On the Diameter of Universal Cover

Sergio Zamora
Fall 2017

Abstract

Here we obtain upper bounds for diameters of covering spaces of compact length spaces with the lifted metric. We give a proof by Sergei Ivanov of the fact that the diameter of an $n$-fold cover of a space of diameter $d$ is bounded above by $dn$. We also show that the bound can be improved to $4d\sqrt{n}$ if the cover is universal.

Let $X$ be a compact length space of diameter $d$ and $\rho : \tilde{X} \to X$ an $n$-fold covering map. Then there is a unique length structure in $\tilde{X}$ satisfying that for any curve $\gamma : [0,1] \to \tilde{X}$, $\ell(\gamma) = \ell(\rho \circ \gamma)$, where $\ell$ denotes length ([2], section 3.4). Since as sets, $\tilde{X}$ is $n$ copies of $X$, one might expect that $diam(\tilde{X}) \leq dn$. However, this is a nontrivial fact by Sergei Ivanov [4].

**Theorem 1.** An $n$-fold covering space $\tilde{X}$ of a compact length space $X$ with the lifted metric satisfies $diam(\tilde{X}) \leq n diam(X)$.

Assume there are $p,q \in \tilde{X}$ with $d(p,q) > dn + \varepsilon$. Take a minimizing geodesic $\gamma : [0,1] \to \tilde{X}$ from $p$ to $q$, then there are $0 = x_0 < x_1 < \ldots < x_n = 1$ with $d(\gamma(x_i), \gamma(x_{i+1})) > d + \frac{\varepsilon}{n}$ for all $i$. Let $p_i = \rho(\gamma(x_i))$ and $\gamma_i = \gamma|_{[x_{i-1},x_i]}$ for each $i$ and take minimizing curves $\alpha_i : [x_{i-1},x_i] \to X$ from $p_{i-1}$ to $p_i$. For each $i$ let $\beta_i$ be the concatenation $\alpha_1 * \alpha_2 * \ldots * \alpha_i * (\rho \circ \gamma_{i+1}) * \ldots * (\rho \circ \gamma_n)$. Since $\ell(\alpha_i) \leq d < \ell(\gamma_i)$, we have $\ell(\beta_i) < \ell(\gamma)$ for all $i$.

Also let $\tilde{\beta}_i$ be the lifts of the $\beta_i$ with $\tilde{\beta}_i(1) = q$. By the pigeonhole principle, there are two curves in the set $\{\gamma, \tilde{\beta}_1, \ldots, \tilde{\beta}_n\}$ with the same initial point. We cannot have $\tilde{\beta}_i(0) = p$ for any $i$, since $\ell(\tilde{\beta}_i) < \ell(\gamma)$ and $\gamma$ is minimizing. Therefore we have $\tilde{\beta}_i(0) = \tilde{\beta}_j(0)$ for some $i < j$. Set $\sigma$ as the lift of $(\rho \circ \gamma_1) * \ldots * (\rho \circ \gamma_i) * \alpha_{i+1} * \ldots * (\rho \circ \gamma_{j+1}) * \ldots * (\rho \circ \gamma_n)$ with $\sigma(1) = q$.

Since $\tilde{\beta}_i$ and $\tilde{\beta}_j$ coincide in $[0,x_i]$, we have $\tilde{\beta}_i(x_i) = \tilde{\beta}_j(x_i)$. Also $\gamma$ and $\tilde{\beta}_i$ coincide in $[x_i,1]$, so $\gamma(x_i) = \tilde{\beta}_i(x_i) = \tilde{\beta}_j(x_i)$. On the other hand $\sigma$ and $\tilde{\beta}_j$ coincide in $[x_i,1]$, so $\sigma(x_i) = \tilde{\beta}_j(x_i) = \gamma(x_i)$. From here we can conclude that $\sigma$ and $\gamma$ coincide in $[0,x_i]$, but that would imply that $\sigma$ is a curve from $p$ to $q$ with $\ell(\sigma) < \ell(\gamma)$.

$\square$
This bound is sharp for all $n$. If we regard $\rho_n : S^1 \to S^1$ as $\rho_n(z) = z^n$, the diameter of the lifted metric is $n$ times the diameter of the base space. The bound is attained in other examples as well.

Now assume that $\tilde{X}$ is the universal cover of $X$ ($|\pi_1(X)| = n$). Pick any $p, q \in \tilde{X}$ at maximal distance and a minimizing $\gamma$ path joining them. Since the cover is regular, that path can be taken by a deck transformation $\phi$ in such a way that $p$ is close to the midpoint of $\phi(\gamma)$. This means that our space cannot have long dead ends, otherwise the bottom would not be close to the middle of any long minimizing path. Intuitively, this means
that at large scale \( \tilde{X} \) has a round shape, so the upper bound for \( \text{diam}(\tilde{X}) \) is expected to be much less than \( dn \). Following A. Petrunin idea of analyzing the growth function in the Cayley graph of the fundamental group \([5]\) we have the following result.

**Theorem 2.** Let \( \tilde{X} \) be the \( n \)-fold universal cover of a compact length space \( X \) with the lifted metric. then \( \text{diam}(\tilde{X}) < 4\sqrt{n} \text{ diam}(X) \).

Before we start the proof we should mention that \( n \)-fold universal covers show up by the Bonnet-Myers Theorem for all complete manifolds with a strictly positive Ricci curvature lower bound \([3]\), section 11.7), as well as for Alexandrov spaces of curvature \( \geq 1 \) \([2]\), section 10.4).

Let \( p \) be any point in \( X \), \( \{p_1, \ldots, p_n\} = \rho^{-1}(p) \) and \( \varepsilon > 0 \). Consider the cover \( \{U_i\}_{i=1}^n \) with \( U_i = \{x \in \tilde{X} \mid d(x, x_i) < d + \varepsilon\} \). This is certainly a cover, since for any \( q \in \tilde{X} \), there is a curve from \( \rho(q) \) to \( p \) of length less than \( d + \varepsilon \), which can be lifted to a curve from \( q \) to some \( p_i \). We will prove that the \( 2 \)-skeleton of the nerve of this covering is simply connected.

Recall the definition of nerve. \( \Delta^{n-1} \) will denote the \((n-1)\)–dimensional simplex \( \{(x_1, \ldots, x_n) \in \mathbb{R}^n \mid x_i \geq 0 \text{ for all } i, \sum_{i=1}^n x_i = 1\} \). For \( x = (x_1, \ldots, x_n) \in \Delta^{n-1} \) we define the support \( \text{supp}(x) \) as \( \{i \in \{1, 2, \ldots, n\} \mid x_i \neq 0\} \). For a subset \( I \subset \{1, 2, \ldots, n\} \), we will denote the subsimplex \( \{x \in \Delta^{n-1} \mid \text{supp}(x) \subset I\} \) as \( \Delta_I \). We define the nerve \( N \) of the cover \( \{U_i\}_{i=1}^n \) as the simplicial complex \( \bigcup_{i \in I} \Delta_I \) with \( I = \{I \subset \{1, 2, \ldots, n\} \mid \cap_{i \in I} U_i \neq \phi\} \).

The following lemma will show that \( N \) is connected.

**Lemma 3.** \( \pi_1(X, p) \) is generated by homotopy classes containing loops of length less than \( 2(d + \varepsilon) \).

Since \( X \) is compact semi-locally simply connected, there is \( \eta > 0 \) such that any loop within a ball of radius \( \eta \) is nullhomotopic. This implies that every loop in \( X \) is homotopic to a loop \( \gamma : [0, 1] \rightarrow X \) of finite length. Such loop can be seen as the concatenation of a sequence of paths \( \gamma_i = \gamma \mid_{[x_i-1, x_i]} \) with length less than \( \varepsilon \) with \( 0 = x_0 < x_1 < \ldots < x_m = 1 \). If \( \sigma_i \) are minimizing paths from \( p \) to \( \gamma(x_i) \), we have

\[
\gamma \simeq (\gamma_1 * \sigma_1^{-1}) * (\sigma_1 * \gamma_2 * \sigma_2^{-1}) * \ldots * (\sigma_m-2 * \gamma_m-1 * \sigma_m-1^{-1}) * (\sigma_m-1 * \gamma_m).
\]

Then for any two vertices \( e_i, e_j \) in \( N \), there is a sequence of points \( p_{i_0} p_{i_1} \ldots p_{i_m} = j \) with \( d(p_{i_k-1}, p_{i_k}) < 2d + \varepsilon \) for each \( k \), meaning that the edges \( e_{i_{k-1}} e_{i_k} \) are in \( N \), connecting \( e_i \) and \( e_j \).
Figure 3: Each loop is homotopic to a concatenation of loops with length less than $2d + \varepsilon$.

**Lemma 4.** $N$ is simply connected.

Since for any simplicial complex the inclusion of the 1-skeleton induces an epimorphism $i_1^*: \pi_1(N^1, e_1) \to \pi_1(N, e_1)$, it is enough to show that any loop of the form $e_1 = e_{i_{l_0}} e_{i_1} \ldots e_{i_m} = 1$ is nullhomotopic. For that, construct a partition of unity $\psi: \tilde{X} \to N$ as follows. For each $i$ let $f_i: \tilde{X} \to \mathbb{R}$ be defined as

$$f_i(x) = \begin{cases} 
  d + \varepsilon - d(x, p_i) & \text{if } d(x, p_i) < d + \varepsilon \\
  0 & \text{if } d(x, p_i) \geq d + \varepsilon 
\end{cases}$$

Now, define $\psi_i: \tilde{X} \to \mathbb{R}$ as $\psi_i(x) = f_i(x)/\sum_{j=1}^n f_j(x)$. Note that $\psi_i(x) \neq 0$ if and only if $x \in U_i$, so $\psi = (\psi_1, \ldots, \psi_n): \tilde{X} \to N$ is well defined. Let $\gamma_k: [k-1, k] \to \tilde{X}$ be shortest paths from $p_{i_{k-1}}$ to $p_{i_k}$.

For each $k$, we can consider the homotopy $H_k: [k-1, k] \times [0, 1] \to \mathbb{R}^n$ defined by

$$H_k(s, t) = (1-t)[(k-s)e_{i_{k-1}} + (s-k+1)e_{i_k}] + t[\psi(\gamma_k(s))].$$
Since \( \text{supp}(H_k(s,t)) \subset \{i_{k-1}, i_k\} \cup \text{supp}(\psi(\gamma_k(s))) = \text{supp}(\psi(\gamma_k(s))) \in \mathcal{Y} \) for all \( s \in [k-1, k] \), \( H_k \) is a homotopy in \( \mathcal{N} \) from the segment \( [e_{i_{k-1}}, e_{i_k}] \) to the curve \( \psi(\gamma_k) \).

Gluing these maps, we get a homotopy \( H : [0, m] \times [0, 1] \to \mathcal{N} \) from \( e_1 = e_0 e_{i_1} \cdots e_{i_m} = 1 \) to \( \psi \circ (\gamma_1 \ast \cdots \ast \gamma_m) \). And since \( \tilde{X} \) is simply connected, the loop \( \gamma_1 \ast \cdots \ast \gamma_m \) is contractible, as is \( \psi \circ (\gamma_1 \ast \cdots \ast \gamma_m) \).

Now, since the inclusion of the 2-skeleton induces an isomorphism \( i_2^* : \pi_1(\mathcal{N}, e_1) \to \pi_1(\mathcal{N}, e_1) \), we obtain that \( \mathcal{N}^2 \) is simply connected. To finish the proof of Theorem 2 we will need the following lemma.

**Lemma 5.** Let \( \mathcal{Z} \) be the Cayley graph of a finite group with the word metric. If \( \mathcal{Z} \) is the 1-skeleton of a simply connected 2-dimensional simplicial complex \( \mathcal{Y} \), then \( m = \text{diam}(\mathcal{Z}) \leq \sqrt{4|\mathcal{Z}| + 1} - 2 \).

Let \( e \in \mathcal{Z} \) be the neutral element. Take \( h \in \mathcal{Z} \) with \( d(h, e) = m \) and a minimizing path \( e = g_0, g_1, \ldots, g_m = h \). For each \( i \), set \( S_i \) be the induced graph by the set of vertices \( \{g \in \mathcal{Z} \mid d(g, e) = i\} \) and let \( T_i \) be the connected component of \( g_i \) in \( S_i \).

Removing \( T_i \) we disconnect \( \mathcal{Z} \). To see that, assume the contrary and take a minimizing path \( e = g'_0, g'_1, \ldots, g'_{m'} = h \) in \( \mathcal{Z} \setminus T_i \). Consider the map \( \Phi : \mathbb{S}^1 = \mathbb{R}/\mathbb{Z} \to \mathcal{Y} \) that sends the interval \([0, 1/2]\) to the path \( e = g_0, g_1, \ldots, g_m = h \) and \([1/2, 1]\) to the path \( g_{m'}, \ldots, g'_1, g'_0 \).

Also take the map \( \Psi : \mathcal{Y} \to \mathbb{S}^1 \) defined as follows. \( \Psi \) restricted to the subcomplex \( \mathcal{Y}_0 \) induced by \( \bigcup_{j=0}^{i-1} S_j \) is identical to 0, restricted to the subcomplex \( \mathcal{Y}_{1/2} \) induced by \( \bigcup_{j=i+1}^{m} S_j \) is identical to 1/2, restricted to the subcomplex \( \mathcal{Y}_{1/4} \) induced by \( T_i \) is 1/4, and restricted to the subcomplex \( \mathcal{Y}_{3/4} \) induced by \( S_i \setminus T_i \) is 3/4. Also takes all the edges and faces joining \( \mathcal{Y}_0 \) with \( \mathcal{Y}_{1/4} \) to the interval \([0, 1/4]\), the same for the intervals \([1/4, 1/2]\), \([1/2, 3/4]\), and \([3/4, 1]\).

The composition \( \Psi \circ \Phi \) is homotopic to the identity in \( \mathbb{S}^1 \), contradicting that \( \mathcal{Y} \) is simply connected.

Denote by \( C_1 \) and \( C_2 \) the connected components of \( e \) and \( h \) in \( \mathcal{G} \setminus T_i \), respectively. Since the left multiplications are graph isomorphisms, removing \( g_i^{-1}T_i \) disconnects \( \mathcal{Z} \) in two components \( C_1' \) and \( C_2' \) isomorphic to \( C_1 \) and \( C_2 \), respectively. If \( g_i^{-1}T_i \) does not intersect \( T_i \), one of \( C_1' \) or \( C_2' \) strictly contains \( C_2 \), but since \( |C_2| = |C_2'| \), we have \( C_2 \sqsubset C_1' \) and \( |C_2| < |C_1| \). Analogously, \( hg_i^{-1}T_i \) separates \( \mathcal{Z} \) in \( C_1'' \) and \( C_2'' \), and if \( hg_i^{-1}T_i \) does not intersect \( T_i \), then \( C_1 \sqsubset C_2'' \) and \( |C_1| < |C_2| \).
Therefore $T_i$ has to intersect $g_i^{-1}T_i$ or $hg_i^{-1}T_i$, so $|T_i| \geq \min\{i + 1, m - i + 1\}$. Finally, since the $T_i$'s are disjoint, we conclude that $|Z| \geq \Sigma_{i=0}^n |T_i| \geq \Sigma_{i=0}^n \min\{i + 1, m - i + 1\}$. This implies that $m \leq \sqrt{4|Z| + 1} - 2$, which is the required inequality. \hfill \Box

\textbf{Figure 4:} If $|T_i| \leq i$, then $(g_i^{-1}T_i) \cap T_i = \phi$. And if $|T_i| \leq m - i + 1$, we have $(hg_i^{-1}T_i) \cap T_i = \phi$.

Let $K \subset \pi_1(X, p)$ be the classes containing loops of length less than $2(d + \varepsilon)$. Then the 1-skeleton $N^1$ is the Cayley graph of $\pi_1(X, p)$ with $K$ as the set of generators. For any $q, r \in \tilde{X}$, there are $p_i, p_j$ with $d(q, p_i), d(r, p_j) \leq d$, and from the previous lemma, $d(p_i, p_j) < \left(\sqrt{4n + 1} - 2\right)(2(d + \varepsilon))$. Since $\varepsilon$ was arbitrary, we obtain that $\text{diam}(\tilde{X}) < 4d\sqrt{n}$.

For the asymptotic behavior as $n \to \infty$, this bound is far from being sharp. Itai Benjamini, Hilary Finucane and Romain Tessera showed \cite{[1]} that if any sequence of finite graphs $G_i$ such that the isomorphism group of each one acts transitively and $|G_i| \to \infty$ satisfies

$$\limsup_{i \to \infty} \frac{\text{diam}(G_i)}{|G_i|^p} > 0$$

for some $p > 0$, then there is a subsequence $G_{i_k}$ such that the re-scaled sequence $G_{i_k}/\text{diam}(G_{i_k})$ converges in the Gromov-Hausdorff sense to a torus. Then for large $k$, $G_{i_k}$ cannot be Gromov-Hausdorff close to a simply connected length space and this behavior cannot happen for Cayley graphs of fundamental groups of length spaces with the set of generators $K$ described above.
From here we can conclude that \( \frac{\text{diam}(\tilde{X})}{\text{diam}(X)} = o(n^p) \) for all \( p > 0 \).
