Maximum Entropy Principle in statistical inference: case for non-Shannonian entropies

In this Letter we show that the Shore–Johnson axioms for Maximum Entropy Principle in statistical estimation theory account for a considerably wider class of entropic functional than previously thought. Apart from a formal side of the proof where a one-parameter class of admissible entropies is identified, we substantiate our point by analyzing the effect of weak correlations and by discussing two pertinent examples: 2-qubit quantum system and transverse-momentum behavior of hadrons in high-energy proton-proton collisions.

The concept of entropy indisputably plays a pivotal role in modern physics \cite{1,2}, statistics \cite{3,4} and information theory \cite{5,6}. In each of these fields the entropy paradigm has been formulated independently and with different applications in mind. While in physics the entropy quantifies the number of distinct microstates compatible with a given macrostate, in statistics it corresponds to the inference functional for an updating procedure, and in information theory it determines a limit on the shortest attainable encoding scheme.

However, recent developments in quantum theory \cite{8,9} and complex dynamical systems in particular \cite{10,11,12,13} have brought about the need for a further extension of the concept of entropy beyond conventional Shannon–Gibbs type of entropies. Consequently, numerous generalizations proliferate in the current literature ranging from additive entropies of Rényi \cite{14} and Burg \cite{15} through rich class of non-additive entropies \cite{16,17,18,19,20} to more exotic types of entropies \cite{21}. Concomitantly with this, efforts are under way to classify all feasible entropic functionals according to their group properties \cite{22,23}, generalized additivity rules \cite{24} or asymptotic scaling \cite{14,22,25}.

Regardless of a particular generalization, the key usage of entropy is in statistical estimation theory, which in turn crucially hinges on the Maximum entropy (MaxEnt) principle (MEP) and its various reincarnations (e.g., the maximum likelihood estimate, principle of minimum Entropy) principle (MEP) and its various reincarnations (e.g., additivity rules \cite{24} or asymptotic scaling \cite{14,22,25,26}).

In this Letter we show that the Shore–Johnson axioms for Maximum Entropy Principle in statistical estimation theory account for a considerably wider class of entropic functional than previously thought. Apart from a formal side of the proof where a one-parameter class of admissible entropies is identified, we substantiate our point by analyzing the effect of weak correlations and by discussing two pertinent examples: 2-qubit quantum system and transverse-momentum behavior of hadrons in high-energy proton-proton collisions.

The heuristic justification behind the MEP is typically twofold: first, maximizing entropy minimizes the amount of prior information built into the distribution (i.e. MaxEnt distribution is maximally noncommittal with regard to missing information); second, many physical systems tend to move towards (or concentrate extremely close to) MaxEnt configurations over time \cite{1,2,11,26}.

MEP was pioneered by Jaynes who first employed Shannon’s entropy in the framework of equilibrium statistical physics \cite{26,27}. On a formal level the passage from Shannon’s information theory to statistical thermodynamics is remarkably simple, namely a MaxEnt probability distribution subject to constraints on average energy, or average energy and number of particles yield the usual Gibbs’ canonical or grand-canonical distributions, respectively. In classical MEP the MaxEnt distributions are always of an exponential form when constrains are phrased in terms of a finite number of moments (situation typical in practice). Applicability of MEP is, however, much wider. Aside from statistical thermodynamics, MEP has now become a powerful tool in non-equilibrium statistical physics \cite{23} and is equally useful in such areas as astronomy, geophysics, biology, medical diagnosis and economics \cite{11,20}.

As successful as Shannon’s information theory has been, it is clear by now that it is capable of dealing...
with only a limited class of systems. In fact, only recently it has become apparent that there are many situations of practical interest requiring more “exotic” statistics which does not conform with the canonical prescription of the classical MaxEnt (known as Boltzmann–Gibbs statistics). On the other hand, it cannot be denied that MaxEnt approach deals with statistical systems in a way that is methodically appealing, physically plausible and intrinsically non-speculative (MaxEnt invokes no hypotheses beyond the evidence that is in the available data). One might be thus tempted to extend MEP also on other entropy functionals particularly when the ensuing MaxEnt distributions differ from Boltzmann–Gibbs ones in some desirable way (e.g., in particular types of heavy tails). Entropy functionals in question should not be, however, arbitrary but they ought to satisfy some “reasonable” properties. From the point of information theory, these properties are typified by coding theorems or axiomatic rules (à la Shannon–Kinchine type of axioms). Recently, however, doubts have been raised about feasibility of this program. Arguments involved primarily rest on Shore–Johnson (SJ) axioms of statistical estimation theory.

Shore–Johnson axioms. — From the point of statistics, MEP is an estimation method, approximating probability distribution from the limited prior information. As such, it should obey some consistency rules. SJ introduced a set of axioms, which ensure that the MEP estimation procedure is consistent with desired properties of inference methods. These axioms are [4]:

1. Uniqueness: The result should be unique.
2. Permutation invariance: The permutation of states should not matter.
3. Subset independence: It should not matter whether one treats disjoint subsets of system states in terms of separate conditional distributions or in terms of the full distribution.
4. System independence: It should not matter whether one accounts for independent constraints related to independent systems separately in terms of marginal distributions or in terms of full-system constraints and joint distribution.
5. Maximality: In absence of any prior information, the uniform distribution should be the solution.

To keep our discussion as simple as possible we focus on discrete probabilities only. Let us note, that for continuous probability distributions, the entropy (or better its continuous counterpart — differential entropy) is not a coordinate-invariant and one must consider the Maximum Relative Entropy principle instead of MEP. The generalization of the SJ axioms for continuous distributions was discussed, e.g., in Refs. [4, 33], and results obtained here are (with minor adjustments) valid also in continuous-state spaces.

In recent years, there has been much discussion of the consistency of MEP for generalized, i.e., non-Shannonian entropies. A typical claim has been that the SJ axioms preclude the use of MEP for generalized entropies, since they introduce an extra bias in the estimation of the ensuing MaxEnt distributions [34, 35]. If this was true then in some important cases, such as in the Rényi entropy-based signal processing and pattern recognition, there would be important new corrections or inconsistencies to some existing analyses. Here we show that the SJ axioms as they stand certainly allow for a wider class of entropic functional than just Shannon’s entropy (SE). Central to this is the following theorem due to Uffink [33].

**Theorem 2 (Uffink Theorem).** MEP satisfies Shore–Johnson consistency axioms if and only if the following prescription holds: Maximize $U_q(P)$ under the set of constraints $C = \{ I_k \}$, where $U_q(P) = (\sum_{i=1}^{n} p_i^q)^{1/(1-q)}$ for any $q > 0$, modulo equivalency condition.

The equivalency condition means that all functionals $f(U_q(P))$ for strictly increasing functions $f$ are equivalent ($\sim$) in the sense that they provide the same MaxEnt distribution [33]. A simple variant of the proof together with related discussion is provided in Supplemental Material [37]. Here we list some pertinent results:

(a) From axioms 1-3 alone follows that the entropy is equivalent to the sum-form functional:

$$U(P) = \sum_{i=1}^{n} g(p_i) \sim f \left( \sum_{i=1}^{n} g(p_i) \right). \quad (3)$$

Axioms 1-3 alone thus rule out a wide class of existent entropies. Examples include: $(a, \lambda)$-escort entropies [38]; $S_{a,\lambda}(P) = 1/(\lambda - a) \left[ (\sum_i p_i^a) / (\sum_i p_i^{1-a}) - 1 \right]$ or JA hybrid entropy [21]; $D_q(P) = \ln_q \exp [- \sum_i p_i (q)]$, where $\ln_q x = (x^{1-q} - 1)/(1-q)$ is the $q$-logarithm and $p_i(q) = p_i^q / \sum_j p_j^q$ is the escort distribution [2]. (b) Axiom 4 ensures that any entropy functional consistent with SJ axioms should be equivalent to $\sum_i p_i^q$. There is a number of entropic functionals that do not conform to this form, examples include: $(c, d)$-entropy [14, 22]; $S_{c,d}(P) = \sum_i \Gamma(1 + d, 1 - c \log p_i)$ or the Kaniadakis entropy [39]; $S_{c}(P) = \frac{1}{2c} \sum_i (p_i^{-c} + p_i^{-1/c})$. (c) Axioms 5 implies that inference functional should be of the form:

$$U_q(P) = \left( \sum_i p_i^q \right)^{1/(1-q)} \quad \text{for} \quad q > 0, \quad (4)$$

(modulo equivalency condition). Only for $q > 0$ it is guaranteed that $U_q(P)$ is Schur-concave which is a sufficient property for maximality axiom [37]. For example, Burg entropy [40] $K(P) = K \sum_i \ln p_i$ provides an example of entropy functional belonging to the class of $U_q(P)$, but not fulfilling the maximality axiom. (d) Shannon’s entropy (SE) is a unique candidate for MEP only when an extra desideratum is added to SJ axioms, namely: Strong system independence (SSI): Whenever two subsystems
of a system are disjoint, we can treat the subsystems in terms of independent distributions.

So far, the additivity property of the entropy functional was not our concern. Note, however, that functionals $\mathcal{U}_q(P)$ — known also as Rényi entropy powers [11], obey the multiplicative composition rule $\mathcal{U}_q(A \cup B) = \mathcal{U}_q(A)\mathcal{U}_q(B)$ for independent events. By choosing appropriately $f$, we can construct ensembles with various types of composition rules. For instance, for $f(x) = \ln x$, we get a class of additive Rényi entropies (including Shannon’s one) [14], if $f(x) = \ln_q x$ is chosen, we obtain $Q$-additive Sharma–Mittal entropies [19]. For $Q = q$ we end up with the class of Tsallis entropies [1]. Consequently, the MEP constraints (in MEP they are uniform) and because the data-driven equations [38] of a system are disjoint, we can treat the subsystems in terms of independent distributions.

Despite this, it is asserted in a number of recent works, cf., e.g., [34, 36], that the only inference functional consistent with the SJ desiderata is SE, i.e., the $q = 1$ case. This was also the original result of SJ. The point of disagreement with these works can be traced back to the axiom of system independence and its implementation in the original SJ proof [3, 4]. Notably, SJ assumed that because the prior distributions $Q_1$ and $Q_2$ are independent (in MEP they are uniform) and because the data-driven constraints $I_1$ and $I_2$ are independent (i.e., they give no information about any interaction in the two systems), the posterior distribution $P$ must be written as a product of marginal distributions $U$ and $V$. However, this goes well beyond the original SJ axiom 4 in that the presumed independency of constraints invokes (unwarranted though often reasonable) unique factorization rule for the posterior. Clearly, having no information about interaction encoded in constraints (i.e., having independent constraints) is not the same as having no correlations among systems. Let us now show that there is an implicit assumption about the state-space structure in the SJ proof yielding the specific factorization rule.

**Factorization rule revisited.** — Let us now concentrate on the composition rule of MaxEnt distributions for two systems described by marginal distributions $U = \{u_i\}_{i=1}^n$ and $V = \{v_j\}_{j=1}^m$ and related constraints $\sum_{i=1}^n I_i u_i = \langle I \rangle$ and $\sum_{j=1}^m J_j v_j = \langle J \rangle$. The MaxEnt distributions $U$ and $V$ are obtained by maximizing $\mathcal{U}_q(U)$ and $\mathcal{U}_q(V)$, respectively. Equations read

$$\frac{q}{1-q}[\mathcal{U}_q(U)]^{q-1}u_i - \alpha_I - \beta_I I_i = 0, \quad (5)$$

$$\frac{q}{1-q}[\mathcal{U}_q(V)]^{q-1}v_j - \alpha_J - \beta_J J_j = 0. \quad (6)$$

The solutions can be written as

$$u_i = [\mathcal{U}_q(U)]^{-1}\left[1 - (q-1)\frac{\beta_I \Delta I_i}{q\mathcal{U}_q(U)}\right]^{1/(q-1)}, \quad (7)$$

$$v_j = [\mathcal{U}_q(V)]^{-1}\left[1 - (q-1)\frac{\beta_J \Delta J_j}{q\mathcal{U}_q(V)}\right]^{1/(q-1)}, \quad (8)$$

with $\Delta I_i = I_i - \langle I \rangle$ (similarly for $\Delta J_j$). Lagrange multipliers $\alpha_I$ and $\alpha_J$ were eliminated via the normalization condition. The MaxEnt distribution of the joint system $P = \{p_{ij}\}$ includes both constraints, so we end with

$$\frac{q}{1-q}[\mathcal{U}_q(P)]^{q-1}p_{ij} - \alpha_I J_i - \beta_I I_i - \beta_J J_j = 0. \quad (9)$$

By inserting (5)–(6) into (9), we obtain

$$[p_{ij} \mathcal{U}_q(P)]^{q-1} = 1$$

$$\frac{1}{p_{ij}} \mathcal{U}_q(P) = \frac{1}{u_i \mathcal{U}_q(U)} \otimes \frac{1}{v_j \mathcal{U}_q(V)}.$$

When we apply to (11) the $q$-logarithm we obtain

$$I_q(P) \otimes S_q(P) = [I_q(U) \otimes S_q(U)] + U \leftrightarrow V. \quad (12)$$

Here $I_q(r_k) = \ln_q (1/r_k)$ is the Tsallis-type Hartley information, $S_q(R) = \ln_q \mathcal{U}_q(R)$ is the Tsallis entropy and $x \otimes_q y = (x - y)/(1 + (1 - q)y)$ is the $q$-difference. Note that (12) represents a $q$-deformed version of the additive entropic rule. For $q \to 1$, we recover the relation $p_{ij} = u_i v_j$, which implies the independence of systems. To proceed, we now re-express (11) in terms of escort distributions $P_{ij}(q), U_i(q)$ and $V_j(q)$ as

$$\frac{P_{ij}(q)}{p_{ij}} = \frac{U_i(q)}{u_i} + \frac{V_j(q)}{v_j} - 1. \quad (13)$$

The factorization rule $p_{ij} = u_i v_j$ valid in the $q \to 1$ limit emerges when $\frac{\Delta q}{q} \equiv \frac{\Delta \mathcal{U}_q}{\mathcal{U}_q}$ is taken on both sides of (13). For $q \neq 1$, we will see that intrinsic correlations are present even when constraints are independent.

**Issue of correlations.** — In order to illustrate the connection to correlations, we investigate the regime where $q$ is close to 1. So, we expand a generic escort distribution $R_k(q)$ in the vicinity of $q = 1 (q \equiv 1 + \Delta q)$, as

$$R_k(q) = r_k - r_k \Delta q[I(r_k) - \Gamma_1^R]$$

$$+ r_k \frac{(\Delta q)^2}{2} \{[I(r_k) - \Gamma_1^R]^2 - \Gamma_2^R\} + \mathcal{O}((\Delta q)^3). \quad (14)$$

where $I(r_k) \equiv I_1(r_k) = \ln(1/r_k)$ is the Hartley information of $k$-th event and $\Gamma_n$ are the cumulants obtained from the generating function $G^R(q) = \ln \sum_k r_k^q$, i.e.,

$$\Gamma_n^R = \frac{d^n G^R(q)}{dq^n} \bigg|_{q=1}. \quad (15)$$

Notably, $\Gamma_1^R = S = -\sum_k r_k \ln r_k$ is the SE and $\Gamma_2^R = \sum_k r_k \ln^2 r_k - (\sum_k r_k \ln r_k)^2$ is the varentropy [3]. By inserting (12) into (13) we obtain

$$I(p_{ij}) - I(u_i) - I(v_j) - (\Gamma_1^R - \Gamma_1^V - \Gamma_1^I)$$

$$= \frac{\Delta q}{2} \left\{[I(p_{ij}) - \Gamma_1^R]^2 - [I(u_i) - \Gamma_1^V]^2ight.$$  

$$\left. - [I(v_j) - \Gamma_1^I]^2 - (\Gamma_2^R - \Gamma_2^V - \Gamma_2^I) \right\}. \quad (15)$$
It is easy to show that for independent systems one has \( \Gamma_k^p + \Gamma_k^q = \Gamma_k^p V \), where \( UV = U \cup V = \{u_i v_j \}_{i,j}^{n,m} \) is the ensuing joint distribution. Thus, the differences \( (\Gamma_k^p - \Gamma_k^q) \) quantify the correlations in the system. This can be seen by considering \( p_{ij} = (1 + \epsilon_{ij}) u_i v_j \), where \( \max_{ij} |\epsilon_{ij}| \ll 1 \). In this case, we have

\[
\begin{align*}
\Gamma_k^p &= \Gamma_k^p + \Gamma_k^q - \frac{1}{2} (\epsilon^2)_{0} + O(\epsilon^3), \\
\Gamma_k^q &= \Gamma_k^p + \Gamma_k^q + (\epsilon \ln^2(UV))_0 + O(\epsilon^2),
\end{align*}
\]

where (see also Supplemental Material [37])

\[
\langle \epsilon^2 \rangle_0 = \sum_{ij} \epsilon_{ij}^2 u_i v_j,
\]

\[
\langle \epsilon \ln^2(UV) \rangle_0 = \sum_{ij} \epsilon_{ij} \ln^2(u_i v_j) u_i v_j.
\]

The term \( \langle \epsilon^2 \rangle_0 \) represents the strength of the correlations, and is always non-negative. The case \( \langle \epsilon^2 \rangle_0 = 0 \) happens only for independent distributions corresponding to \( q = 1 \). \( \Gamma_k^p \) represents a specific heat of the system (e.g., \( C_p \) in thermal systems) [3, 44]. Expression (19) thus represents the difference in specific heat \( \Delta C \) with and without correlations \( \epsilon_{ij} \). A connection of the \( q \) parameter with \( \epsilon_{ij} \) can be established by inserting (18) into (14), multiplying the whole equation by \( u_i v_j \) and summing over \( i \) and \( j \). At the leading order in \( \epsilon \) we get

\[
q = 1 - 2 \frac{\langle \epsilon^2 \rangle_0}{\langle \epsilon \ln^2(UV) \rangle_0} = 1 + 4 \frac{\Delta S}{\Delta C}.
\]

Systems where the SJ implicit assumption about the product rule for disjoint systems fails are, e.g., systems where the number of accessible states \( W(N) \) does not grow exponentially with the number of distinguishable subsystems (e.g., particles), i.e. \( W(N) \neq \mu^N, \mu > 1 \) for \( N \gg 1 \). Indeed, in such cases \( W(N + M) \neq W(N) W(M) \) and hence the asymptotic equipartition property [7, 11]:

\[
\lim_{N \to \infty} \{S[P_N] + \ln W(N)/N\} = 0, \quad (P_N = \{p_{ij}\}_{i=1}^N),
\]

is not warranted. However, sub- (or super-) exponential behavior is often found in strongly correlated systems in quantum mechanics [38, 39], high-energy particle physics [33, 40], or astrophysics [50, 51]. Let us now focus on two examples.

**Examples:** We consider first a generic 2-qubit quantum system (e.g., a bipartite spin-1/2 system). Starting from un-entangled states \( |11\rangle, |10\rangle, |01\rangle, |00\rangle \) we pass to the Bell basis of maximally entangled orthonormal states \( |\Phi^\pm\rangle = \frac{1}{\sqrt{2}} (|00\rangle \pm |11\rangle) \) and \( |\Psi^\pm\rangle = \frac{1}{\sqrt{2}} (|01\rangle \pm |10\rangle) \). Let us examine the situation where the only available constraint is given by a Bell-CHSH observable [52, 53]

\[
B = |\Phi^+\rangle \langle \Phi^+ | - |\Psi^-\rangle \langle \Psi^- | \quad \text{mean value of which yields the (scaled) CHSH Bell inequality} \quad \frac{\Gamma_{01}^2}{2} \geq 3.5.
\]

According to MEP we should maximize \( S(\rho) = \text{Tr}(\rho^2)^{1/(1-q)} \) \((q > 0)\) subject to constraints \( \text{Tr}(\rho) = 1 \) and \( \text{Tr}(\rho B) = b \) with \(|b| \leq 1 \). The corresponding MEP state, is given by [37]

\[
\rho_{\text{MEP}} = Z^{-1}(x, q) \left[ (|\Phi^+\rangle \langle \Phi^+ | + |\Psi^-\rangle \langle \Psi^- |) + (1 + x)^{1/(q-1)} |\Phi^+\rangle \langle \Phi^+ | + (1 - x)^{1/(q-1)} |\Psi^-\rangle \langle \Psi^- | \right],
\]

where \( x = \beta/\alpha \) is the ratio of Lagrange multipliers and \( Z(x, q) = 2 + (1 + x)^{1/(q-1)} + (1 - x)^{1/(q-1)} \). We see that \( \rho_{\text{MEP}} \) is diagonal in the Bell basis. This Bell-diagonal state is not entangled if and only if [52] all its eigenvalues are less than or equal to \( 1/2 \). From concavity of \((1 \pm x)^{1/(q-1)}\) for \( q \geq 2 \) and ensuing Jensen’s inequality it is easy to conclude [37] that all eigenvalues of \( \rho_{\text{MEP}} \) are \( \leq 1/2 \). Consequently, for \( q \geq 2 \) we obtain that \( \rho_{\text{MEP}} \) is not entangled (i.e. is separable). Situation for \( q < 2 \) is not conclusive, though inseparability can be deduced numerically. Fortunately, the case \( q = 1 \) (i.e. SE case) is accessible analytically [37]. In this case the eigenvalues of \( \rho_{\text{MEP}} \) are: \( p_{\Phi^+} = p_{\Phi^-} = \frac{1}{4} (1 - b^2), \quad p_{\Psi^+} = \frac{1}{4} (1 - b)^2, \quad p_{\Psi^-} = \frac{1}{4} (1 + b)^2 \). So, particularly for \( b \in (\sqrt{2} - 1, 1) \) Shannonian MEP clearly predicts entanglement. However, one can find a non-ME-state [52], namely \( \rho = b|\Phi^+\rangle \langle \Phi^+ | + \frac{1}{2} (1 - b) \left( |\Psi^+\rangle \langle \Psi^+ | + |\Psi^-\rangle \langle \Psi^- | \right) \), (22) which satisfies the MEP constraint and is separable for \( b \leq \frac{1}{2} \). Hence, Shannonian MEP predicts entanglement even if for \( b \in (\sqrt{2} - 1, 1) \) there is a separable state that is fully compatible with the constraining data.

Clearly, the correct inference scheme (such as presumed Shannonian MEP) should not yield an inseparable state if there exists (albeit only theoretically) a separable state compatible with the constraining data, or else one may get erroneous results (e.g., in quantum communication) by trying to use the entanglement inferred by the MEP, while in reality, there is no entanglement present [52]. Note, that when the MEP with \( \mathcal{U}_q, q \geq 2 \) is chosen, one can avoid the fake entanglement for any \( b \leq 1 \). The reason why Shannonian MEP implies spurious (quantum) correlations is that in analyzed quantum system does not comply with SSE due to use of the non-local Bell-CHSH observable. We note that problems with Shannonian MEP should be generically expected in entangled systems as entanglement does not conform to SSI because measurement results on (possibly distant) non-interacting subsystems (giving according to SJ independent constraints) are still correlated. Situation should be particularly pressing in strongly-entangled \( N \)-partite systems because there \( W(N) \propto N^\rho, \rho > 0 \), cf. [52, 55].

As a second example we consider the transverse momentum \( \langle p_T \rangle \) distributions of hadrons produced in \( pp \) collisions at very high energies (center-of-mass energies \( \sim 10^2 - 10^3 \) GeV) as measured in RHIC and LHC experiments. The term transverse relates to the direction of colliding protons. From particle phenomenology it is known that in these cases the effective number of distinguishable states with energy \( E \) shows a sub-exponential growth [50, 52], i.e., \( W(E) \sim \exp((N)^\gamma) \) with
0 < \gamma < 1 \text{ and } \{\ldots\} \text{ taken with respect to an appropriate multipicity distribution. SSI (and hence Shannon’s MEP) is thus not warranted in these cases. In fact, the single-particle } p_x \text{ distributions are best fitted by the } q\text{-gaussian distributions (resulting from MEP based on } U_q \text{ with } q \in [1.05, 1.10] \text{ depending on the type of the collision } [4, 64, 65]. \text{ In these cases the constraint } [2] \text{ is represented by the mean of the transverse energy } E_T = \sqrt{p_x^2 + m^2} \text{ (} m \text{ is hadron’s rest mass). Typical picture is that out of many hadrons produced in a given event only one is selected (system } A). \text{ Remaining } (N-1) \text{ particles (} N \text{ is event dependent) act as a kind of a heat bath (HB) (system } B) \text{ described by some apparent temperature. In this HB the single-hadron } p_x \text{ is effectively distributed according to the Maxwell–Jüttner distribution. The final distribution } u(p_x) \text{ is obtained by averaging over many events with distinct apparent temperatures. Systems } A \text{ and } B \text{ are clearly disjoint, but due to event-to-event temperature fluctuations the joint distribution } p(p_x, p_y) \neq u(p_x)u(p_y), \text{ so SSI is indeed violated. Now, since } q \text{ is close to } 1, \text{ we can consider only the leading order of } \epsilon_{ij} \text{ in } (q-1), \text{ i.e. } \epsilon_{ij} = (1-q)\beta^2 \Delta E_i^p \Delta E_j^p. \text{ From (20) then follows that } [57]

\begin{equation}
q = 1 + \frac{(N)-1}{\beta^2 (\langle \Delta E^v \rangle_0)^2} = 1 + \frac{(N)-1}{C_V'}, \tag{23}
\end{equation}

where } \langle (\Delta E^v)^2 \rangle_0 = \beta^2 \log Z'/\beta^2 = C_V'/\beta^2 \text{ (} Z' \text{ and } C_V' \text{ represent partition function (i.e., } U_q(V) \text{) and heat capacity of the HB) and } (N-1) = \beta\langle E^v \rangle_0 \text{ is the virial relation where } 1/\beta \text{ is the kinetic temperature of the hadronic HB. Note that system } A \text{ factored out. Relations of the type } [23] \text{ frequently appear in phenomenological studies on high-energy } pp \text{ collisions } [3, 58, 59]. \text{ Conclusions. — In summary, we have shown that the SJ axiomatization of the inference rule does account for substantially wider class of entropic functionals than just SE. The root cause could be retraced to unreazonably strong assumptions employed by SJ in their proof — assumptions that go beyond the original SJ axioms. In particular we have shown that Shannonian MEP is singled out as an unique method of statistical inference only insofar as an extra axiom of strong system independence is added to the SJ desiderata. While, for systems where state-space scales exponentially with its size (e.g., in (quasi-)ergodic systems) SE is the only entropy compatible with SJ axioms, for systems with sub-} (super-) exponential growth the assumption of SSI is not justified and the original proof of SJ needs revision. In our revised version of the proof we identified a one-parameter class of admissible entropies whose utility was illustrated with two phenomenologically relevant examples: 2-qubit quantum system and hadron productions in } pp \text{ collisions.}

Proof of an inference rule based on SJ axioms; part I — the sum form (3)

For the sake of completeness, we demonstrate here that axiom of uniqueness, permutation invariance and subset invariance lead to the sum form of the entropy (3), i.e.

$$U(P) = \sum_{i=1}^{n} g(p_i) \sim f \left( \sum_{i=1}^{n} g(p_i) \right).$$

where $f$ is a monotonic function. In our exposition we will loosely follow the main steps from the SJ original proof [1]. Let us first remind several observations. First, from the permutation invariance axiom we obtain that $U(P)$ is a symmetric function of $P = \{p_1, \ldots, p_n\}$. Let us now focus on the third axiom, i.e., subset invariance. Let us choose a subset $M \subseteq N = \{1, \ldots, n\}$. We further consider a constraint on the subset $M$, i.e.,

$$\sum_{j \in M} I_j^M p_j = \langle I^M \rangle \equiv I^M.$$

This constraint can be easily expanded to the whole state-space, when we define $I_j^M = 0$ for $j \notin M$. Conditional probabilities on $M$ are defined as

$$q_j^M = P(x_j|x_j \in M) = \frac{p_j}{\sum_{j \in M} p_j}.$$ (3)

Let us denote $r = \sum_{j \in M} p_j$. The conditional distribution on the set $N \setminus M$ is then defined as $q_j^{N \setminus M} = p_j/(1 - r)$. From the subset independence axiom, it should not matter whether we use MEP for the conditional distributions $Q^M = \{q_1^M, \ldots, q_m^M\}$ and $Q^{N \setminus M} = \{q_1^{N \setminus M}, \ldots, q_m^{N \setminus M}\}$ or for the full distribution $P$. The conditional distribution $Q^M$ does not depend on $Q^{N \setminus M}$ neither on $n$, because it is a solution of the MEP on the reduced space $M$.

Let us start by examining the MEP in terms of above Qs. From the subset independence axiom, we obtain that the MaxEnt procedure is equivalent to maximization of two functionals

$$U(Q^M) - \alpha_M \sum_{j \in M} q_j^M - \beta_M \sum_{j \in M} r I_j^M q_j^M,$$

$$U(Q^{N \setminus M}) - \alpha_{N \setminus M} \sum_{j \in N \setminus M} q_j^M,$$

which yield equations

$$\frac{\partial U(Q^M)}{\partial q_i^M} = \alpha_M (Q^M) + r \beta_M I_i^M = f(q_i^M, Q^{M-}) \equiv f_i^M,$$

$$\frac{\partial U(Q^{N \setminus M})}{\partial q_i^{N \setminus M}} = \alpha_M (Q^{N \setminus M}),$$

where $Q^{M-}$ is $Q^M$ without $q_i^M$. The form of $f$ is a consequence of permutation invariance of $U$.

Alternatively, we can formulate the problem for the full distribution as $U(P) - \alpha \sum_j p_j - \sum_j I_j^M p_j$ leading to

$$\frac{\partial U(P)}{\partial p_i} = \alpha(P) + \beta(P) I_i^M = h(p_i, P^{N-}) \equiv h_i,$$
where $P^{N-i}$ is $P$ without $p_i$. Let us now take $i \in M$ and express $\partial \mathcal{U}(P)/\partial p_i$ in terms of $Q^M$, i.e.

$$
\frac{\partial \mathcal{U}(P)}{\partial p_i} = \sum_{j \in M} \frac{\partial \mathcal{U}(Q^M)}{\partial q^M_j} \frac{\partial q^M_j}{\partial p_i}.
$$

(9)

In fact, since

$$
\frac{\partial q^M_j}{\partial p_i} = \frac{1}{r} - \frac{p_i}{r^2}, \quad \text{and} \quad \frac{\partial q^M_i}{\partial p_i} = -\frac{p_j}{r^2} \quad \text{for} \quad j \neq i,
$$

(10)

we have

$$
h_i = \frac{f^M_i}{r} - \frac{1}{r} \sum_{j \in M} q^M_j f^M_j.
$$

(11)

To proceed, we define the quantity

$$
W_{ijk} = \frac{h_i - h_j}{h_k - h_j} = \frac{f^M_i f_j^M}{f_k^M f_j^M},
$$

(12)

for $i, j, k \in M$. It is easy to check that $W$ fulfills the following functional relation

$$
W_{ijk} = \frac{W_{irv} - W_{jrv}}{W_{krv} - W_{jrv}}.
$$

(13)

This is the so-called Cantor functional equation which has the general solution

$$
W_{ijk} = \frac{u(p_i) - u(p_j)}{u(p_k) - u(p_j)},
$$

(14)

where $u(x)$ is an arbitrary function. By employing (12) and (14) we can deduce that

$$
h_i = \frac{\partial \mathcal{U}(P)}{\partial p_i} = s(P)u(p_i) + z(P).
$$

(15)

Here $s(P) = (h_k - h_j)/(u(p_k) - u(p_j))$ and $z(P) = h_j - u(p_j)s(P)$ ($j \in M$ is arbitrary). Note that $s(P)$ and $z(P)$ do not depend on an actual choice of indices $k, j \in M$. Indeed, for $s(P)$ we may write

$$
s(P) = \frac{h_k - h_j}{u(p_k) - u(p_j)} = \frac{h_i - h_j}{u(p_i) - u(p_j)} = \frac{h_j - h_l}{u(p_j) - u(p_l)} = \frac{h_r - h_l}{u(p_r) - u(p_l)},
$$

(16)

where 2nd and 4th equality results from the combination of Eqs. (12) and (13) while in 3rd equality we have simultaneously multiplied numerator and denominator by $-1$. Indices $l, r \in M$ are arbitrary. Independence of $z(P)$ on $j$ follows then immediately from the invariance of $h_i$ under arbitrary permutation of elements $p_j \in P^{N-i}$.

Since the above analysis does not depend on the cardinality of $M$, we can set now $M = N$. From (15) thus follows

$$
d\mathcal{U}(P) = \sum_i h_i dp_i = s(P) \sum_i u(p_i) dp_i + z(P) d\left(\sum_i p_i\right) = s(P) dG(P),
$$

(17)

where $d\mathcal{U}(P)$ is the exact differential and $G(P) = \sum_i g(p_i)$ with $g(x)$ being an antiderivative of $u(x)$, i.e., $u(x) = dg(x)/dx$. Result (17) directly shows that $\mathcal{U}(P)$ must be a function of $G(P)$, and the function itself, say $f$, is obtained by solving the equation $s(P) = df(G)/dG$. Moreover, the $f$-function must be monotonic, because $s(P)$ does not flip the sign. Indeed, if $P$ and $Q$ would be two distributions such that $s(P) > 0$ and $s(Q) < 0$ then for any trajectory $P(t)$ such that $P(0) = P$ and $P(1) = Q$ would need to exist a point $t_0 \in (0, 1)$, such that $s(P(t_0)) = 0$. However, from the definition of $s(P)$ it follows that $s(P) = 0$ if and only if $h_k = h_j$ for all $i, j$, which happens only for a single point in the probability simplex, namely the point corresponding to a uniform distribution $P_u$. Since the general trajectory connecting any two points in the probability simplex does not cross point $P_u$, $s(P)$ must always have the same sign with $P_u$ being merely extremal point of $s(P)$. This concludes the proof.
Proof of an inference rule based on SJ axioms; part II — axiom 4 without SJ factorization assumption

Axiom 4 can be restated as follows: Let us consider two systems A and B with the elementary outcomes \( \{a_i\}_{i=1}^n \) and \( \{b_j\}_{j=1}^m \), respectively. We denote the joint distribution of the composed system \( A \cup B \) as \( P(A=a_i, B=b_j) = p_{ij} \) and corresponding marginal distributions as \( u_i = \sum_j p_{ij} \) and \( v_j = \sum_i p_{ij} \). We further consider two independent constraints, affiliated with the two subsystem, i.e., \( \sum_{i=1}^n I_i u_i \equiv I \) and \( \sum_{j=1}^m J_j v_j \equiv J \). Each constraint can be naturally rewritten in terms of the joint distribution \( p_{ij} \), so that the Lagrange functional for the full distribution can be expressed (modulo equivalency condition) as

\[
\sum_{ij} g(p_{ij}) - \alpha \sum_{ij} p_{ij} - \beta_I \sum_{ij} I_i p_{ij} - \beta_J \sum_{ij} J_j p_{ij},
\]

which leads to

\[
g'(p_{ij}) - \alpha - \beta_I I_i - \beta_J J_j = 0.
\]

Similarly, the same problem can be formulated directly in terms marginal distributions \( u_i \) and \( v_j \). This immediately implies that the entropy functional is composable, i.e., \( \mathcal{U}(p_{ij}) = \Phi(\mathcal{U}(u_i), \mathcal{U}(v_j)) \) for some function \( \Phi \). By employing the assumption of the axiom 4, i.e., that independent systems with related constraints considered separately (i.e., in terms of marginal distributions) should be equivalent to (18), we see that \( \Phi \) must be proportional to the multiplication operation, i.e.

\[
\mathcal{U}(p_{ij}) = \mathcal{U}(u_i) \mathcal{U}(v_j) = \sum_i g(u_i) \sum_j g(v_j).
\]

As a result, we obtain that the Lagrange functional is equal to

\[
\sum_{ij} g(u_i)g(v_j) - \alpha \sum_{ij} u_i v_j - \beta_I \sum_{ij} I_i u_i - \beta_J \sum_{ij} J_j v_j.
\]

Our aim is now to rewrite the Lagrange functional in terms of \( u_i \) and \( v_j \). We first note that the term corresponding to the normalization condition can be rewritten as \( \alpha \sum_{ij} u_i v_j \) because \( \sum_{ij} p_{ij} = \sum_i u_i = \sum_j v_j = \sum_{ij} u_i v_j \). Note that this is true without assuming that \( p_{ij} = u_i v_j \). In other words, we do not need to assume anything about the actual factorization rule. This is indeed the crux of this work. Second, from permutation invariance of entropy and the fact that the subsystems are disjoint, we obtain that the Lagrange functional is symmetric under permutation of states. This is easily seen when (21) is rewritten as:

\[
\sum_{ij} g(u_i)g(v_j) - \alpha \sum_{ij} u_i v_j - \beta_I \sum_{ij} I_i u_i - \beta_J \sum_{ij} J_j v_j.
\]

The extremization procedure provides the equations determined by derivatives under \( u_i \) and \( v_j \), respectively, i.e.

\[
g'(u_i) \sum_j g(v_j) - \alpha \sum_j v_j - \beta_I \sum_j I_i v_j - \beta_J \sum_j J_j v_j = 0,
\]

\[
g'(v_j) \sum_i g(u_i) - \alpha \sum_i u_i - \beta_J \sum_i J_i u_i - \beta_J \sum_i J_i v_j = 0.
\]

By taking another derivative w.r.t. \( v_j \) and \( u_i \), respectively, we obtain a single identity

\[
g'(u_i)g'(v_j) - \alpha - \beta_I I_i - \beta_J J_j = 0.
\]

By comparing (19) with (23) we obtain the multiplicative Cauchy functional equation \( g'(u_i)g'(v_j) = g'(u_i)g'(v_j) \), which has the general solution \( g(x) = x^r \) for any \( r \in \mathbb{R} \). Consequently, \( g(x) = x^{r+1}/(r+1) + a \) with \( a \in \mathbb{R} \). So, any entropy functional consistent with SJ axioms should be equivalent to \( \sum_i p_i^a \), where \( q = r + 1 \).

At this stage one should distinguish two cases, i.e., \( q \leq 1 \), and \( q \geq 1 \). For \( q \leq 1 \), the function \( g(x) = x^q \) is concave, while for \( q \geq 1 \) it is convex. Thus, one might merge both cases into a single functional of the form (cf. also (8))

\[
U_q(P) = \left( \sum_i p_i^q \right)^{1/(1-q)}
\]
which is Schur-concave for \( q > 0 \). It should be stressed that the Schur-concavity is a sufficient condition for \textit{maximality axiom} (see, e.g., Refs. [2, 5]). The case \( q > 0 \), is ruled out by the \textit{maximality axiom}, because for \( q \leq 0 \) we obtain a local minimum for \( P_u \), instead of the required maximum. This closes the proof. In passing we might note that for \( q \to 1 \) we obtain \( \mathcal{U}_1(P) = \exp[\mathcal{H}(P)] \) where \( \mathcal{H}(P) = -\sum p_i \log p_i \) is the Shannon entropy. Functional \( \mathcal{U}_1(P) \) is known as Shannon’s entropy power.

Let us finally stress that should we have assumed (in addition to the SJ axioms) the factorization rule \( p_{ij} = u_i v_j \), then as shown in the main text only \( \mathcal{U}_1(P) \) would be consistent with this requirement. Then, Shannon’s entropy (modulo equivalency condition) would be indeed the only consistent candidate for MEP. So, the uniqueness of Shannon’s entropy can be ensured only when an extra axiom is added to SJ consistency axioms, namely:

\textit{Strong system independence}: Whenever two subsystems of a system are disjoint, we can treat the subsystems in terms of independent distributions.

\textit{Expansion of cumulants for weak correlations}

Here we show how one can obtain equations (21) and (22) in the main text. Let us remind the definition of the cumulants \( \Gamma_i^R \) and \( \Gamma_{ij}^R \) (the varentropy), namely

\[
\Gamma_i^R = -\sum_k r_k \ln r_k, \quad \Gamma_{ij}^R = \sum_k r_k \ln^2 r_k - \left( \sum_k r_k \ln r_k \right)^2. \tag{27}
\]

We further consider two subsystems with respective distributions \( U = \{u_i\}_1^n \) and \( V = \{v_j\}_1^m \). The resulting compound system is described by the probability distribution \( P = \{p_{ij}\}_{i,j}^{n,m} \). Let us now assume that the systems are \textit{weakly correlated} so that we can write

\[
p_{ij} \approx (1 + \epsilon_{ij}) u_i v_j, \tag{28}
\]

for some matrix \( \epsilon_{ij} \) with the \textit{max norm} satisfying \( \|\epsilon\|_{\max} = \max_{ij} |\epsilon_{ij}| \ll 1 \). The corresponding \( \Gamma_i^P \) reads

\[
\Gamma_i^P \approx -\sum_{ij} (1 + \epsilon_{ij}) u_i v_j \left[ \ln(u_i v_j) + \epsilon_{ij} - \frac{1}{2} \epsilon_{ij}^2 \right]
\]

\[
= -\sum_{ij} u_i v_j \ln(u_i v_j) - \sum_{ij} \epsilon_{ij} u_i v_j \ln(u_i v_j) - \sum_{ij} \epsilon_{ij} u_i v_j - \frac{1}{2} \sum_{ij} \epsilon_{ij}^2 u_i v_j, \tag{29}
\]

where we used that \( \ln(1 + \epsilon_{ij}) \approx \epsilon_{ij} \). Clearly, only the first and last term are non-zero. This can be easily seen by realizing that Eq. (28) implies \( \sum_i \epsilon_{ij} u_i = \sum_j \epsilon_{ij} v_j = 0 \) and hence for any two non-singular functions \( f \) and \( g \) we have

\[
\sum_{ij} \epsilon_{ij} u_i v_j [f(u_i) + g(v_j)] = \sum_i f(u_i) u_i \sum_j \epsilon_{ij} v_j + \sum_j g(v_j) v_j \sum_i \epsilon_{ij} u_i = 0. \tag{30}
\]

The second and third term in Eq. (29) have exactly this form and are therefore zero. The first term can be rewritten in terms of cumulants of the marginal distributions and the last term is just the average value of \( \epsilon_{ij}^2 \). By using the fact that \( v_j \) and \( u_i \) are positive, then the last term is zero if and only if \( \epsilon_{ij} = 0 \) for all \( i, j \), i.e., for \textit{independent} systems. Consequently, one can rewrite \( \Gamma_i^P \) as

\[
\Gamma_i^P = \Gamma_i^U + \Gamma_i^V - \frac{1}{2} \langle \epsilon^2 \rangle_0 + \mathcal{O}(\epsilon^3), \tag{31}
\]

where \( \langle \epsilon^2 \rangle_0 = \sum_{ij} \epsilon_{ij}^2 u_i v_j \). Along the same lines we can write also \( \Gamma_{ij}^P \), namely

\[
\Gamma_{ij}^P = \sum_{ij} p_{ij} \ln^2 p_{ij} - [\Gamma_i^P]^2 \approx \sum_{ij} (1 + \epsilon_{ij}) u_i v_j \left[ \ln^2(u_i v_j) + 2 \epsilon_{ij} \ln(u_i v_j) + \epsilon_{ij}^2 \right] - \left( \Gamma_i^U + \Gamma_j^V - \frac{1}{2} \langle \epsilon^2 \rangle_0 \right)^2
\]

\[
= \sum_{ij} u_i v_j \left( \ln^2 u_i + 2 \ln u_i \ln v_j + \ln^2 v_j \right) + \sum_{ij} \epsilon_{ij} u_i v_j \ln^2(u_i v_j) - \left( \Gamma_i^U \right)^2 - \left( \Gamma_j^V \right)^2 - 2 \Gamma_i^U \Gamma_j^V + \mathcal{O}(\epsilon^2), \tag{32}
\]

where we neglected all terms containing \( \epsilon_{ij}^2 \) and higher orders. Putting everything together, we obtain

\[
\Gamma_{ij}^P = \Gamma_{ij}^U + \Gamma_{ij}^V + \langle \epsilon \ln^2(UV) \rangle_0 + \mathcal{O}(\epsilon^2), \tag{33}
\]

where \( \langle \epsilon \ln^2(UV) \rangle_0 = \sum_{ij} \epsilon_{ij} \ln^2(u_i v_j) u_i v_j = 2 \langle \epsilon \ln(U) \ln(V) \rangle_0 \).
Calculation of $\rho_{\text{MEP}}$

Here we calculate $\rho_{\text{MEP}}$. The variation of the related Lagrange functional yields the equation

$$0 = \frac{q}{1-q} [U_q(\rho)]^q \text{Tr} \left( \rho^{q-1} \delta \rho \right) - \alpha \text{Tr} (\delta \rho) - \beta \text{Tr} (B \delta \rho),$$

which gives [cf. (5) and (6)]

$$\frac{q}{1-q} [U_q(\rho)]^q \rho^{q-1} - \alpha \rho - \beta B = 0,$$

and hence

$$\rho_{\text{MEP}} = \left\{ \frac{(1-q)}{q} [U_q(\rho_{\text{MEP}})]^{-q} [\alpha + \beta B] \right\}^{1/(q-1)} = \frac{(\alpha + \beta B)^{1/(q-1)}}{\text{Tr} \left[ (\alpha + \beta B)^{1/(q-1)} \right]}.$$

Let us note that when we multiply (35) by $\rho$ and simultaneously take $\text{Tr} \cdots$ we obtain

$$\alpha = \frac{1}{1-q} U_q(\rho_{\text{MEP}}) - \beta b,$$

where $b = \text{Tr}(B \rho)$. This directly provides the forms (7) and (8).

To proceed we notice that the Bell-CHSH observable $B$ is a (scaled) involutory operator, namely $B^{2n} \equiv A = |\Phi^+\rangle\langle \Phi^+| + |\Psi^-\rangle\langle \Psi^-|$ and $B^{2n-1} = B$ with $n = 1, 2, \ldots$. By employing the binomial expansion we get

$$(\alpha + \beta B)^{1/(q-1)} = \alpha^{1/(q-1)} \sum_{k=0}^{\infty} \left( \frac{1-q}{q} \right)^k \left( \frac{\beta}{\alpha} \right)^k B^k = \alpha^{1/(q-1)} (|\Phi^+\rangle\langle \Phi^+| + |\Psi^-\rangle\langle \Psi^-|) + (\alpha + \beta)^{1/(q-1)} |\Phi^+\rangle\langle \Phi^+| + (\alpha - \beta)^{1/(q-1)} |\Psi^-\rangle\langle \Psi^-|,$$

where

$$\left( \frac{1-q}{q} \right)^k = \frac{1}{q-1} \left( \frac{1}{q-1} - 1 \right) \left( \frac{1}{q-1} - 2 \right) \cdots \left( \frac{1}{q-1} - k + 1 \right),$$

is the (generalized) binomial coefficient. With this we can write

$$\rho_{\text{MEP}} = \frac{\alpha^{1/(q-1)} (|\Phi^+\rangle\langle \Phi^+| + |\Psi^-\rangle\langle \Psi^-|) + (\alpha + \beta)^{1/(q-1)} |\Phi^+\rangle\langle \Phi^+| + (\alpha - \beta)^{1/(q-1)} |\Psi^-\rangle\langle \Psi^-|}{2\alpha^{1/(q-1)} + (\alpha + \beta)^{1/(q-1)} + (\alpha - \beta)^{1/(q-1)}}$$

$$\equiv p_{\Phi^+} |\Phi^+\rangle\langle \Phi^+| + p_{\Psi^-} |\Psi^-\rangle\langle \Psi^-| + p_{\Phi^+} |\Phi^+\rangle\langle \Phi^+| + p_{\Psi^-} |\Psi^-\rangle\langle \Psi^-|.$$

Consequently, $\rho_{\text{MEP}}$ is diagonal in the Bell basis. Note that the uniqueness theorem requires that $\alpha \geq |\beta|$, which also ensures that $\rho_{\text{MEP}}$ has real and positive spectrum. From (40) we see that $p_1$ and $p_2$ are clearly $\leq 1/2$. In addition, for $q \geq 2$ we can conclude that $p_3$ and $p_4$ are also $\leq 1/2$. Indeed, from concavity of $x^{1/(q-1)}$ for $q \geq 2$ we have

$$\alpha^{1/(q-1)} = \left[ \frac{1}{2} (\alpha + \beta) + \frac{1}{2} (\alpha - \beta) \right]^{1/(q-1)} \geq \frac{1}{2} (\alpha + \beta)^{1/(q-1)} + \frac{1}{2} (\alpha - \beta)^{1/(q-1)},$$

where the last inequality is due to Jensen’s inequality for concave functions. Hence

$$p_{\Phi^+} = \frac{(\alpha + \beta)^{1/(q-1)}}{2\alpha^{1/(q-1)} + (\alpha + \beta)^{1/(q-1)} + (\alpha - \beta)^{1/(q-1)}} \leq \frac{(\alpha + \beta)^{1/(q-1)}}{2(\alpha + \beta)^{1/(q-1)} + 2(\alpha - \beta)^{1/(q-1)}} \leq \frac{1}{2};$$

and similarly for $p_{\Psi^-}$. Consequently, according to [65] we have for $q \geq 2$ that $\rho_{\text{MEP}}$ is not entangled (i.e. is separable).

Situation for $q < 2$ is not conclusive and we should determine the Lagrange multipliers to be more specific. To this end we notice that in $\rho_{\text{MEP}}$ it is only the ratio $\beta/\alpha$ that needs to be determined. By employing the constraint $b = \text{Tr}(B \rho)$ we obtain from (40)

$$b = \frac{(1 + \frac{\beta}{\alpha})^{1/(q-1)} - (1 - \frac{\beta}{\alpha})^{1/(q-1)}}{2 + (1 + \frac{\beta}{\alpha})^{1/(q-1)} + (1 - \frac{\beta}{\alpha})^{1/(q-1)}}.$$
This is a transcendental equation for $\beta/\alpha$ which allows, at least numerically, to solve $\rho_{MEP}$ for desired values of $q$ and $b$. Analytical form of the solution for generic $q$ and $b$ is not possible but fortunately the case $q = 1$ (i.e. Shannon’s case) can be done quite easily. In this case we obtain

$$p_{\Phi^-} = p_{\Phi^+} = \frac{1}{4} (1 - b^2) , \quad p_{\Psi^+} = \frac{1}{4} (1 - b)^2 , \quad p_{\Psi^-} = \frac{1}{4} (1 + b)^2.$$  \hspace{1cm} (44)

So, particularly for $b > \sqrt{2} - 1$ we have entanglement (i.e. the MEP state is *inseparable*) or, in other words, for $b \in (\sqrt{2} - 1, 1]$ Shannonian MEP predicts entanglement even if there exists for $b \in (\sqrt{2} - 1, 1]$ a *separable* state that is fully compatible with the constraining data.
