(Dated: November 12, 2018)

Time crystals in periodically driven systems have initially been studied assuming either the ability to quench the Hamiltonian between different many-body regimes, the presence of disorder or long-range interactions. Here we propose a scheme to observe discrete time crystal dynamics in a one-dimensional driven quantum system of the Ising type with short-range interactions and no disorder. The system is subject only to a periodic kick by a global magnetic field, and no extra Hamiltonian quenching is performed. We analyze the emerging time crystal stabilizing mechanisms via extensive numerics as well as using an analytic approach based on an off-resonant transition model. Our proposal can be implemented with current experimental platforms including trapped ions, Rydberg atoms, and superconducting circuits.

Introduction. — In 2012, Wilczek proposed the idea of quantum time crystals which spontaneously break the continuous time translation symmetry [1]. He suggested that a ring of interacting bosons prepared in the ground state can switch to a periodic motion in time if the magnetic flux through the ring is properly chosen. However, a no-go theorem later pointed out that such a time crystal phase is forbidden in equilibrium [2, 3]. Alternatively, Sacha first proposed to search for time crystal dynamics in periodically driven systems [4] which was further concretized by Khemani et al. [5] and Else et al. [6] respectively studying many-body models. In the presence of strong disorder, the system is many-body localized (MBL) and does not absorb heat from the drive. In this MBL regime, the system can oscillate with a period which is different from the drive’s without thermalizing to an infinite temperature. Such a phase is known as a discrete (or Floquet) time crystal (DTC) to emphasize the discreteness and to differentiate from the original proposal by Wilczek. Subsequent theoretical and numerical studies have demonstrated the existence of DTC in various disordered Floquet systems [7–10].

Recently, DTCs have been observed in various experiments with trapped ions [11], spatial crystals ammonium dihydrogen phosphate NH$_4$H$_2$PO$_4$ [12, 13], and nitrogen-vacancy centers in diamond [14] in the presence of disorder or long-range interactions. While in Ref. [11], DTCs were realized in the MBL phase, the disorder in Ref. [12–14] was insufficient for reaching the MBL regime. This triggered a search for DTCs that are not protected by MBL [15–24]. Driven many-body systems without disorder that exhibit a DTC have been proposed for quenched Hamiltonian with short-range interactions in cold atoms [22], in two dimensions or higher [19], in the regime with all-to-all spin interactions [23] and ultracold atoms bouncing on an oscillating atom mirror [24].

In this work, we study a DTC in the periodically driven one-dimensional Ising quantum chains with finite-range two-body interactions and no disorder. In contrast to Ref. [22] where the driving protocol involves quenching between two many-body Hamiltonians, our drive consists of delta kicks generated by a global magnetic field that periodically applies a $\pi/2$-pulse to each spin.

Using exact diagonalization and the time-evolving block decimation (TEBD) algorithm [25], we find that spin-spin interactions, regardless of their range, help to stabilize the time crystal with a period doubling against small errors in the driving protocol. We analyze the stabilizing mechanism by providing a perturbative model that analyzes the effect of unwanted off-resonant transitions to other undesired states created by errors in the driving protocol. Our setup can be experimentally implemented in all quantum technologies platforms that can realize the quantum Ising model, including trapped ions [26–30], Rydberg atoms [31, 32], superconducting circuits [33], and solid state LiHoF$_4$ [34].

The system, state preparation and driving protocol: We consider the dynamics of the Ising model in a transverse field described by the Hamiltonian

$$H_0 = -J \sum_i \sigma_i^x \sigma_{i+1}^x - h \sum_i \sigma_i^z$$

under a periodic delta kick in the absence of disorder. Here $\sigma_i^\kappa$ ($\kappa = x, y, z$) is the Pauli matrix operator at site $i$, $h$ is the strength of the transverse field and $J$ is the spin-spin coupling strength. The model exhibits a quantum phase transition at $h_c = J$ in the thermodynamic limit. For $h > h_c$, the system’s ground state is a quantum paramagnet while for $h < h_c$, the system breaks the $\mathbb{Z}_2$ symmetry spontaneously and becomes a ferromagnet [35].

The initial state $|\Psi(0)\rangle$ is prepared in one of the two ferromagnetic ground states of $H_0$ with $h = 0$. These ground states are simply the product states $|R\rangle \equiv \otimes_i |\rightarrow_i\rangle_i$ and $|L\rangle \equiv \otimes_i |\leftarrow_i\rangle_i$, where $|\rightarrow_i\rangle_i$ and $|\leftarrow_i\rangle_i$ are eigenstates of $\sigma_i^x$. After evolving the system with $H_0$ for
a time τ, we apply a delta kick

\[ K_\phi = \exp \left[ -i \phi \sum_i \sigma_i^z \right], \]  

which rotates the spins about the z axis by an angle \( \phi = \pi (1/2 - \epsilon) \), where \( \epsilon \) is a perturbation. The procedure is then repeated. The time evolution operator over one period is thus

\[ U = K_\phi U_0 = K_{-\epsilon \phi} K_{\pi/2} U_0, \]  

where \( U_0 = \exp [-i H_0 \tau] \) and \( h = 1 \). For \( \epsilon = 0 \) and \( h = 0 \), the kick operator will just flip the spins at every time \( n \tau \) and the system returns to the initial state at every \( 2\tau \).

As will be shown below, the spin-spin interaction in \( H_0 \) can ‘correct’ the imperfect spin flip for a small but finite \( \epsilon \) (Fig. 1(a)), causing the formation of the time-crystal [36].

To observe the DTC, we measure the total magnetization in the x direction at every period, i.e.,

\[ m^x(n) = \frac{1}{N} \langle \Psi(n) | \sum_i \sigma_i^x | \Psi(n) \rangle, \]  

where \( N \) is the number of spins in the system and \( | \Psi(n) \rangle = U^n | \Psi(0) \rangle \) is the wavefunction of the system just before the \( n \)-th kick. We will show that, under an off-resonant driving condition, \( m^x(n) \) fulfills the following criteria for the DTC in the thermodynamic limit [22, 23].

1. **Time-translational symmetry breaking:** \( m^x(n+1) \neq m^x(n) \).
2. **Rigidity:** \( m^x(n) \) shows a fixed oscillation period without fine-tuned Hamiltonian parameters. (3) **Persistence:** The oscillations must persist for infinitely-long times. Thus the Fourier transform of \( m^x(n) \) has a pronounced peak at \( \pi \).

**Effective analytic model.** To understand the DTC dynamics in our model, let us first consider the trivial case with \( J_\tau = h = 0 \) where all spins are disconnected and start with an initial state |\( R \rangle \). The state after \( n \) driving periods is simply \( | \Psi(n) \rangle = K_\phi^n | R \rangle = K_{-\epsilon n}^n | R \rangle \) with the magnetization \( m^x(n) = (-1)^n \left[ 2 \cos^2(\epsilon n) - 1 \right] \). Hence, the Fourier spectrum of \( m^x(n) \) has two peaks at \( \pi \pm 2\epsilon \tau \), as depicted in Fig. 1(c). This is not a time crystal since the positions of the peaks depend on \( \epsilon \) regardless of the system size.

When the interaction is switched on (\( J_\tau \neq 0, h = 0 \)), the above situation changes dramatically. As will be shown, when the drive is off-resonant, the two main peaks will be separated by a distance proportional to \( (\epsilon/\epsilon^*)^{m_e N} \) for a critical value \( \epsilon^* \) and a positive constant \( m_e \sim O(1) \), as depicted in Fig. 1(d). The main peaks’ separation will converge to zero as \( N \to \infty \) for \( \epsilon < \epsilon^* \). To see this peak merging, let us consider the state after \( n \) driving periods \( | \Psi(n) \rangle = (K_{-\epsilon} K_{\pi/2} U_0)^n | R \rangle \). The driving scheme is depicted in Fig. 1(b). Since \( \langle L | K_{-\epsilon} | R \rangle = 1 \),
the kick operator $K_\tau$ only flips the two ground states $|R\rangle$ and $|L\rangle$. It does not connect them to the excited states. The operator $K_{-\epsilon\tau}$, on the other hand, generates transitions to the excited states. In first order in $\epsilon$, it does not connect the two ground states. We can see this by approximating $K_{-\epsilon\tau}$ to first order in $\epsilon$ by $K_{-\epsilon\tau} \approx 1 + i\epsilon\pi\sum_{i=1}^{N}\sigma_i^z$. Since $K_{-\epsilon\tau}$ only flips one spin, it follows that $\langle j|K_{-\epsilon\tau}|R\rangle \to 0$ as $\epsilon \to 0$. However, the kick operator couples the ground state to the first excited states $|j\rangle = \sigma_j^z |R\rangle$ for $j \in \{1,2,\cdots, N\}$ as $\langle j|K_{-\epsilon\tau}|R\rangle \sim \epsilon$. If the driving frequency $\omega_d = 2\pi/\tau$ is much larger than the energy gap $\Delta E$ of $H_0$, the corresponding transition to the excited states is too far off-resonant to get significantly populated. Hence $K_{-\epsilon\tau}$ is effectively switched off, as will be confirmed by exact diagonalization below.

With the above conditions, the Fourier spectrum of $m^2(n)$, defined as $\tilde{m}^2(\omega)$, will show a main peak at $\omega_\tau = \pi$ and side peaks of height $\sim \epsilon^2$. When $\epsilon$ becomes large, one has to take into account higher order terms in the expansion of $K_{-\epsilon\tau}$. The $N$-th order term, in particular, couples the two ground states $|L\rangle$ and $|R\rangle$, leading to the splitting of the main peak $\delta \omega = |\omega_f \tau - \pi| \approx (\epsilon/\epsilon^*)^{m_*N}$ with $m_* = 1$, and $\omega_f$ is the main peak’s frequency.

**Discrete time crystal with nearest-neighbour interactions.** To validate the above picture, we calculate the time evolution using exact diagonalization. The corresponding driving frequency is $\omega_d = 2\pi/\tau \approx 10.5 J$, while the energy gap of $H_0$ is $\Delta E = 2J$. In Fig. 1(e), we plot the splitting $\ln(\delta \omega)$ as a function of $\ln(\epsilon)$ for various system’s sizes $N$. The data for each $N$ is fitted linearly, i.e., $\ln(\delta \omega) = b(N) + a(N) \ln(\epsilon)$. As shown in Fig. 1(f), $a(N)$ and $b(N)$ are approximately linearly dependent on $N$ with the slopes $m_b \approx 0.88$ and $m_a \approx 1.33$, respectively. This linear dependence agrees well with the perturbation theory which predicts $m_a = 1$. In the limit $N \to \infty$, the splitting $\delta \omega \approx (\epsilon/\epsilon^*)^{m_*N}$ goes to zero when $\epsilon < \epsilon^* = \exp(-m_b/m_a) \approx 0.22$ and diverges otherwise.

To analyze the full spectrum including side peaks, in Fig. 2(a) we plot a color map of the Fourier spectrum as a function of $\epsilon$. The spectrum is divided into three regimes: (1) $\epsilon \lesssim 0.14$ where there are two main peaks separated by $(\epsilon/\epsilon^*)^{m_*N}$ around $\omega_\tau = \pi$, (2) $0.14 \lesssim \epsilon \lesssim 0.35$ where there is no prominent peak, and (3) $0.35 \lesssim \epsilon < 0.5$ where there is one prominent peak at $\omega = 0$. To quantify the transitions, we calculate the Kullback-Leibler (KL) divergence defined as $\text{KLD} \equiv \sum_\omega A_\omega \ln (A_\omega/A_{\omega}^\text{ref})$, where $A_\omega$ is the Fourier spectrum of $m^2(n)$ and $A_{\omega}^\text{ref}$ is the Fourier spectrum of a perfect cosine function with $\omega_\tau = \pi$. The sum of the Fourier spectra are normalized to one, i.e. $\sum_\omega A_\omega = \sum_\omega A_{\omega}^\text{ref} = 1$. Figure 2(d) shows the KLD as a function of $\epsilon$. The KLD shows distinct behavior in the three regimes mentioned above, as expected. The dynamics of the three cases can be understood by considering three limiting cases. (1) When $\epsilon = 0$, there is one prominent peak at $\omega_\tau = \pi$ as discussed earlier. (2) When $\epsilon = 0.25$, the kick operator rotates $|R\rangle$ to $\prod_i (|\rightarrow_i + |\langle \leftarrow_i|)/\sqrt{2}$, hence maximizing the overlap with the excited states. Thus the Fourier spectrum shows no prominent peak. (3) When $\epsilon = 0.5$, the kick operator is turned off and the state does not evolve. Hence, the Fourier spectrum has a prominent peak at $\omega = 0$.

In Fig. 2(b), we plot the Fourier spectrum as a function of $J_\tau$. The spectrum shows five different regimes as $J_\tau$ is varied from zero to $\pi$. The corresponding transitions, labeled by $J_\tau^q$ with $q \in \{1,2,3,4\}$, are captured by the KLD, as depicted in Fig. 2(e). These transitions can be understood as follows. In the limit of $J_\tau = 0$, as shown in Fig. 1(c), the spectrum displays two main peaks separated by $2\pi \epsilon$. When $J_\tau$ is increased, these two peaks create a beating effect where the envelope oscillates over the period $\tau/\epsilon$. The kick operator creates excitations that oscillate on the timescale of $2\pi/\Delta E = \pi/J$. The first transition happens when these two timescales become comparable, i.e., $J_\tau^1 = \pi \epsilon \approx 0.4$. This approxi-
imated value agrees with the transition shown in Fig. 2(b) and Fig. 2(c). As $J_{\tau}^* < J_{\tau} < J_{\tau}^*$, the drive is off-resonant with $\Delta E$ leading to the DTC as discussed earlier. At $J_{\tau} = 0.5\pi$, the drive hits the second harmonic ($\omega_d \sim 2\Delta E$) of the system. In this regime, after two driving periods, the excitations gain the phase of $2\Delta E\tau = 2\pi$. Hence, in the rotating frame that oscillates with the period $2\tau$, the system will behave as if $J_{\tau} = 0$, leading to two peaks at $\pi \pm 2\pi$. When moving back to the original frame that oscillates with the period $\tau$, there is an extra peak at $\pi$. The phase boundaries can be calculated as $J_{\tau}^* = 0.5\pi - \epsilon\pi$ and $J_{\tau}^* = 0.5\pi + \epsilon\pi$. At $J_{\tau} = \pi$, the drive hits the first harmonic of the system. The excitations gain the phase of $2\pi$ after one driving period. Hence, the situation is the same as $J_{\tau} = 0$. The phase boundary is $J_{\tau}^* = \pi - \epsilon\pi$. At $J_{\tau}^* < J_{\tau} < J_{\tau}^*$, the drive is off-resonant with the first and the second harmonic of the system, leading to the DTC.

In Fig. 2(c), we plot the Fourier spectrum as a function of $h/J$. The spectrum shows a transition at $h^*/J \approx 0.5$ which also appears in the corresponding KLD plot in Fig. 2(f). At $h/J > h^*/J$, we observe that the splitting of the main peak grows linearly with $h/J$ with the rate $2\tan\theta \sim 0.40$. This splitting can be understood as follows. In the limit $h/J \gg 1$, the magnetic field dominates the spin-spin interactions and $[U_0, K_\alpha] \approx 0$. Hence, the system evolves with the approximated operator $K_{0.5\pi-\epsilon\pi-hr} = K_{r(0.5-\epsilon)}$, where $\epsilon' = \epsilon + h\tau\pi$. Hence the splitting rate is $2\epsilon'/\delta(h/J) = 2\tau/\pi \sim 0.38 (J_{\tau} = 0.6)$, in agreement with the splitting observed in Fig. 2(c). This relation also holds for other values of $J_{\tau}$.

For general values of the driving parameters $\epsilon, J_{\tau}$ and $h/J$, the approximate phase boundaries of DTC are captured by the KLD as shown in Fig. 3(a) and (b). The DTC phases are stable up to $h/J \sim 0.6$. For $h/J \neq 0$, the energy spectrum becomes dispersive and bands are formed. In particular, the energy span of the second band increases as $h/J$ increases. This results in the wedge-like shape of phase C in Fig. 3(b). Moreover, the first DTC phase (on the left) is more robust than the second DTC phase (on the right). This is because in order to get out of the first DTC phase, resonance to the states in the second band is required and is more difficult to achieve than populating the states in the first band (which melts the second DTC) since a higher order perturbation in the kick operator is involved.

The effect of long-range interactions. - Now let us consider the effect of the range of interaction in stabilizing the DTC. The Hamiltonian is modified to $H_0 = -J \sum_{i<j} \sigma_i^x \sigma_j^x / i - j^\alpha - h \sum \sigma_i^z$, with $\alpha$ characterizing the interaction range $[42, 43]$. Figure 3(c)-(f) show the phase diagrams for various values of $\alpha$ in the $(h/J) - \epsilon$ and $(h/J) - J_{\tau}$ planes respectively. Upon decreasing $\alpha$ (increasing the range of interactions), the DTC phase becomes more robust to the perturbations in the external transverse field (left column of Fig. 3). The long-range interaction helps to maintain the system in the symmetry broken state with a finite magnetization in the $x$ direction as well as stabilizing the DTC against perturbations in the imperfection of the spin-flip $\epsilon$. On the other hand, the two DTC phases observed in the nearest neighbour interacting case in the $J_{\tau}$ parameter space shrink upon introducing long range interactions. To understand this, let us consider the limiting case $h = 0$. In the presence of long-range interactions, spin flips at different sites have different energies. This results in a broadening of the energy spectrum and increasing the probability of populating the excited states. Hence, the stability of the DTC phase decreases.

Conclusions. - We showed the possibility to observe a stable DTC in an Ising spin system in the absence of disorder subjected only to a periodic drive without the need for any other Hamiltonian control [44]. The simplicity of the global driving protocol should trigger further theoretical and experimental studies in this direction. Among future works, one could consider the effect of the shape of the periodic drive with Gaussian with finite lifetime instead of a delta. The possibility to observe such behavior for different spin Hamiltonians and the dimensionality dependence might be of interest as well.
We thank J.I. Cirac for fruitful discussions and support from the National Research Foundation and the Ministry of Education of Singapore. [35] A similar kicking protocol has been used for the infinite range in the Lipkin-Meshkov-Glick (LMG) model [23].
[36] See Supplemental Material for an analytical form of the magnetization derived from first-order perturbation theory.
[37] See Supplemental Material for a review.
[38] See Supplemental Material for the Fourier spectrum cut at $\epsilon = 0.1, 0.25, 0.5$.
[40] A small noise of order $10^{-5}$ is added to $A_{ref}$ to avoid divergence caused by a zero in the denominator in Eq. 3.
[41] See Supplemental Material for $J\tau = 0.8$ and $J\tau = 1$.
[44] In the Supplemental Material, the Fourier spectrum with a ferromagnetic initial state prepared at $0 < J/J < 1$ and a noisy $\epsilon$, and over $10^5$ periods is also shown. The eigen- spectrum of the unitary operator in Eq. 4 and the $\pi$-spectral pairing [27, 23] is also analyzed. These further show the dynamics fulfills the rigidity and persistence conditions as required in a DTC.
Supplemental Material

In this Supplemental Material, we derive the stroboscopic magnetization to the lowest order of \( \epsilon \) from perturbation theory in section I. In section II, the Fourier spectrum of the stroboscopic magnetization for specific value of \( \epsilon \) from three different regimes in Fig. 2(a) in the main text is shown. In section III, the color maps of the Fourier spectrum with \( h/J \) as the driving parameter for different values of \( J\tau \) are shown. In section IV, we present the simulation result with an ferromagnetic initial state prepared at \( 0 < h/J < 1 \) in the NN interacting case. The eigenspectrum of the time evolution operator and its relation to the existence of DTC in the NN Ising model is studied in section V. In section VI, the results with a noisy \( \epsilon \) in the kick is presented. These further support that the time crystal is stable without fine-tuning the Hamiltonian parameters.

I. PERTURBATIVE TREATMENT IN THE INFINITE-RANGE INTERACTING CASE

In this section, we expand the kick operator in terms of \( \epsilon \) and show that the first order term gives rise to a main central peak and two side peaks of order \( \epsilon^2 \) in the Fourier spectrum.

The kick operator up to the first order in \( \epsilon \tau \) is given by

\[
U_{\text{kick}} = K_{-\epsilon \tau}K_{\pi/2} = \sum_{\mu=0}^{\infty}(i\epsilon \tau S^z)^\mu K_{\pi/2},
\]

with short hand notation \( S^z = \sum_i \sigma^z_i \), and \( K_{\theta} = \exp[-i\theta \sum_i \sigma^z_i] \). Take the initial state \( \vert 0 \rangle = \vert R \rangle = \vert \rightarrow, \rightarrow, \rightarrow, \ldots, \rightarrow \rangle \).

At time \( t = \tau \), the system is in the state

\[
\vert 1 \rangle = U \vert 0 \rangle = [K_{\pi/2} + i\epsilon \tau S^z K_{\pi/2}] \vert 0 \rangle.
\]

The state \( S^z \vert L \rangle \) where \( \vert L \rangle = \sum \mu c_\mu \vert \mu \rangle \) is in general not an eigenstate of \( H_0 \), i.e. \( S^z \vert L \rangle = \sum \mu c_\mu \vert \mu \rangle \) with coefficients \( c_\mu \). At \( t = 2\tau \), the system is in the state

\[
\vert 2 \rangle = U \vert 1 \rangle = [K_{\pi/2} + i\epsilon \tau (S^z K_{\pi/2}^2 + K_{\pi/2} K_{\pi/2} S^z) K_{\pi/2}] \vert 0 \rangle,
\]

where \( U_0 = \exp[-iH_0\tau] \). At \( t = 3\tau \), the system is in the state

\[
\vert 3 \rangle = U \vert 2 \rangle = [K_{\pi/2}^3 + i\epsilon \tau (K_{\pi/2}^3 + K_{\pi/2} K_{\pi/2} U_0 K_{\pi/2} + (K_{\pi/2} U_0)^2 S^z) \vert 0 \rangle,
\]

and at \( t = 4\tau \),

\[
\vert 4 \rangle = U \vert 3 \rangle = [K_{\pi/2}^4 + i\epsilon \tau (K_{\pi/2}^4 + K_{\pi/2} U_0 K_{\pi/2}^3 + (K_{\pi/2} U_0)^2 K_{\pi/2}^2 + (K_{\pi/2} U_0)^3 K_{\pi/2} S^z) \vert 0 \rangle.
\]

In general, at \( t = n\tau \), one obtains

\[
\vert n \rangle = \left[ K_{\pi/2}^n + i\epsilon \tau \left( \sum_{\nu=0}^{n-1} (K_{\pi/2} U_0)^\nu K_{\pi/2} S^z \right) \right] \vert 0 \rangle + O(\epsilon^2).
\]

For the LMG model where the interaction is of infinite range, the Hamiltonian reads

\[
H_{\text{LMG}} = -\frac{1}{4N} \sum_{i,j} \sigma^x_i \sigma^x_j - \frac{h}{2} \sum_i \sigma^z_i.
\]

The prefactor \( 1/N \) is to ensure the energy is extensive in the thermodynamic limit. Using the total spin operator \( S^z = \sum \sigma^z_i/2 \) (with \( \kappa = x, y, z \) obeying \( \vert S^z, J^\pm \rangle = \pm J^\pm \) and \( \vert J^+, J^- \rangle = 2J^z \), the Hamiltonian can be rewritten as a single particle model

\[
H_{\text{LMG}} = -\frac{1}{N} (S^z)^2 - h S^z.
\]

This Hamiltonian commutes with the total spin \( S^z \), thus conserving angular momentum, and with \( K_{\pi/2} \), corresponds to the parity symmetry. Thus, \( H_{\text{LMG}} \) can be diagonalized in each sector \( S \in [0, N/2] \) separately. In the subspace of \( S = N/2 \) which contains the ground state, the eigen-basis is given by the Dicke states \( \vert S, M \rangle \) where \( M \in [-S, -S+1, \ldots, S] \). For the ferromagnetic interaction that we are considering here, the ground state is \( \vert S, S \rangle \) and \( \vert S, -S \rangle \).
Since \([H_0, K_{\pi/2}] = 0\) for the LMG model, Eq. \(S6\) simplifies to

\[
|n\rangle = K^n_{\pi/2} \left[ 1 + i\pi\epsilon \sum_{\nu=0}^{n-1} U^\nu_{0} S_z \right] |0\rangle + O(\epsilon^2), \tag{S9}
\]

with \(|0\rangle = |S,S\rangle\). The action of \(S_z\) generates a lower eigenstates of the Dicke ladder, i.e. \(S_z |S,S\rangle = \sqrt{N} |S,S-1\rangle\). Using \(H_{\text{LMG}} |S,S\rangle = 0\) and \(H_{\text{LMG}} |S,S-1\rangle = \omega_1 |S,S-1\rangle\), we find

\[
|n\rangle = K^n_{\pi/2} |S,S\rangle + i\pi\epsilon \sqrt{N} \sum_{\nu=0}^{n-1} (e^{-i\omega_1 \tau})^\nu K^n_{\pi/2} |S,S-1\rangle, \tag{S10}
\]

where

\[
\chi_n = 1 - e^{-i\omega_1 n\tau} \tag{S11}
\]

To calculate the magnetization

\[
m^z_n = \frac{1}{N} \langle n | S^z | n \rangle, \tag{S12}
\]

we start with

\[
S^z |n\rangle = (-1)^n S |S,S\rangle + i\pi\chi_n (-1)^n \sqrt{N} (S-1) |S,S-1\rangle \tag{S13}
\]

using the fact that the Dicke states are eigenstates of \(S^z\). For large \(N\), we can approximate \(S-1 \approx S = N/2\). We get

\[
m^z_n = (-1)^n \left[ 1 - \epsilon^2 |\chi_n|^2 N \right]. \tag{S14}
\]

Using \((-1)^n = \cos(n\pi)\) and

\[
|\chi_n|^2 = \frac{1 - \cos(\omega_1 n\tau)}{1 - \cos(\omega_1 \tau)}, \tag{S15}
\]

we find

\[
m^z_n = \left[ 1 - \frac{\epsilon^2 \pi^2 N}{1 - \cos(\omega_1 \tau)} \right] + \frac{\epsilon^2 \pi^2 N}{1 - \cos(\omega_1 \tau)} \frac{1}{2} \left[ \cos(n\pi - n\omega_1 \tau) + \cos(n\tau + n\omega_1 \tau) \right]. \tag{S16}
\]

The Fourier transform of the above equation gives three peaks at 0 and \(\omega_1 \pi\) with heights depending on the prefactor of the cosine functions which in turn depends on \(\tau\) and \(\epsilon\).

II. FOURIER SPECTRA FOR THE NEAREST NEIGHBOUR INTERACTING CASE FOR SPECIFIC \(\epsilon\)

![Fourier spectrum](image)
III. SPLITTING OF MAIN FOURIER PEAKS IN THE NEAREST NEIGHBOR INTERACTING CASE WITH $h/J$ AS THE DRIVING PARAMETER

Figure S2 shows the colormaps of the Fourier spectrum for $J\tau = 0.8$ and $J\tau = 1.0$. Similar to Fig. 2(c) in the main text, we can also observe a linear splitting of the main peaks with $h/J$ at a rate of $2\tan \theta \simeq 2J\tau/\pi$ for $h/J > h^*/J$.

IV. DTC IN THE NEAREST NEIGHBOR INTERACTING CASE WITH INITIAL STATE PREPARED AT $0 < h/J < 1$

Here we consider the same driving protocol as described in the main text but with an initial state prepared from one of the symmetry broken ground-states of $H_0$ in Eq. 1 for $0 < h/J < 1$. In experiment, such a state can be prepared by cooling the system in the presence of a strong magnetic field in the $x$ direction at two ends of the chain. As we can see from Fig. S3 the period doubling in the stroboscopic magnetization remain robust in this case.
FIG. S3. (a)-(c) Stroboscopic magnetization as a function of time for various values of \( \epsilon \) and the corresponding Fourier spectrum performed over \( 10^5 \) kicking periods. The period doubling persists in a long time. Here \( N = 14, h/J = 0.32, J\tau = 0.6 \).

(d) Stroboscopic magnetization from TEBD simulation for \( N = 80, \epsilon = 0.02, J\tau = 0.6, h/J = 0.32 \). The lines are just guide to the eyes. The period doubling remain robust in a large system.

V. SPECTRUM OF THE TIME EVOLUTION OPERATOR IN THE TIME CRYSTAL

To have a stable time crystal phase, Ref. S1 showed that the spectrum of the time evolution operator (Floquet operator) has to have a particular structure. Unless otherwise specified, we consider \( J = 1 \) in this section. Any eigenstate of the Floquet operator with quasi-energy \( \mu_\alpha \) needs to have a partner with quasi-energy \( \mu_\alpha + \pi/\tau \) (where \( \tau \) is the driving period), a.k.a \( \pi \) spectral pairing.

To understand this, let’s recall the Floquet unitary operator of our system

\[
U = K_{-\epsilon\pi} K_{\pi/2} U_0,
\]  

where \( U_0 = \exp[-iH_0\tau] \) is the free evolution operator and \( K_\phi = \exp[-i\phi \sum_\sigma \sigma^z_i] \). The eigensystem of the Floquet operator is usually written as

\[
U(\tau)|\alpha\rangle = e^{-i\mu_\alpha \tau} |\alpha\rangle,
\]  

and \( \mu_\alpha \) is known as the quasi-energy.

Note that the parity operator \( P = \prod_\sigma \sigma^z \) commutes with \( H_0 \) as well as \( U \). Both the eigen-energy \( E_s \) of \( H_0 \) and the parity eigenvalues \( p = \pm 1 \) are good quantum numbers. For illustration, consider the case of \( h = 0 \) and perfect spin flip \( \epsilon = 0 \), the eigenstates of the Floquet operator can be expressed in the form of

\[
|\pm\rangle \sim |E_s, p = \pm 1\rangle = \frac{1}{\sqrt{2}} (|\sigma^z_s\rangle + |\overline{\sigma^z_s}\rangle),
\]  

where \(|\sigma^z_s\rangle\) and \(|\overline{\sigma^z_s}\rangle\) are the \( \mathbb{Z}_2 \) symmetry-breaking states of \( H_0 \). We have

\[
U|\pm\rangle = \left\{ \begin{array}{ll}
\pm e^{iE_s \tau} |\pm\rangle & \text{for } N = 4m \\
\mp e^{iE_s \tau} |\pm\rangle & \text{for } N = 4m + 2
\end{array} \right.
\]  

where \( N \) is the system size and \( m \) is a positive integer. In either case, we have a pair of eigenstates \(|+\rangle, |-\rangle\) having an eigenvalue of opposite sign. This translates into a \( \pi/\tau \) difference in the quasi-energy. If one prepares the initial state as a superposition of the \(|+\rangle \) and \(|-\rangle \), that is a symmetry broken state of \( H_0 \), it will undergo Rabi oscillation with a frequency \( \pi/\tau \). More explicitly,

\[
|\Psi(0)\rangle = \frac{1}{\sqrt{2}} (|+\rangle + |-\rangle)
\]  

\[
|\Psi(n\tau)\rangle = U_{f0}^n |\Psi(0)\rangle = \frac{1}{\sqrt{2}} (e^{-i\mu_+ n\tau} |+\rangle + e^{-i\mu_- n\tau} |-\rangle).
\]
If \( \mu = \mu_+ + \pi/\tau \),

\[
|\Psi(n\tau)\rangle = \begin{cases} 
\frac{1}{\sqrt{2}} e^{-i\mu_+ n\tau}(|+\rangle - |-\rangle) & \text{for odd } n \\
\frac{1}{\sqrt{2}} e^{-i\mu_+ n\tau}(|+\rangle + |\rangle) = e^{-i\mu_+ n\tau} |\Psi(0)\rangle & \text{for even } n
\end{cases}
\]

and so the observable returns to itself every \( 2\tau \).

![Figure S4](image)

**FIG. S4.** Blue crosses show the Floquet spectrum for various \( \epsilon \) for \( N = 4, h = 0 \) and \( \tau = 0.6 \). The red circles are the \( \pm \pi/\tau \) shift of the quasi-energies. For \( \epsilon = 0 \), each of the blue cross with quasi-energy \( \mu_\alpha \) has a red circle that corresponds to an eigenstate with quasienergy \( \mu_\alpha' \pm \pi/\tau \) to pair up. For a larger value of \( \epsilon = 0.2 \), the Floquet spectrum is significantly modified and the \( \pi \) pairing of Floquet eigenstates is inhibited.

Figure S4 illustrates the \( \pi \) pairing in the Floquet spectrum for \( N = 4 \) and \( h = 0 \) for the NN Ising model. The Floquet spectrum is modified when \( \epsilon \neq 0 \). Depending on the value of \( \epsilon \) and how the energy gap between adjacent states and that of the even and odd parity states are modified, the pairing may be inhibited (like in Fig. S4(c)) and the period doubling in the observable does not persist.

More generally, Ref. [S1] and [S2] introduced a scheme to check for the \( \pi \)-spectral pairing by considering the quasi-energy gaps

\[
\Delta_0^{(\alpha)} = \mu_{\alpha+1} - \mu_\alpha \quad \text{and} \quad \Delta_\pi^{(\alpha)} = \mu_\alpha + \Re/2 - (\mu_\alpha + \pi/\tau),
\]

for all \( \alpha \)'s, and \( \Re \) is the dimension of the Hilbert space. If the system is a time crystal and there’s \( \pi \)-spectral pairing, we expect \( \langle \log \Delta_\pi \rangle \) to be much smaller than \( \langle \log \Delta_0 \rangle \). Moreover, in order to have the pairing in the thermodynamic limit, we need \( \langle \log \Delta_\pi \rangle \) scales down faster than \( \langle \log \Delta_0 \rangle \) with the system size.

Figure S5(a) shows a plot of \( \langle \log \Delta_0/\pi \rangle \) as a function of \( \epsilon \) in the NN Ising model for \( h = 0.32, \tau = 0.6 \). For each of the \( \epsilon \), we perform numerical linear fitting to

\[
\langle \log \Delta_0/\pi \rangle = a + b \log N,
\]

and plotted the slope as a function of \( \epsilon \) in Fig. S5(b).
FIG. S5. (a) The adjacent quasienergy gap $\Delta_0$ and the even-odd parity states gap $\Delta_\pi$ as a function of $\epsilon$. (b) Scaling exponent of $\langle \log \Delta_0/\epsilon \rangle$ to the system size $N$ as a function of $\epsilon$. For $\epsilon \lesssim 0.05$, the $\pi$-spectral pairing is favorable. Here the NN Ising model for $h = 0.32$ and $\tau = 0.6$ is considered.

VI. WITH A NOISY KICKING PROTOCOL

In the main text, we considered a delta kick parameterized by a fixed variable $\epsilon$. One can also introduce noise in the kick by taking $\epsilon$ as a random variable, i.e. $U_{\text{kick}} = \exp \left[ -i \sum_i \phi_i \sigma_i^z \right]$, where $\phi_i = \pi (1/2 - \epsilon_i)$ and $\epsilon_i$ is drawn from a uniform distribution $[0, \epsilon_0]$. The result is shown in Fig. S6. The DTC phase remain robust.

FIG. S6. Stroboscopic magnetization as a function of time and the corresponding Fourier spectrum for various $\alpha$ and $\epsilon_0$. Here $N = 14, h/J = 0.32, J\tau = 0.6$.
