_i)\) exist and can be calculated. As with any Riemann integral, it requires \(f(x)\) to be sufficiently regular for the integral to exist.

**B. The Lebesgue quadrature**

\[\text{Riemann integral}\] sums the measure of all \([x : x + dx]\) intervals. \[\text{Lebesgue integral}\] sums the measure of all \(x\) intervals for which the value of function is in the interval \([f : f + df]\), see demonstrating Fig. 1 of Ref. [7]. Consider \(n\)-point Lebesgue quadrature \((f_i, w_i)\); \(i = 0 \ldots n - 1\):
\[
\int f(x) d\mu = \langle f \rangle \approx \sum_{i=0}^{n-1} f_i w_i \quad (13)
\]
Now quadrature nodes \(f_i\) are in function value space, not in function argument space as in \(\text{(9)}\). We will call them \text{value–nodes}. To obtain the value–nodes and weights of the
Lebesgue quadrature for the measure $d\mu$ and function $f$ consider arbitrary polynomial $P(x)$ of degree $n - 1$ or less and expand it on (7) eigenfunctions:

$$P(x) = \sum_{i=0}^{n-1} \langle P \mid \psi[i] \rangle \psi[i](x)$$  \hspace{1cm} (14)

Taking into account that $\langle P \mid f \mid \psi[i] \rangle = \lambda[i] \langle P \mid \psi[i] \rangle$ the expression for $\langle P \mid f \mid S \rangle$ can be written (here $P(x)$ and $S(x)$ are arbitrary polynomials of degree $n - 1$ or less):

$$\langle P \mid f \mid S \rangle = \sum_{i=0}^{n-1} \lambda[i] \langle P \mid \psi[i] \rangle \langle S \mid \psi[i] \rangle$$  \hspace{1cm} (15)

$$\langle f \rangle = \sum_{i=0}^{n-1} \lambda[i] \langle \psi[i] \rangle^2$$  \hspace{1cm} (16)

The (16) (the case $P = S = 1$) is eigenvalues averaged with the weights $\langle \psi[i] \rangle^2$ (note that $\langle (\psi[i])^2 \rangle = 1$). The (16) give Lebesgue quadrature value–nodes and weights:

$$f_i = \lambda[i]$$  \hspace{1cm} (17)

$$w_i = \langle \psi[i] \rangle^2$$  \hspace{1cm} (18)

The Lebesgue quadrature (13) can be considered as a Lebesgue integral interpolating formula, by $n$–point discrete measure, the value–nodes $f_i$ select optimal positions of function values, they are $\|f\|$ operator eigenvalues (7), the weight $w_i$ is the measure corresponding to the value $f_i$. Note, that weights (18) give $\langle 1 \rangle = \sum_{i=0}^{n-1} w_i$, same as for (12) Gauss weights. As with the Gauss quadrature (9) the Lebesgue quadrature (13) is exact for some class of functions.

**Theorem 1.** If $n$–point Lebesgue quadrature (13) is constructed for a measure $d\mu$ and a function $f(x)$, then any integral $\langle P(x)f(x) \rangle$, where $P(x)$ is a polynomial of degree $2n - 2$ or less, can be evaluated from it exactly.

**Proof.** When $P(x)$ is of degree $n - 1$ or less, then apply (15) with $S = 1$. For a degree above $n - 1$ expand $P(x) = \sum_{j,k=0}^{n-1} Q_j(x)M_{jk}Q_k(x)$. The matrix $M_{jk}$ is non–unique, but always exists and can be obtained e.g. by synthetic division $P(x) = Q_{n-1}(x)q(x) + r(x)$, or using density matrix approach of Appendix A. The integral $\langle fP(x) \rangle = \sum_{j,k=0}^{n-1} \langle Q_j \mid f \mid Q_k \rangle M_{jk}$
then can be evaluated using formula:

\[
\langle fP(x) \rangle = \sum_{i=0}^{n-1} \lambda^{[i]} w^{(P)}_i = \sum_{i=0}^{n-1} \lambda^{[i]} \left\langle \psi^{[i]} \left| \hat{P} \right| \psi^{[i]} \right\rangle \tag{19}
\]

\[
w^{(P)}_i = \sum_{j,k=0}^{n-1} \left\langle Q_j \left| \psi^{[i]} \right\rangle M_{jk} \left\langle \psi^{[i]} \right| Q_k \right\rangle = \left\langle \psi^{[i]} \left| \hat{P} \right| \psi^{[i]} \right\rangle \tag{20}
\]

The formula (19) has the same eigenvalues \( \lambda^{[i]} \), but they are now averaged with the weights \( w^{(P)}_i \), that are not necessary positive as in (18), note that \( \langle P(x) \rangle = \sum_{i=0}^{n-1} w^{(P)}_i \).

**Remark.** The Gauss quadrature can be considered as a special case of the Lebesgue quadrature. If one put \( f = x \), then \( n \)-point Lebesgue quadrature, that gives exact answer for any integral \( \langle fP(x) \rangle \) with a polynomial \( P(x) \) of a degree \( 2n - 2 \) or less, is reduced to a quadrature that is exact for \( \langle xP(x) \rangle \), i.e. to the Gauss quadrature with exact \( \langle \hat{P}(x) \rangle \) answer for a polynomial \( \hat{P}(x) \) of a degree \( 2n - 1 \) or less. When \( f = x \) Lebesgue quadrature value–nodes are equal to the Gauss nodes. The most remarkable feature of Lebesgue quadrature is that it directly estimate the distribution of \( f \): each \( w_i \) from (18) is the measure of \( f(x) \approx f_i \) sets.

Theorem 1 gives an algorithm for \( \langle fP(x) \rangle \) integral calculation: use the same value–nodes \( f_i \) from (17), but the weights are now from (20). The Lebesgue quadrature allows to obtain the value of any \( \langle fP(x) \rangle \) integral, adjusting only the weights, value–nodes remain the same, what give a range of opportunities in applications.

One more question arise about most convenient way to store and apply a quadrature. As both the Gauss and the Lebesgue quadratures are obtained from generalized eigenvalue problem \( n \) pairs \((\lambda^{[i]}, \psi^{[i]})\) completely define the quadrature. For the Gauss quadrature \( f(x) = x \), the eigenvalues are the nodes, the eigenvectors are Lagrange interpolating polynomial built on \( x_i \) roots of orthogonal polynomial \( \pi_n(x) \) degree \( n \) relatively the measure \( d\mu: \psi^{[i]}(x) = \text{const} \cdot \pi_n(x)/(x - x_i) \). For \( f(x) = x \) eigenvectors \( \left\langle x^n \right| \psi^{[i]} \right\rangle = x_i^{n} \left\langle \psi^{[i]} \right\rangle \), the (20) is then \( w^{(P)}_i = P(x_i)^2 \left\langle \psi^{[i]} \right\rangle \), hence it is more convenient to store Gauss quadrature as \((x_i, w_i)\) pairs rather than as \((x_i, \psi^{[i]})\) pairs. For Lebesgue quadrature \( w^{(P)}_i \) dependence (20) on \( P(x) \) is not that simple, it requires an access to eigenvectors \( \psi^{[i]} \) to calculate, for this reason it is more convenient to store Lebesgue quadrature as \((f_i, \psi^{[i]})\) pairs, rather than as \((f_i, w_i)\) pairs. Specific form of quadrature storage is determined by application, in any case all the results are obtained from defining the quadrature \((\lambda^{[i]}, \psi^{[i]})\), unique solution of (7) problem.
C. Numerical Estimation Of Radon–Nikodym Derivative

Radon–Nikodym derivative is typically considered as probability density \( \frac{dv}{d\mu} \) relatively two Lebesgue measures \( dv \) and \( d\mu \). Consider \( f = \frac{dv}{d\mu} \), then (7) is generalized eigenvalue problem with \( \langle Q_j | \frac{dv}{d\mu} | Q_j \rangle \) and \( \langle Q_j | Q_j \rangle \) matrices (basis functions product \( Q_j Q_k \) averaged with respect to the measure \( dv \) and \( d\mu \) respectively). If at least one of these matrices is positively defined then (7) has a unique solution.

**Theorem 2.** The eigenvalues \( \lambda[i] \) \( i = 0 \ldots n - 1 \) are \( \frac{dv}{d\mu} \) Radon–Nikodym derivative extremums in the basis of (7).

**Proof.** Consider first variation of \( \langle \psi | \frac{dv}{d\mu} | \psi \rangle \) in the state \( \tilde{\psi}(x) = \psi(x) + \delta \psi \), then

\[
\frac{\langle \psi + \delta \psi | \frac{dv}{d\mu} | \psi + \delta \psi \rangle}{\langle \psi + \delta \psi | \psi + \delta \psi \rangle} = \left( \frac{dv}{d\mu} \right) \langle \psi | \psi \rangle + 2 \left[ \langle \psi | \frac{dv}{d\mu} | \delta \psi \rangle - \langle \psi | \frac{dv}{d\mu} \rangle \langle \psi | \delta \psi \rangle \right] + \ldots
\]

when \( |\psi\rangle \) is (7) eigenvector, then the first variation (21) (linear in \( \delta \psi \)) is zero because of \( \left| \frac{dv}{d\mu} \right| \psi\rangle = \lambda |\psi\rangle \) relation for (7) eigenvectors. \( \square \)

**Remark.** If \( \delta \psi \) does not belong to the original basis space of (7) problem, then extremal property may no longer hold.

Other estimates of Radon–Nikodym derivative can be easily expressed in terms of (7) eigenvectors. For example Nevai operator \([10]\) is equal to eigenvalues \( \lambda[i] \) averaged with \( (\psi[i](x))^2 \) weights:

\[
\frac{dv}{d\mu}(x) = \frac{\sum_{i=0}^{n-1} \lambda[i] (\psi[i](x))^2}{\sum_{i=0}^{n-1} (\psi[i](x))^2}
\]

Other estimates, such as \([3, 11]\), can also be expressed in a form of \( \lambda[i] \) averaged, but with the other weights, different estimators converge to each other when \( n \to \infty \). A distinguishing feature of Radon–Nikodym derivative estimate as (7) spectrum is that it is not linked to the states localized in \( x \)-space (such as (22)), but is linked to extremal states of Radon–Nikodym derivative \( dv/d\mu \) instead. The \( \psi[i](x) \) in (22) is \( \psi[i](x) = \sum_{k=0}^{n-1} \alpha[i]_k Q_k(x) \), i.e. it can be considered as the distribution of \( x \) with a single support point: the moments are
equal to $Q_k(x)$. Now assume $Q_k(x)$ correspond to some actual distribution of $x$ and $q_k$ are the moments of this distribution. Then $\frac{d\nu}{d\mu}(x)$ is:

$$\frac{d\nu}{d\mu}(x) = \frac{\sum_{i=0}^{n-1} \lambda[i] \left( \sum_{k=0}^{n-1} \alpha_k^{[i]} q_k \right)^2}{\sum_{i=0}^{n-1} \left[ \sum_{k=0}^{n-1} \alpha_k^{[i]} q_k \right]^2}$$

The (23) is averaged eigenvalues $\lambda[i]$ with positive weights, it coincide with $x$–localized (22) for $q_k = Q_k(x)$, but (23) is much more general, it allows to obtain Radon–Nikodym derivative for non–localized states. The (23) give the value of Radon–Nikodym derivative for a distribution with given $q_k$ moments. Such “distributed” states naturally arise, for example, in distribution regression problem\[12, 13\], where a bag of $x$–observations is mapped to a single $f$–observation. There is one more generalization, considered in\[7, 14\]: density matrix mixed states, that cannot be reduced to a pure state of a $\psi(x)$, we are going to discuss this generalization elsewhere in details, see Appendix A for an example. Our approach can estimate both: the measure (as Lebesgue quadrature) and two measures density (as Radon–Nikodym derivative), together with available numerical implementation, this make the approach extremely attractive to a number of practical problems, for example to joint probability estimation\[15\].

III. NUMERICAL ESTIMATION

The ($\lambda[i], \psi[i]$) pairs of (7) problem (for the Gauss with $\langle Q_j \mid x \mid Q_k \rangle$ and $\langle Q_j \mid Q_k \rangle$ matrices, and for the Lebesgue with $\langle Q_j \mid f \mid Q_k \rangle$ and $\langle Q_j \mid Q_k \rangle$ matrices) are required to calculate a quadrature. A question arise about numerically most stable and efficient way of doing calculations. Any $\langle Q_j \mid f \mid Q_k \rangle$ matrix ($j, k = 0 \ldots n - 1$) can be calculated from $\langle Q_m f \rangle$ moments ($m = 0 \ldots 2n - 2$) using multiplication operator:

$$Q_j Q_k = \sum_{m=0}^{j+k} c_{j,k}^{m} Q_m$$

The value of $c_{j,k}^{m}$ is analytically known (see numerical implementation in Appendix A of Ref. [3]) for four numerically stable $Q_k(x)$ bases: Chebyshev, Legendre, Hermite, Laguerre (all the bases give mathematically identical results, because (7) is invariant with respect to arbitrary
non–degenerated linear transform of the basis, but numerical stability of calculations depend greatly on basis choice).

Once the matrices $\langle Q_j \mid f \mid Q_k \rangle$ and $\langle Q_j \mid Q_k \rangle$ are calculated the (11) can be solved using e.g. generalized eigenvalue problem subroutines from Lapack[10]. With a good basis choice numerically stable results can be obtained for 2D problem[17] with up to $100 \times 100$ elements in basis, i.e. for 10,000 basis functions.

In Appendix A & B of Ref. [3] the description of API and java implementation of polynomial operations in Chebyshev, Legendre, HermiteE, Laguerre, Shifted Legendre, Monomials bases is presented. The code is available from[18], file code_polynomials_quadratures.zip. See the program com/polytechnik/algorithms/ExampleRadonNikodym_F_and_DF.java for usage example, this program reads $(x_i, f_i)$ pairs from tab–separated file, then calculate (17) value–nodes and (18) weights for Lebesgue integral of the functions: $f(x)$, $df/dx$ with the measure $d\mu = dx$, and $\frac{1}{f}df/dx$ with the measure $d\mu = f dx$, see Ref. [3] Appendix A for usage description. As a proof–of–concept a simple matlab implementation com/polytechnik/utils/LebesgueQuadraturesWithEVData.m, the class calculates Lebesgue quadrature value–nodes and weights $(f_i, w_i)$ either from two matrices, or, second option, given $f(x)$ in analytic form, calculate two matrices first, then calculate Lebesgue quadrature. Usage demonstration in available from com/polytechnik/utils/LebesgueQuadratures.m. This unoptimized code calculate $\langle Q_j \mid f \mid Q_k \rangle$ and $\langle Q_j \mid Q_k \rangle$ matrices in monomials and Chebyshev bases, then build Gauss or Lebesgue quadratures.

IV. CONCLUSION

Obtained Lebesgue quadrature is a new class of quadratures, besides being suitable for $\langle fP(x) \rangle$ integrals estimation, it can be applied to estimation of the distribution of $f$: each $w_i$ from (18) is the measure of $f(x) \approx f_i$ sets. This is especially important for $f(x)$ of relaxation type, this approach is superior to typically used approaches based on $\langle f \rangle$, $\langle f^2 \rangle$, $\langle f^3 \rangle$, $\langle f^3 \rangle$, skewness and kurtosis approaches[19]. In our early works[6, 20] the (7) equation was obtained, and the distribution of eigenvalues $\lambda^{[i]}$, all the eigenvalues were considered to have the same weight, was interpreted as related to the distribution of $f(x)$, similar interpretation is used in random matrix theory[21].

In this paper an important step forward is made. Lebesgue quadratures show, that each
FIG. 1. Two stage degradation model with the slope on first and second stages $-10^{-4}$ and $-5\cdot10^{-4}$ per cycle respectively. The stages length is 500:500 for (a), (b), (c) and 800:200 for (d), (e), (f). The (a) and (d) are $C(N)$ models for which $f = dC/dN$ is put to (7). The (b) and (e) are the distributions of $\lambda[i]$ from (7), Ref. [20] results. The (c) and (f) are the distributions of $\lambda[i]$ with (18) weights, the peaks correspond exactly to stage length because of chosen $d\mu = dN$. The calculations are performed for $n = 50$ in polynomial basis.

$\lambda[i]$ should have [18] weight $\langle \psi[i] \rangle^2$, not the same weights as in our previous works (first time the Eq. [18] was obtained in Ref. [14] as cluster coverage, formula (20) for $C[i]$, but its importance was not then understood).

To demonstrate the difference in weights accounting take two-stage degradation data model from Ref. [20]. Li–ion batteries capacity fade with each cycle, the degradation rate per cycle $dC/dN$ is the characteristics of interest. Consider $x = N$ and the measure $d\mu = dN$ (recent and old cycles are equally important), use $f(x)$ as battery degradation rate $f = dC/dN$. As in Ref. [20] consider $C(N)$ for 1000 cycles, the degradation rate for the first and second stages is $10^{-4}$ and $5\cdot10^{-4}$ per cycle respectively. Two processes with first:second stages ratio as 500:500 ($f = -10^{-4}$ for $0 \leq x \leq 500$; $f = -5 \cdot 10^{-4}$ for $500 \leq x \leq 1000$)
and 800:200 \((f = -10^{-4} \text{ for } 0 \leq x \leq 800; f = -5 \cdot 10^{-4} \text{ for } 800 \leq x \leq 1000)\) are used as model data, Fig. 1. In our previous works\cite{6,20} we established, that the distribution of \(\lambda^{[i]}\) from (7) is related to the distribution of \(f\). In this paper this relation is found, the weights are \(18\) Lebesgue quadrature weights. Note, that for the data in Fig. 1 the peaks height for (c) and (f) correspond exactly to stage length, because of the measure chosen \(d\mu = dN\).

Lebesgue quadrature \((f_i, w_i)\) can be interpreted as \(f(x)\) discrete distribution. The selection of value–nodes is optimal, such a quadrature perform optimal \(n\)–point discretization of \(f(x)\). The approach is applicable to non–Gaussian distributions (e.g. with infinite standard deviation (but not with infinite mean), burst of many orders of magnitude, etc.). The situation is similar to the one in quantum mechanics: when quantum Hamiltonian is known incorrectly and have some energy state, that is greatly different from the ground state, such a state does not change system behavior at all, because it has close to zero probability. The Lebesgue quadrature has similar ideology, it separates system state on observable value \(f_i\) and probability of it \(w_i\). Similar path have been successfully tried earlier in our quantum–mechanics approach to machine learning of Ref. \cite{14}, where we separated system properties (described by the outcomes) and system testing conditions (described by the coverage).

**Appendix A: Density matrix, corresponding to a given polynomial**

In Section 11B the integral \(\langle P(x)f(x) \rangle\) with a polynomial \(P(x)\) of a degree \(2n - 2\) or less is considered. The technique of \cite{3} deals mostly with \(\langle \psi^2(x)f(x) \rangle = \langle \psi | f | \psi \rangle\) type of integrals, and it is of practical value to be able to reduce a state described by an arbitrary polynomial:

\[
P(x) = \sum_{k=0}^{2n-2} \gamma_k Q_k(x) \tag{A1}
\]
to the state described by the density matrix:

\[
\rho(x, y) = \sum_{i=0}^{n-1} \lambda[i] \psi[i](x) \psi[i](y) \\
P(x) = \rho(x, x)
\] (A2)

such that \( P(x) = \rho(x, x) \), and \( \lambda[i] \); \( \psi[i](x) \) are the eigenvalues and the eigenvectors of some operator \( \|\rho\| \).

**Theorem 3.** For a non–degenerated basis \( Q_k(x) \) relatively the measure \( d\mu \) such operator always exists and is generated by the measure with \( \langle Q_k(x) \rangle_P \) moments.

**Proof.** To find a measure, such that \( P(x) = \sum_{j,s,t,k=0}^{n-1} Q_j(x) \left[ G^{-1}_{js} \langle Q_s Q_t \rangle_P G^{-1}_{tk} \right] Q_k(x) \) (here \( G^{-1} \) is Gram matrix \( G_{jk} = \langle Q_j Q_k \rangle \) inverse) apply multiplication operator \( c^i_j \) from (24) to obtain:

\[
\sum_{m=0}^{2n-2} \gamma_m Q_m(x) = \sum_{j,s,t,k=0}^{n-1} j + k s + t \sum_{m=0}^{n-1} \sum_{l=0}^1 c^i_j G^{-1}_{js} c^s_t G^{-1}_{tk} \langle Q_l \rangle_P Q_m(x)
\] (A4)

Comparing the coefficients by \( Q_m(x) \) obtain linear system of \( 2n - 1 \) dimension, from which the \( \langle Q_i \rangle_P ; l = 0 \ldots 2n - 2 \) moments are found:

\[
\sum_{j,s,t,k=0}^{n-1} j + k s + t \sum_{m=0}^{n-1} \sum_{l=0}^1 c^i_j G^{-1}_{js} c^s_t G^{-1}_{tk} \langle Q_l \rangle_P = \gamma_m
\] (A5)

Then construct \( \langle Q_j Q_k \rangle_P \) Gram matrix of the measure corresponding to found moments \( \langle Q_i \rangle_P \), this gives the required \( P(x) = \sum_{j,s,t,k=0}^{n-1} Q_j(x) G^{-1}_{js} \langle Q_s Q_t \rangle_P G^{-1}_{tk} Q_k(x) \). To construct \( \|\rho\| \) operator, eigenvalues/eigenvectors of which give (A3): solve (7) generalized eigenvalue problem with the matrices \( \langle Q_j Q_k \rangle_P \) and \( \langle Q_j Q_k \rangle \) in (7) left– and right– hand side respectively, obtained eigenvalues/eigenvectors pairs give (A3) expansion over the states of \( \|\rho\| \) operator:

\[
\sum_{k=0}^{n-1} \langle Q_j Q_k \rangle_P \alpha_k[i] = \lambda[i] \sum_{k=0}^{n-1} \langle Q_j Q_k \rangle \alpha_k[i]
\] (A6)

\[
\rho(x, y) = \sum_{i=0}^{n-1} |\psi[i]\rangle \lambda[i] \langle \psi[i]| = \sum_{i=0}^{n-1} \lambda[i] \psi[i](x) \psi[i](y)
\] (A7)

\[
P(x) = \rho(x, x)
\] (A8)

\[\square\]

**Remark.** The expansion of \( P(x) = \sum_{j,s,t,k=0}^{n-1} Q_j(x) G^{-1}_{js} \langle Q_s Q_t \rangle_P G^{-1}_{tk} Q_k(x) \) with a matrix \( \langle Q_j Q_k \rangle_P \) generated by a measure is unique, the measure moments are (A3) linear system.
solution; without a requirement that the matrix to be generated by a measure, the solution is non–unique. Another non–uniqueness can arise from the degeneracy of \( \langle Q_j Q_k \rangle_P \) matrix, for example, take Christoffel function, \( 1/K(x) = P(x) = \sum_{j,k=0}^{n-1} Q_j(x) G_{jk} Q_k(x) \): the solution (A5) and the matrix \( \langle Q_j Q_k \rangle_P \) are unique, but the (A3) expansion is non–unique due to (A6) spectrum degeneracy (all the eigenvalues are equal to one), \( 1/K(x) = \sum_{i=0}^{n-1} [\psi^{|i}(x)]^2 \) is correct for any orthogonal basis \( |\psi^{|i}\rangle \).

Note. This prof is actually an algorithm to construct the density matrix \( \|\rho\| \), producing a given polynomial \( P(x) \). In provided implementation `com/polytechnik/algorithms/OrthogonalPolynomialsABasis.java` the method `getMomentsOfMeasureProducingPolynomialInKK_MQQM()` solve linear system and, for a given \( P(x) \), obtain the moments \( \langle Q_m \rangle_P \). The method `getDensityMatrixProducingGivenPolynomial()` use these moments to solve (A6), to obtain the \( \|\rho\| \) from (A7) as the Lebesgue quadrature, the spectrum of which corresponds to a given polynomial \( P(x) \) (A3).

From (A3) immediately follows that the sum of all \( \|\rho\| \) eigenvectors is equal to \( \langle P(x) \rangle = \sum_{i=0}^{n-1} \lambda^{|i} \), particularly for Christoffel function we have: \( \langle 1/K(x) \rangle = \sum_{i=0}^{n-1} \lambda^{|i} = n \), and in general case:

\[
\langle f(x) P(x) \rangle = \sum_{i=0}^{n-1} \lambda^{|i} \langle \psi^{|i} \mid f \mid \psi^{|i}\rangle \tag{A9}
\]

The (A9) is a representation of \( \langle f(x) P(x) \rangle \) integral as a sum of \( f \)–moments over the states of density matrix \( \|\rho\| \) operator (A6). This formula is a complementary one to (19), which is a representation of \( \langle f(x) P(x) \rangle \) integral as a sum of \( P \)–moments over the states of \( \|f\| \) operator (7).

Finally, we want to emphasize, that used all of the above \( \langle \psi \rangle^2 \) is a special case of density matrix. Consider \( \|\rho\| = |1\rangle \langle 1| \), then \( \langle \psi \rangle^2 = \langle \psi \mid \rho \mid \psi \rangle \), and for an operator \( \|f\| \), \( \langle f \rangle = \text{Spur} \|f|\rho\| \) Similarly, a spur with a density matrix \( \|\rho\| \), e.g. corresponding to a polynomial \( P(x) \), can be used instead of all averages:

\[
\langle f \rangle \to \text{Spur} \|f|\rho\| \tag{A10}
\]

This way the developed approach can be extended not only to polynomial by operator products study, but also to operator–by–operator products. Then, instead of \( \text{Spur} \|f|\rho\| \),
which can be written either in (19) or in (A9) representation, a general case of two operators \( \|f\|g\| \) can be considered. The first attempt to explore this direction is presented in [15].
