Bounding extrema over global attractors using polynomial optimization

David Goluskin*

Department of Mathematics and Statistics, University of Victoria, Canada

Abstract

We describe a framework for bounding extreme values of quantities on global attractors of differential dynamical systems. A global attractor is the minimal set that attracts all bounded sets; it contains all forward-time limit points. Our approach uses (generalized) Lyapunov functions to find attracting sets, which must contain the global attractor, and the choice of Lyapunov function is optimized based on the quantity whose extreme value one aims to bound. We also present a non-global framework for bounding extrema over the minimal set that is attracting in a specified region of state space. If the dynamics are governed by ordinary differential equations, and the equations and quantities of interest are polynomial, then our methods can be implemented computationally using polynomial optimization. In particular, we enforce nonnegativity of certain polynomial expressions by requiring them to be representable as sums of squares, leading to a convex optimization problem that can be recast as a semidefinite program and solved computationally. This computer assistance lets one construct complicated polynomial Lyapunov functions. Computations are illustrated using three examples. The first is the chaotic Lorenz system, where we bound extreme values of various monomials of the coordinates over the global attractor. In the second example we bound extreme values in a nine-mode truncation of fluid dynamics which displays long-lived chaotic transients. The third example has two locally stable limit cycles, each with its own basin of attraction. We apply our non-global framework to construct bounds for one basin that do not apply to the other. For each example we compute Lyapunov functions of polynomial degrees up to at least eight. In cases where we can judge the sharpness of our bounds, they are sharp to at least three digits when the polynomial degree is at least four or six.

1 Introduction

In many complicated dynamical systems it is desirable to predict the magnitudes of extreme events—for instance, the greatest instantaneous force applied by a turbulent fluid flow, or

*Email: goluskin@uvic.ca
the maximum height of a rogue wave. The present work considers extreme events in eventual behavior, as opposed to transient behavior. In particular we consider dynamical systems governed by differential equations, especially those with complicated invariant sets that attract nearby trajectories, such as chaotic attractors or saddles, and we bound the values that quantities of interest can assume on these invariant sets.

When solutions of a differential equation cannot be characterized exactly, a common way to estimate their eventual behavior is to find attracting sets—subsets of state space that attract all bounded sets of initial conditions. The global attractor of a dynamical system can be defined as the minimal attracting set or, equivalently, as the maximal compact invariant set [43]. (Here the term invariant refers to sets that are invariant in both time directions.) All forward-time limit points are contained in the global attractor. Thus, extreme values of any given quantity at late times are bounded by its extrema over the global attractor, which in turn are bounded by extrema over any other attracting set. Attracting sets can be found using Lyapunov functions, as described below, but generally there exist an infinite number of such functions. A typical approach is to first construct one or several of the simplest possible Lyapunov functions, often quadratic functions, and then use them to estimate properties of the global attractor. In the present work we combine these two steps. For each quantity whose extrema over the global attractor one wants to bound, the construction of a corresponding Lyapunov function that implies the sharpest possible bound is posed as an optimization problem.

Our general approach can be carried out analytically or numerically for broad classes of ordinary and partial differential equations (ODEs and PDEs). In practice, however, the construction of optimal Lyapunov functions can be prohibitively difficult, even with computer assistance. An important exception is the case of ODE systems with polynomial righthand sides. As long as the dimensions and polynomial degrees of such systems are not too large, optimal Lyapunov functions can be constructed computationally using methods of polynomial optimization.

The reason the polynomial ODE case is computationally tractable is that the sufficient conditions we use to construct bounds become, in this case, nonnegativity constraints on polynomial expressions. We enforce this nonnegativity by requiring the expressions to admit decompositions as sums of squares of other polynomials. The optimization over Lyapunov functions subject to these sum-of-squares (SOS) constraints can be carried out numerically after being recast as a semidefinite program (SDP)—a standard type of convex optimization problem [5]. The use of SDPs to solve SOS optimization problems was proposed two decades ago [25, 36, 38] and has found numerous applications in the study and control of ODEs. These applications include the construction of Lyapunov functions to show that a particular solution is attracting and approximate its basin of attraction [4, 7, 10, 18, 37, 38, 47, 50], as well as related methods for bounding infinite-time averages [6, 12, 15]. Some progress has been made applying SOS methods to nonlinear PDEs also [16, 17, 19, 20]. These works are similar in spirit to our present method, which was suggested but not applied in [16], but they are not the same. As far as we know, the
present study is the first to construct Lyapunov functions by optimizing the bounds that they imply.

Section 2 formulates a convex optimization framework for bounding extreme values on global attractors, as well as a modified framework for bounding extrema over sets that attract locally but not globally. Computationally tractable versions of each framework based on SOS constraints are then given for the case of polynomial ODEs. Section 3 reports bounds computed in this way for three polynomial ODEs. For an example with a chaotic attractor, in section 3.1 we study the Lorenz system, computing bounds on various monomials of the coordinates. For an example of a chaotic saddle with long transients, in section 3.2 we study a nine-dimensional ODE that models fluid dynamics in the regime of transition to turbulence [32]. Section 3.3 concerns an ODE with two locally attracting limit cycles; we test the non-global version of our framework by computing bounds that apply to one limit cycle but not the other. In the first and third example, extreme values can be estimated precisely by searching over particular trajectories, so we can compare our computed bounds to these estimates. In each such case, our computations appear to produce arbitrarily sharp bounds as the polynomial degree of Lyapunov functions is raised. Section 4 offers conclusions and open questions.

2 Constructing bounds using convex optimization problems

Consider an autonomous ODE system,

\[ \frac{d}{dt} x(t) = f(x(t)), \quad x(0) = x_0, \]  

that is well-posed for any initial condition \( x_0 \in \mathbb{R}^n \). Assume that all trajectories eventually remain in a bounded subset of \( \mathbb{R}^n \), as often can be proved by Lyapunov function methods similar to those in this work, and that all trajectories are differentiable. The bounding conditions presented below can be generalized beyond ODEs on \( \mathbb{R}^n \), including to parabolic PDEs on Banach spaces as in §2.2 of [16]. We speak in terms of ODEs here, for simplicity and because this is the case that we can tackle computationally.

The global attractor \( \mathcal{A} \) of (1) can be defined as the maximal compact subset of \( \mathbb{R}^n \) that is invariant under the dynamics, or equivalently as the minimal set that attracts all initial conditions in every bounded subset of \( \mathbb{R}^n \) [43]. Let \( \Phi : \mathbb{R}^n \to \mathbb{R} \) denote a quantity of interest for solutions to (1). We seek the maximum and minimum values of \( \Phi(x) \) over the global attractor \( \mathcal{A} \),

\[ \Phi^+_\mathcal{A} := \max_{\mathcal{A}} \Phi(x), \quad \Phi^-_\mathcal{A} := \min_{\mathcal{A}} \Phi(x). \]  

In particular, our objective is to compute upper bounds on \( \Phi^+_\mathcal{A} \) and lower bounds on \( \Phi^-_\mathcal{A} \). Such results also bound values of \( \Phi \) along trajectories \( x(t) \) at sufficiently late times since
forward-time limit points lie in the global attractor. That is,

$$\Phi^-_A \leq \inf_{x_0 \in \mathbb{R}^n} \liminf_{t \to \infty} \Phi(x(t)) \leq \sup_{x_0 \in \mathbb{R}^n} \limsup_{t \to \infty} \Phi(x(t)) \leq \Phi^+_A.$$  

(3)

It suffices to discuss upper bounds since lower bounds on \(\Phi^-_A\) are equivalent to upper bounds on \(-\Phi^+_A\).

In systems with multiple basins of attraction, often one is interested only in the dynamics in a particular basin. Extrema over the global attractor \(A\) might not be useful in such cases since \(A\) includes points from every basin. Instead, suppose all trajectories of interest eventually remain in some set \(X\). We can define a set \(A_X\) that is like the global attractor for \(X\) alone. That is, \(A_X\) is the minimal set that attracts all trajectories eventually remaining in \(X\). In addition to a method for bounding the global maximum \(\Phi^+_A\), section 2.1 below gives a method for bounding the non-global maximum

$$\Phi^+_X := \max_{A_X} \Phi(x).$$  

(4)

2.1 Bounds implied by optimal Lyapunov functions

We bound \(\Phi^+_A\) above by constructing attracting sets. Every attracting set contains \(A\), so the maximum of \(\Phi\) over any attracting set is an upper bound on \(\Phi^+_A\). Like many authors, we find attracting sets using functions \(V: \mathbb{R}^n \to \mathbb{R}\), where \(V\) is in the set \(C^1\) of continuously differentiable functions on \(\mathbb{R}^n\). We refer to these \(V\) as Lyapunov functions, although they need not have properties that sometimes define Lyapunov functions, such as boundedness below or polynomial growth as \(|x| \to \infty\). We aim to show that a sublevel set of \(V\),

$$\Omega^C_V := \{x \in \mathbb{R}^n : V(x) \leq C\},$$  

(5)

is attracting for some fixed \(C\). A sufficient condition for \(\Omega^C_V\) to be attracting is that

$$\lambda f \cdot \nabla V(x) \leq C - V(x)$$  

(6)

throughout \(\mathbb{R}^n\) for some \(\lambda > 0\). To see why the above suffices, note that \(\frac{d}{dt} V(x(t)) = f \cdot \nabla V(x(t))\) along all trajectories of (1), so (6) implies

$$\frac{d}{dt} [V(x(t)) - C] \leq -\frac{1}{\lambda} [V - C(x(t))].$$  

(7)

A trajectory inside \(\Omega^C_V\) cannot leave it since the righthand side of (7) is zero on the set’s boundary. Meanwhile, consider a trajectory that is outside \(\Omega^C_V\) up to some time \(\tau\), meaning that \(V(x(t)) - C > 0\) for \(t \in [0, \tau]\). The differential inequality (7) can be integrated up to time \(\tau\) by separation of variables to show that \(V(x(\tau)) - C \leq e^{-\tau/\lambda}[V(x_0) - C]\). This upper bound decreases to zero as \(\tau \to \infty\), and therefore the set \(\Omega^C_V\) is attracting.
The attracting set $\Omega^C_V$ contains $A$ by definition, so
\[ \Phi^+_A \leq \max_{x \in \Omega^C_V} \Phi(x). \] (8)

The righthand maximum in (8) can be prohibitively difficult to evaluate for complicated $V$. We avoid this difficulty by adding a second constraint on $V$, requiring not only (6) but also $\Phi(x) \leq V(x)$ throughout $\mathbb{R}^n$. Then the righthand maximum in (8) is bounded above by $\max_{x \in \Omega^C_V} V(x)$, whose value is simply $C$, so we arrive at the upper bound $\Phi^+_A \leq C$. Optimizing this bound over all choices of $\lambda$ and $V$ gives
\[ \Phi^+_A \leq \inf_{\lambda \geq \mathbb{R}} C \quad \text{s.t.} \quad V(x) - \Phi(x) \geq 0 \forall x \in \mathbb{R}^n, \quad C - V(x) - \lambda \mathbf{f} \cdot \nabla V(x) \geq 0 \forall x \in \mathbb{R}^n. \] (9)

For various computational examples in section 3, the lefthand inequality in (9) appears to be an equality, meaning that our bounding conditions can give arbitrarily sharp bounds on $\Phi^+_A$. It remains an open challenge to prove this equality in general under suitable conditions on $\mathbf{f}$ and $\Phi$.

The optimization (9) is convex in $V$ for each fixed value of $\lambda$, and the same is true when the convex set $C^1$ is replaced by any convex subset. This convexity makes it tractable to optimize $V$ computationally in certain cases, at least over finite-dimensional subsets of $C^1$, which is why we favor the inequalities in (9) over other sufficient conditions for $\Phi^+_A \leq C$. Many previous authors have taken a different approach, choosing a particular function or simple ansatz for $V$ at the start of their analyses. With $V$ so fixed, one can use more complicated sufficient conditions that might give attracting sets $\Omega^C_V$ with smaller values of $C$ than can be obtained using (6). Nonetheless, there are many examples in the literature where the best bounds on $\Phi^+_A$ are not close to being sharp. We propose that better bounds can be obtained by considering larger classes of Lyapunov functions, even with our less powerful sufficient conditions. This is borne out by the computational examples of section 3.

Any $V$ that gives a bound $\Phi^+_A \leq C$ also gives information about where on the global attractor the value of $\Phi$ can be close to $C$. Let $x^\varepsilon$ denote any point on $A$ where $\Phi(x^\varepsilon) + \varepsilon \geq C$. (If the bound $C$ is not sharp, such a point exists only when $\varepsilon$ is sufficiently large.) The constraints on $V$ in (9) and the fact that $x^\varepsilon$ is in $\Omega^C_V$ imply that $C - \varepsilon \leq V \leq C$ and $\mathbf{f} \cdot \nabla V \leq \varepsilon/\lambda$ at $x^\varepsilon$. For fixed $(V, C, \lambda, \varepsilon)$, these inequalities define a subset of $\mathbb{R}^n$ in which any near-optimal $x^\varepsilon$ must lie. Such subsets could be used to identify parts of state space in which extreme behavior occurs, similar to what is done for other types of extreme behavior in [48] and [11], but we do not pursue this idea here.

---

1One weaker sufficient condition is to let $C$ be the maximum of $V$ on the set where $\mathbf{f} \cdot \nabla V$ vanishes [22]. This amounts to imposing (6) on that set instead of on $\mathbb{R}^n$; the value $C$ is attained at a stationary point of the Lagrangian $V + \lambda \mathbf{f} \cdot \nabla V$, where here $\lambda$ is a Lagrange multiplier. Additionally, constraints on $V$ can be restricted to subsets of $\mathbb{R}^n$ already known to be attracting, and various attracting sets can be intersected to produce a smaller attracting set.
A small modification to the framework (9) can be used to bound maxima over \( A_X \), the minimal set that attracts all sets of initial conditions which are bounded and lead to trajectories eventually remaining in \( X \). The same arguments leading to (9) give an optimization problem for non-global bounds:

\[
\Phi^+_A \leq \inf_{\lambda > R} \min_{V \in C^1(X)} C \quad \text{s.t.} \quad V(x) - \Phi(x) \geq 0 \quad \forall x \in X \\
C - V(x) - \lambda f \cdot \nabla V(x) \geq 0 \quad \forall x \in X 
\]

(10)

It some cases it may be difficult to find a suitable choice of \( X \). For instance, one may be interested in a particular basin of attraction, but typically such a basin is not known exactly and may be a fractal. Then the challenge is to find a choice of \( X \) that is small enough to lie inside the basin and large enough so that every trajectory inside the basin eventually remains in \( X \).

2.2 Computing bounds by polynomial optimization

Optimization over Lyapunov functions as in (9) can be carried out by methods of polynomial optimization if the ODE righthand side \( f(x) \) and quantity of interest \( \Phi(x) \) are both polynomials. Henceforth we assume this is the case, and we optimize Lyapunov functions not over all of \( C^1 \) but over the the set of real polynomials in \( n \) variables up to a specified degree \( d \)—that is, the set \( \mathbb{R}[x]_{n,d} \). The inequalities in (9) then require nonnegativity of two multivariable polynomials on \( \mathbb{R}^n \). Deciding whether a polynomial is nonnegative has NP-hard computational complexity unless \( n \) or \( d \) is small [35], and we want to optimize among higher-degree Lyapunov functions for which such computations would be intractable. Thus we employ a standard SOS relaxation, replacing nonnegativity of a polynomial with the generally stronger constraint that the polynomial can be represented as a sum of squares of other polynomials [39]. The resulting SOS optimization is

\[
\Phi^+_A \leq \inf_{\lambda > R} \min_{V \in \mathbb{R}[x]_{n,d}} C \quad \text{s.t.} \quad V(x) - \Phi(x) \in \Sigma_n, \\
C - V(x) - \lambda f \cdot \nabla V(x) \in \Sigma_n, 
\]

(11)

where \( \Sigma_n \) denotes the set of SOS polynomials in \( n \) variables. The optimization in (11), relative to that in (9), has a smaller set of admissible \( V \) and so gives an upper bound that is at least as large. This bound improves or remains unchanged as the polynomial degree \( d \) of \( V \) is raised. Convergence as \( d \to \infty \) is discussed below.

The inner minimization in (11) can be reformulated as a semidefinite program (SDP) because the SOS constraints and optimization objective are linear in the tunable variables, which are \( C \) and the coefficients of \( V \) [39]. This linearity is why we do not optimize over \( \lambda \) simultaneously, instead tuning \( C \) and \( V \) with fixed \( \lambda \). The outer minimization might be difficult in some cases since the dependence of the inner minimum on \( \lambda \) need not be convex or even continuous. It is only a one-dimensional search, however, and at least for the examples of section 3 we find simple dependence on \( \lambda \).
The non-global bounding formulation (10) also can be altered so that nonnegativity on \( X \) is enforced by SOS constraints that imply nonnegativity on \( X \) but not on \( \mathbb{R}^n \). We assume the set \( X \) is semialgebraic, meaning it can be specified by a finite number of polynomial inequalities and equalities. For convenience, suppose it can be specified by a single inequality, so there exists a polynomial \( g \) such that \( g(x) \geq 0 \) if and only if \( x \in X \). A sufficient condition for any polynomial \( p \) to be nonnegative on \( X \), without necessarily being nonnegative outside of \( X \), is that there exists an SOS polynomial \( s \) such that \( p - gs \) also is SOS. This standard approach, which often is called the S-procedure [47] or a weighted SOS condition [26], readily gives an SOS relaxation of (10):

\[
\Phi_{A_X}^+ \leq \inf_{\lambda > \mathbb{R}} \min_{V \in \mathbb{R}[x]_{n,d}} \min_{s_1 \in \mathbb{R}[x]_{n,d_1}} \min_{s_2 \in \mathbb{R}[x]_{n,d_2}} \quad C \quad s.t. \quad V(x) - \Phi(x) - g(x)s_1(x) \in \Sigma_n, \quad (12)
\]

As in (11), the inner minimization problem can be reformulated as an SDP and solved computationally.

For a general semialgebraic set \( X \) that is specified by inequalities \( g_j(x) \geq 0 \) and equalities \( h_k(x) = 0 \), each \( g(x)s_i(x) \) term in (12) can be replaced by a term of the form \( \sum_{j=1}^J g_j(x)s_j(x) + \sum_{k=1}^K h_k(x)r_k(x) \), where the \( s_j \) are SOS but the \( r_k \) are arbitrary polynomials. If the specification of \( X \) includes an inequality of the form \( g_j(x) = R^2 - |x|^2 \geq 0 \) for some constant \( R \) (which for compact \( X \) always can be added without changing the set), then Putinar’s Positivstellensatz theorem [41] implies that the optimum of the SOS problem converges to that of the original optimization (10) as the polynomial degrees approach infinity [26]. For the global formulation, we cannot say in general that the optimum of (11) converges to that of (9) as \( d \to \infty \). If such a convergence guarantee is important, one option is to find \( R \) such that \( g(x) = R^2 - |x|^2 \geq 0 \) on the global attractor \( A \), and then solve the optimization in (12) instead of (11). In practice, no such modification may be required; in the example of section 3.1, the global SOS formulation (11) provides very sharp bounds on \( \Phi_{A_X}^+ \) as \( d \) is raised.

### 2.3 Exploiting structure

To reduce computational cost and improve numerical conditioning when solving (11) or (12), often one can impose some structure \textit{a priori} on the polynomial ansätze of \( V \) without changing the optimal bounds. In the examples of section 3, we impose structure in two ways.

The first source of structure is symmetry. Let \( \mathcal{T} : \mathbb{R}^n \to \mathbb{R}^n \) be an invertible linear transformation that generates a finite group, meaning that composing \( \mathcal{T} \) a finite number of times gives the identity. Suppose the ODE and the quantity to be bounded both are invariant under \( \mathcal{T} \), meaning \( \frac{d}{dt} \mathcal{T} x = f(\mathcal{T} x) \) and \( \Phi(\mathcal{T} x) = \Phi(x) \). (Each ODE in section 3 has such a symmetry, which is shared by some of the \( \Phi \) we bound but not all.) Imposing the invariance \( V(\mathcal{T} x) = V(x) \) does not change the optimum of (11). We omit the proof of this
statement because it is closely analogous to the proof of Proposition A.1 in [16] or Theorem 2 in [24]. Essentially, any non-symmetric $V$ can be averaged over the group orbit of $T$ to obtain a symmetrized $V$ that proves the same bounds. In the non-global formulation (12), if the function $g$ defining $X$ is also invariant under $T$, then we can impose $T$-invariance on $V$ and each $s_i$ without changing the optimal bound. With $T$-invariance imposed on $V$ in (11), or on $V$ and the $s_i$ in (12), the expressions that are constrained to be SOS also are $T$-invariant. This can be exploited when reformulating the SOS optimizations as SDPs [39], leading to smaller and better-conditioned SDPs.

There is a second source of structure when the ODE right-hand side $f$ has highest-degree terms of even polynomial degree. In the typical situation where $\deg(V) > \deg(\Phi)$, the first and second constraints in (11) require that the highest-degree terms in $V$ and $f \cdot \nabla V$, respectively, are of even degree. When $\deg(f)$ and $\deg(V)$ both are even, one generally expects $\deg(f \cdot \nabla V)$ to be odd. However, the degree of $f \cdot \nabla V$ can be reduced by one if the highest-order terms in $V$ cancel in the expression $f \cdot \nabla V$. This cancellation constrains the highest-order terms of $V$ in a way that can be deduced a priori. We do so in the examples of section 3.1 and section 3.2, where $f$ is quadratic.

3 Computational examples

Each of the following three subsections reports bounds that we have computed for an ODE example. In the first two examples we compute bounds over global attractors by solving (11), and in the last example we compute non-global bounds by solving (12). In all computations, the parser YALMIP [28, 29] (version R20190425) was used to translate SOS optimizations into SDPs, which were solved using MOSEK 9.0 [34]. In all cases MOSEK converged with relative infeasibilities below $5 \times 10^{-7}$.

The numerical computations are subject to rounding error, so the reported bounds are not rigorous to the standards of a computer-assisted proof. Rather, much as numerical integration approximates a particular solution with uncontrolled but often small rounding error, our computations approximate global statements about dynamics. It is possible to make SOS computations rigorous using interval arithmetic, as was done in [15] for the SDP solver but not the parser, however we do not do so here.

3.1 The Lorenz system

To test the quality of bounds computed using (11) for a system with a chaotic attractor, we consider the Lorenz equations [30], for which the components of the generic ODE (1) are

$$x = (x, y, z), \quad f = (-\sigma x + \sigma y, \quad rx - y - xz, \quad -\beta z + xy).$$

We fix the parameters to their standard chaotic values $(\beta, \sigma, r) = (8/3, 10, 28)$, at which there exists a strange attractor to which almost every trajectory tends [49]. Invariant
structures embedded in the strange attractor include an equilibrium at the origin and an infinite number of periodic orbits, as well as their unstable manifolds [8, 44]. The global attractor $\mathcal{A}$ includes all such structures, as well as the invariant structures which are not part of the strange attractor: the two equilibria $x_\pm = (\pm 6\sqrt{2}, \pm 6\sqrt{2}, 27)$ and their unstable manifolds. As described below, the $\Phi$ we bound turn out to be extremized on the strange attractor, rather than on the unstable manifolds of $x_\pm$, so the sharp bounds we compute on $\Phi^+_A$ and $\Phi^-_A$ are also sharp bounds for strange attractor alone.

The quantities we have bounded are various monomials $\Phi = x^l y^m z^n$ up to cubic degree, although our framework applies just as easily to more general polynomials. Bounds were computed by solving (11) as described above—sweeping through $\lambda$ and solving the inner minimization as an SDP—with $V(x, y, z)$ of polynomial degrees up to 8. Numerous authors have found that, for SDPs coming from dynamically motivated SOS optimizations, numerical conditioning is improved if ODE variables are rescaled so that the relevant dynamics lie approximately in the cube $[-1, 1]^n$. Here such rescaling is again crucial. We solved (11) with the Lorenz equations rescaled by $(x, y, z) \mapsto 25(x, y, z)$ as in [15], then the computed bounds were converted back to the original scaling.

Rather than using fully general polynomial ans"atze for $V$, we can impose some structure without changing the optimal bounds, as described in section 2.3. First, since $f$ is quadratic and $\deg(V)$ and $\deg(f \cdot \nabla V)$ both must be even, the highest-degree terms in $V$ must cancel in $f \cdot \nabla V$. Such cancellation occurs if and only if all highest-degree terms of $V$ take the form $x^p(y^2 + z^2)^q$ [15, 46], so we impose this on $V$. Second, for $\Phi$ that are invariant under the symmetry $(x, y) \mapsto (-x, -y)$ of the Lorenz equations, we can impose the same invariance on $V$ without changing the optimal bounds.

In order to judge the sharpness of our bounds we have sought extreme values of each $\Phi$ among particular trajectories of the Lorenz equations. Such a search might be impossible in more complicated systems, which is one motivation for our bounding approach, but it is possible here. Trajectories we examined include numerical integrations beginning from random initial conditions (with initial transients removed), numerical integration approximating the one-dimensional unstable manifold of the origin, and the many periodic orbits computed by Viswanth [51, 52]. It is on the origin or its unstable manifold that we find the extreme values of each $\Phi$, and the closeness of these values to our computed bounds suggests that they are indeed global extrema. Numerical integration from random initial conditions does not give very good approximations to these various extrema; integrating for $10^7$ times steps of size 0.005 gives values that share one or two digits with the true extrema but no more.

Bounds produced by the inner minimization problem in (11) depend on $\lambda$ and the degree of $V$ in similar ways for all $\Phi$ bounded here. As a typical example, figure 1 shows this dependence for upper bounds on the maximum of $x$ over $\mathcal{A}$. For all $\Phi$, our computations give finite bounds with degree-$d$ Lyapunov functions when $\lambda \in (1/d, \infty)$, and the bounds are convex in $\lambda$ on these intervals. Thus it is not hard to optimize $\lambda$ over these intervals,
Figure 1: Upper bounds $C$ on the maximum of $x$ over the global attractor of the Lorenz equations at the standard parameters. The bounds are optima of the inner minimization in (11) for various $\lambda$ and $V$ of polynomial degrees 2 (-----), 4 (-- --), 6 (----), and 8 (-----).

which apparently suffices to give arbitrarily sharp bounds as the degree of $V$ is raised. However, this dependence of $C$ on $\lambda$ is particular to the Lorenz equations.\(^2\)

As an example of the attracting sets $\Omega^C_V$ that give the upper bounds on $x$ reported in figure 1, let us consider quadratic and quartic $V$ at the approximately optimal values of $\lambda = 0.5659$ and $\lambda = 0.3743$, respectively. Figure 2 shows the quadratic and quartic attracting sets $\Omega^C_V$, where $V$ and $C$ solve the inner minimization in (11) at the specified $\lambda$ values. Also shown in figure 2 is a numerical approximation to the unstable manifold of the origin, which is part of the strange attractor.

Attracting sets constructed by solving (11) do not necessarily localize the global attractor well since this is not the optimization objective. The quartic attracting set in figure 2 provides a very good bound on $x$ but a poor localization of the attractor as a whole. Nonetheless, some other attracting sets constructed by solving (11) do localize the global attractor well. Figure 3 shows one such $\Omega^C_V$, which was constructed by optimizing upper bounds on $z$ using $V$ of degree 8. This may be the smallest attracting set that has been reported for the Lorenz equations. It would be harder to minimize the volume of $\Omega^C_V$ directly because this volume does not have convex dependence on the coefficients of $V$.

For all monomials $x^iy^mz^n$ considered here, we have computed bounds on extreme values over the global attractor of the Lorenz equations that are either exactly sharp or very close to being so. For convenience we normalize our bounds by each monomial’s value at the

\(^2\)For the Lorenz equations, terms in $V$ of the form $c_1x^d$, $c_2y^d$, and $c_3z^d$ produce terms in $-(V + \lambda f \cdot \nabla V)$ of the form $c_1(-1 + \sigma \lambda d)x^d$, $c_2(-1 + \lambda d)y^d$, and $c_3(-1 + \beta \lambda d)z^d$, respectively. The latter three coefficients must be nonnegative in order for the second constraint in (11) to hold. At the standard parameters this requires $\lambda \geq 1/d$ if $c_1, c_2, c_3 > 0$. In almost all cases we obtain finite bounds only when $c_1, c_2, c_3 > 0$, and thus only when $\lambda \geq 1/d$ also. An exception is the lower bound on $z$ with quadratic $V$, where finite bounds are possible with $c_2 = 0$ and $\lambda = 3/8 \notin [1/2, \infty)$.\[10\]
Figure 2: Attracting sets $\Omega_V^C$ that give our best upper bounds $C$ on the maximum of $x$ over the global attractor of the Lorenz equations, for Lyapunov functions $V$ of degree 2 (-----) and 4 (----). Each pair $(V, C)$ solves the inner minimization in (11) with $\lambda = 0.5659$ and $\lambda = 0.3743$, respectively. The plotted curves are boundaries of the projections of $\Omega_V^C$ onto the $xz$-plane. Also shown are numerically integrated trajectories (—) starting along each half of the origin’s unstable manifold.

Figure 3: Attracting set $\Omega_V^C$ for $\lambda = 3/8$ and the degree-8 $V$ that optimizes the resulting bound $C$ on the maximum of $z$ over the global attractor of the Lorenz equations. Also shown are numerically integrated trajectories starting along each half of the origin’s unstable manifold.
nonzero fixed points $x_{\pm}$, meaning that we report results for

$$
\Phi = \frac{x^l y^m z^n}{|x^l y^m z^n|_{x_{\pm}}} = \frac{x^l y^m z^n}{(6\sqrt{2})^{l+m+2}n},
$$

(14)

although the bounds were computed using unnormalized monomials. Table 1 reports upper bounds on these $\Phi$ for all monomials up to cubic degree, along with the apparently maximal values of $\Phi$ found on the unstable manifold of the origin. Quadratic Lyapunov functions, to which many past studies have been confined, do not produce particularly good bounds. On the other hand, $V$ of degree 4 and 6 produce upper bounds for all 13 monomials that are sharp to at least 2 and 4 digits, respectively.

As for minima over the global attractor of the Lorenz system, many lower bounds can be anticipated without additional computation. Manifestly nonnegative $\Phi$ such as $x^2$ attain their minima on the equilibrium at the origin. For $\Phi$ that are antisymmetric under the symmetry $(x,y) \mapsto (-x,-y)$ of the Lorenz equations, the upper bound $\Phi^+_{A} \leq C$ implies the lower bound $-C \leq \Phi^−_{A}$. Thus we compute lower bounds only for symmetric monomials that are not obviously nonnegative. Table 2 reports our lower bounds on such monomials up to cubic degree, computed by solving (11) for upper bounds on $-x^l y^m z^n$. In all cases, the bounds appear to become sharp as the degree of $V$ is raised.

Complications arise with the lower bounds on $z$, $x^2 z$, and $y^2 z$ that did not arise with our upper bounds. These three quantities are minimized at the origin, whereas all other extrema we have bounded appear to occur elsewhere on the origin’s unstable manifold. The sharp lower bound $0 \leq z$ can be proved using the sufficient condition (6) with quadratic $V$ only if $\lambda = 3/8$, but a naive search over $\lambda$ may not find this result since other $\lambda$ values smaller than $1/2$ do not give finite bounds. Raising the degree of $V$ to $d \geq 4$ removes this difficulty since then the value $\lambda = 3/8$ falls in the interval $[1/d, \infty)$ over which the lower bound on $z$ is convex in $\lambda$. The nonnegativity of $z$ on the global attractor implies that $x^2 z$ and $y^2 z$ are nonnegative also. However, as reflected in table 2, we have not been able to prove exact lower bounds on $x^2 z$ and $y^2 z$ directly with the framework of (11).

Various bounds on coordinates of the Lorenz equations have appeared in the literature, and bounds on other functions of $(x,y,z)$ can be inferred from previously known attracting sets. The bounds reported in tables 1 and 2 are sharper than the best results in the literature, except for the already sharp lower bound $0 \leq z$. For the example of upper bounds on $y$ and $z$, the best prior results we know of are identical to the bounds we report in table 1 for quadratic $V$; both bounds follow from the fact that the cylinder $y^2 + (z - r)^2 \leq \frac{\beta^2 y^2}{4(\beta - 1)}$ is attracting when $\beta \geq 2$ [9, 27]. These bounds exceed the true maxima of $y$ and $z$ by more than 4% and 17%, respectively, whereas the bounds we compute with quartic $V$ are

\[3\]

With $\lambda = 1/\beta$, $C = 0$, and $\Phi = -z$, the quadratic Lyapunov function $V = -z + \frac{1}{2\beta} x^2$ satisfies (6) and thus proves the known result $z \geq \frac{1}{2\beta} x^2$. In the past this has been proved by showing that a condition like (6) holds on a compact set already known to be attracting [14, 44], but choosing $\lambda = 3/8$ lets (6) hold on all of state space.
Table 1: Upper bounds on maxima over the global attractor of the Lorenz equations for all normalized monomials (14) up to cubic degree, computed by solving (11) with $V$ of degrees 2, 4, and 6. Powers of $x, y, z$ are omitted since their extrema are determined by the extrema of $x, y, z$. Also shown is an approximation of $\Phi_A^+$ from below, found by numerical integration of the unstable manifold of the origin. All values have been rounded to the precision shown. The values of $\lambda$ giving the tabulated bounds are reported by table 5 in the Appendix.

much sharper. While most authors have considered only quadratic Lyapunov functions for the Lorenz equations, a few have suggested particular quartic functions [22, 40, 45]. None of these quartic functions do as well as our optimized quartic $V$, although the quartic attracting set of [45] implies bounds on $y$ and $z$ that are slightly better than our quadratic-$V$ results.

Some bounds in the literature on the Lorenz equations use analyses more complicated than the sufficient condition (6). The best prior upper bound on $x$ seems to be that of [23], whose approach [21] is to first use a quadratic Lyapunov function to show that a certain ellipsoid is attracting, and then use $V = |x|$ as a Lyapunov function on that ellipsoid. The resulting bound, normalized according to (14), is about 3.180. This is sharper than our quadratic-$V$ bound of 3.9317 but not our quartic-$V$ bound of 2.3378. Similarly, a large number of quadratic Lyapunov functions are constructed in [42] using computer algebra, and the implied bounds are stronger than those of a single quadratic $V$ but weaker than those of quartic $V$. These results reflect the fact that the sufficient condition (6) is not the strongest possible. However, they also suggest that inferring the best possible bound from a particular $V$ is not as important as having a computationally tractable way to optimize over $V$ beyond the quadratic case.

As a final example for the Lorenz system, suppose we want to find the smallest possible ball that contains the global attractor. By symmetry this ball must be centered on the $z$-axis. Fixing its center to some $z$-coordinate $z_0$, we choose $\Phi = x^2 + y^2 + (z - z_0)^2$. The bound on $\Phi_A$ found by solving (11) give the squared radius of a sphere centered at $z_0$ which contains $A$, and we can solve (11) repeatedly to find the $z_0$ value that minimizes this radius.
Using \( V \) of degree 6, we find that the ball of radius 32.7044 centered at \( z_0 = 29.9587 \) contains the global attractor. This ball is shown in figure 4, along with numerically integrated trajectories starting along the unstable manifold of the origin. Repeating the computations with \( V \) of degree 8 gives a ball whose radius is barely smaller, differing only after the fifth digit.

### 3.2 Transient chaos

To test the quality of bounds computed using (11) for a system with a chaotic saddle, we consider the so-called nine-mode model of Moehlis et al. [32]. It is a modal truncation of the Navier–Stokes equations that captures several qualitative features in the regime of transition to turbulence. The state vector of the system is \( a \in \mathbb{R}^9 \), we fix the geometric parameters to \((\alpha, \beta, \gamma) = (1/2, \pi/2, 1)\), and we fix the Reynolds number parameter to \( Re = 105 \). At these parameters the system displays chaotic transients that eventually tend to the steady state \( a = e_1 \), where \( e_1 \) is the unit vector in the direction of the first coordinate [32]. These transients explore a complicated invariant set, which appears to be a chaotic saddle and is part of the global attractor \( \mathcal{A} \). A generic trajectory starting away from the global attractor will have a short initial transient during which it is attracted to the chaotic saddle. The initial transient need not lie in \( \mathcal{A} \), so our bounds to not apply to it. Then there is typically a much longer chaotic transient during which the trajectory is so close to the saddle that it lies in \( \mathcal{A} \) up to any reasonable numerical precision. Our bounds do apply to this part of the transient.

Quantities of physical interest in the nine-mode model include the perturbation energy \( \mathcal{E} \) and total dissipation \( \mathcal{D} \),

\[
\mathcal{E} := |a - e_1|^2, \quad \mathcal{D} := \frac{1}{Re} \sum_{i=1}^{9} \lambda_i a_i^2, \quad (15)
\]

where \( \lambda_i \) is the coefficient on the linear terms in the evolution equation for \( a_i \). The simple steady state \( a = e_1 \) minimizes \( \mathcal{E} \) and maximizes \( \mathcal{D} \). On the other hand, relatively large values of \( \mathcal{E} \) and small values of \( \mathcal{D} \) are found only on complicated trajectories. Here we compute upper bounds on \( \mathcal{E} \) and lower bounds on \( \mathcal{D} \) over the global attractor by solving (11). Before doing so, we can impose some structure on \( V \), as described in section 2.3. First, in order for \( V \) and \( f \cdot \nabla V \) to both have highest-degree terms of even degree, which is necessary to satisfy the SOS constraints, we require the highest-degree terms of \( V \) to take the form \( |a|^{2p}(a_1 - a_9)^{2q} \). Second, the quantities \( \mathcal{E} \) and \( \mathcal{D} \) to be bounded are invariant under the two symmetries of the ODEs [24], so we can restrict \( V \) to be invariant under these same symmetries:

\[
(a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8, a_9) \mapsto (a_1, a_2, a_3, -a_4, -a_5, -a_6, -a_7, -a_8, a_9),
\]
\[
(a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8, a_9) \mapsto (a_1, -a_2, -a_3, a_4, a_5, -a_6, -a_7, -a_8, a_9). \quad (16)
\]
Table 3: Upper bounds on the maximum perturbation energy ($\mathcal{E}$) and lower bounds on the minimum scaled dissipation ($\hat{\mathcal{D}} = Re \mathcal{D}$) over the global attractor of the nine-mode model. Bounds are computed by solving (11) with $V$ of polynomial degrees 2, 4, 6, and 8. The values of $\lambda$ giving the tabulated bounds are reported by table 7 in the Appendix. Also shown are the maximum $\mathcal{E}$ and minimum $\hat{\mathcal{D}}$ found by numerical integration (see text).

<table>
<thead>

<tr>
<td>$\hat{\mathcal{D}}$</td>
<td>0.0001</td>
<td>0.030</td>
</tr>
</tbody>
</table>

Table 3 reports the upper bounds on $\mathcal{E}$ and lower bounds on $\mathcal{D}$ that we have computed by solving (11) for $V$ of polynomial degrees up to 8. (To avoid small quantities, we report results using the scaled dissipation $\hat{\mathcal{D}} := Re \mathcal{D}$.) The bounds improve with each increase in degree and have not yet converged at degree 8. We do not report results of degree-10 computations, which were inaccurate due to poor numerical conditioning.

To judge the sharpness of our bounds, we sought trajectories on the chaotic saddle that attain large $\mathcal{E}$ or small $\mathcal{D}$. The dimension of state space makes this search much harder than for the Lorenz system in the previous subsection; some unstable periodic orbits of the nine-mode model have been computed [24, 33] but not many, and their unstable manifolds have not been examined. However, a recently discovered periodic orbit appears to both maximize the infinite-time average of $\mathcal{E}$ and minimize the infinite-time average of $\mathcal{D}$ when $Re = 105$ [24]. We focus our search on the unstable manifold of this orbit, called PO1 in [24], which indeed gives relatively large maximum $\mathcal{E}$ and small minimum $\mathcal{D}$. To explore the unstable manifold, we chose a point on PO1 and numerically integrated $2 \times 10^4$ trajectories starting from small random perturbations of this point. The largest $\mathcal{E}$ and smallest $\hat{\mathcal{D}}$ found among the resulting trajectories are reported in table 3. These values agree in their first digits with the corresponding degree-8 bounds, confirming that the bounds are fairly tight.

We cannot say exactly how tight the bounds are because the extreme values found by numerical integration are unlikely to be true extrema over the global attractor. Indeed, the great difficulty of searching over the global attractor is what makes a priori bounds valuable.

3.3 Multiple basins of attraction

To illustrate how our non-global framework (12) applies to systems with multiple basins of attraction, we consider a two-dimensional example from [13] that has two locally attracting limit cycles. For this system, the components of the generic ODE (1) are

$$\mathbf{x} = (x, y), \quad \mathbf{f} = (y - x(x^2 - 2)(x^2 - 1)(x^2 - 1/4), -x).$$

(17)
As shown by the phase portrait in figure 5, the basins of the two attracting limit cycles are separated by a repelling limit cycle, and there is a repelling equilibrium at the origin.

Suppose we are interested only in trajectories starting inside the middle limit cycle. All such trajectories eventually remain in the ball $X$ of radius $4/5$ centered at the origin. (This $X$ contains the inner limit cycle and does not intersect the middle limit cycle.) The minimal set $A_X$ that attracts all trajectories eventually remaining in $X$ is composed of the inner limit cycle and the area within it. We seek upper bounds on the maxima of $\Phi = x^2$, $xy$, and $y^2$ over $A_X$. Sharpness of such bounds is easy to judge since each maximum is attained on the inner limit cycle and can be found by numerical integration. It would be impossible for the global formulation (11) to give a sharp bound on $\Phi_{A_X}$ in these cases since the global maxima $\Phi_{A_X}$ are attained on the outer limit cycle and are strictly larger than $\Phi_{A_X}^+$. We computed upper bounds on the maxima of $\Phi = x^2$, $xy$, and $y^2$ by solving (12) with $g(x, y) = (4/5)^2 - x^2 - y^2$. For $V$ of polynomials degrees up to 10, we performed computations with $\deg(s_i) = \deg(V) - 2$ and $\deg(s_i) = \deg(V)$. Bounds are reported only for the latter choice, which improves bounds by enough to merit the additional computational cost. The ODE was rescaled by $\lambda \rightarrow 1.6(x, y)$ so that all limit cycles lie in $[-1, 1]^2$, which improves numerical conditioning, and then the computed bounds were multiplied by $1.6^2$ to recover the original scaling. The $\Phi$ to be bounded share the symmetry $(x, y) \mapsto (\lambda x - y)$ of the ODE, so we can impose this same symmetry on $V$ a priori, as described in section 2.3.

The optimal bounds given by the inner minimization problem in (12) display non-convex but continuous dependence on $\lambda$, unlike the $\lambda$-dependence we observed for the global problem that is typified by figure 1. As an example in the non-global case, figure 6 shows how upper bounds on the maximum of $x^2$ over $A_X$ depend on $\lambda$. The fact that $X$ contains $A_X$ gives the trivial bound $\max_{A_X} x^2 \leq \max_X x^2 = (4/5)^2$. For $V$ of degrees 2, 4,
Figure 6: Upper bounds $C$ on the maximum of $x^2$ over the minimal set $A_X$ that attracts all subsets of the ball $X$ of radius $4/5$ for the system (17). The bounds are optima of the inner minimization in (12) for various $\lambda$ and $V$ of polynomial degrees 2 (---), 4 (-----), and 6 (----).

Table 4: Upper bounds over the minimal set $A_X$ that attracts all subsets of the ball $X$ of radius $4/5$ for the system (17), computed by solving (12) with $V$ of degrees up to 10. In all cases $\text{deg}(s_i) = \text{deg}(V)$. Also shown is a numerical approximation of each maximum, $\Phi^+_{A_X}$, which occurs on the inner limit cycle shown in figure 5. The values of $\lambda$ giving the tabulated bounds are reported by table 8 in the Appendix.

</table>

and 6, bounds on $x^2$ are better than this trivial bound approximately when $\lambda$ is less than 0.624, 12.7, and 234, respectively.

Table 4 reports the optimal bounds we find by carrying out the non-convex but one-dimensional minimization over $\lambda$ in (12). Also shown are numerical approximations of each $\Phi^+_{A_X}$, found by numerically integrating a trajectory that tends to the inner limit cycle. Bounds improve as the degrees of $V$ and $s_i$ are raised, and at degree 10 they are sharp to at least 4 digits.
4 Conclusions

We have presented a method for bounding extreme values of chosen quantities over global attractors—that is, over the minimal set \( \mathcal{A} \) that attracts all bounded sets of initial conditions. We also have presented a non-global version for bounding extreme values over \( \mathcal{A}_X \), the minimal set that attracts all trajectories remaining in a given set \( X \). Our approach involves constructing Lyapunov functions by solving convex optimization problems. When all quantities are polynomial, a version of the framework can be implemented computationally by solving polynomial optimization problems subject to sum-of-squares constraints.

To illustrate our computational approach, we have reported bounds on various quantities for three ODE examples: the chaotic Lorenz system, a nine-mode model displaying transient chaos, and a system with multiple basins of attraction. Bounds over global attractors were computed for the first two examples, and bounds over a subset of the global attractor in a particular basin were computed for the third example. For every quantity bounded in the Lorenz system and the multiple-basin example, the computed bounds are very sharp and appear to become arbitrarily sharp as the polynomial degree of Lyapunov functions is raised. Most bounds in the prior literature on the Lorenz equations are not nearly as sharp. In the transient chaos example we cannot judge the sharpness of bounds well enough to say that they become arbitrarily sharp, nor is there any indication to the contrary. Preliminary computations (not reported here) for some other ODEs, including the Lorenz-84 model [31] and truncations of the Kuramoto–Sivashinsky equation, also appear to become arbitrarily sharp with increasing polynomial degree.

A fundamental theoretical question that remains open is: under what conditions does the present method produce sharp bounds? In particular, when are the maxima defining the lefthand quantities in (9) and (10) equal to the minima of the righthand problems? Results of this type have been proved for similar variational methods which give bounds on infinite-time averages [48] or extreme events [11]. Sharpness of the formulation (10) would imply sharpness of its computational relaxation (12) in the polynomial case, as discussed at the end of section 2.2, thereby ensuring that our successful examples are in fact typical. Another theoretical question of practical importance is: under what conditions do the inner minima in (11) or (12) have convex dependence on \( \lambda \), thereby simplifying the outer minimization problems?

The results reported here constitute yet another instance where methods based on polynomial optimization, when applicable, produce stronger results about dynamical systems than any other approach. Related methods have been similarly successful in demonstrating stability [4, 37, 38], bounding time averages [6, 12, 15], and estimating basins of attraction [4, 7, 10, 18, 47, 50]. Application to high-dimensional dynamical systems remains a practical challenge that calls for improving scalability, perhaps by replacing sum-of-squares constraints with stronger constraints that are more computationally tractable [1, 2, 3, 53, 54]. Nevertheless, the further development of polynomial optimization methods for ordinary
differential equations is sure to remain fruitful, as is the extension of such methods to partial differential equations.

Appendix: Optimal $\lambda$ values

Tables 5 to 8 give the values of $\lambda$ that yield the bounds reported in tables 1 to 4, respectively. The first three tables report solutions of the global bounding formulation (11), while the last reports solutions of the non-global formulation (12). We believe these $\lambda$ values are globally optimal, but we cannot be certain because the optimizations over $\lambda$ in (11) and (12) are non-convex in general. Bounds are fairly insensitive to the value of $\lambda$, especially when the degree of $V$ is large. This can be seen in figures 1 and 6. Thus, to compute bounds that are optimal up to the precision reported in tables 5 to 8, less precision is needed in $\lambda$. This is reflected in the precision of the $\lambda$ values reported in tables 1 to 4, which is low but still sufficient to give the optimal bounds.
