Collapse of Kondo state and ferromagnetic quantum phase transition in YbFe$_2$Zn$_{20}$

Udhara S. Kaluarachchi, Li Xiang, Jianjun Ying, Tai Kong, Viktor Struzhkin, Alexander Gavriliuk, Sergey L. Bud’ko, and Paul C. Canfield

INTRODUCTION

Among the rare-earth-based intermetallic compounds, Ce and Yb-based materials have attracted much attention due to their peculiar properties [1–14]. The properties of these compounds are usually dominated by two characteristic energy scales: Ruderman-Kittel-Kasuya-Yosida (RKKY) [15–17] and Kondo [18, 19] interaction energies. The exchange interaction, $J$, which determines the interaction energy between local moments and conduction electron, $T_K \propto e^{-1/J}$, is also responsible for the coupling between local moments through the RKKY interaction, $T_{RKKY} \propto J^2$. Hence, the ground state of these compounds is determined by the competition between these two energy scales and often described by the Doniach phase diagram [20]. When $T_K \gg T_{RKKY}$ the ground state in nonmagnetic and when $T_K \ll T_{RKKY}$, magnetic order can be established. The most interesting situation occurs when the two energy scales are comparable and the system can be tuned through a $T = 0$ K magnetic instability at a quantum phase transition (QPT). Application of external pressure is one of the ways to tune the $J$ [21, 22], bringing the material to a QPT or QCP (quantum critical point).

Often Yb is considered as a "hole" equivalent of Ce. In contrast to Ce compounds, where magnetic ordering is suppressed by pressure, in Yb systems, increasing pressure can tune the system from a nonmagnetic state to a magnetic one [8, 12]. There are only a few examples of the pressure induced, nonmagnetic-to-magnetic phase transitions in Yb compounds [2, 5, 6, 23–28] and, so far, superconductivity has been reported in only two materials [11, 29].

The Yb$T_2$Zn$_{20}$ ($T = $Fe, Ru, Os, Co, Rh, Ir) series is a Yb-based heavy fermion system [30–34] which belongs to the $RT_2$Zn$_{20}$ family [35]. For all six members, at high temperature, the magnetic susceptibility measurements show Curie-Weiss behavior with the effective moment close to the Yb$^{3+}$ [30, 31]. In the resistivity measurements, there are no signs for the magnetic ordering down to 20 mK [30, 31]. Among this Yb$T_2$Zn$_{20}$ series, YbCo$_2$Zn$_{20}$ has the lowest $T_K$ and the largest Sommerfeld coefficient of the six members [30, 31]. By combining the Doniach model with this small $T_K$ and large Sommerfeld coefficient, one can assume that YbCo$_2$Zn$_{20}$ is close to a possible magnetic QCP. With this idea, Saiga et al. [26] performed a high pressure resistivity measurement on YbCo$_2$Zn$_{20}$ and observed a pressure induced QCP at a critical pressure $\sim$ 1 GPa and antiferromagnetic (AFM) ordering at higher pressures. Apart from this, a field induced ordered phase has been observed at the ambient pressure in YbCo$_2$Zn$_{20}$, possibly due to the crystal electric field level crossing [36–41]. A pressure induced QCP has also been estimated for YbIr$_2$Zn$_{20}$ ($\approx 5.2$ GPa) and YbRh$_2$Zn$_{20}$ ($\approx 5.2$ GPa), however, for YbRh$_2$Zn$_{20}$ no pressure induced magnetic transitions have been observed so far [42–45].

Several years ago, high pressure resistivity measure-
ments were performed up to 8.23 GPa for YbFe$_2$Zn$_{20}$ [46]. Increasing pressure drives $T_K$ to lower values and enhanced the $A$-coefficient ($\Delta \rho(T) \propto AT^2$): a QCP of $\sim$ 10 GPa was inferred [46]. In this work, by employing a diamond anvil cell in a dilution refrigerator, we extend the pressure range up to $\sim$ 26 GPa and lower the base temperature to 50 mK. As a result we find a clear feature in resistivity that we identify as a magnetic phase transition in YbFe$_2$Zn$_{20}$ for $p > 18.2$ GPa. The transition temperature is about 1 K and does not change with further increase of pressures up to 26 GPa. We tentatively identify the transition as ferromagnetic in nature and associate the step-like feature in $T_C(p)$ with an avoided quantum criticality QPT.

**EXPERIMENTAL METHODS**

Single crystals used for this study were grown using a high-temperature solution growth technique [47, 48] with the help of frit-disc crucible set [49]. More details about the crystal growth can be found in Refs. 30, 50, and 51. Temperature and field dependent resistivity measurements were carried out using a Quantum Design Physical Property Measurement System from 1.8 K to 300 K. A dilution refrigerator option was utilized to perform measurements down to 50 mK. The resistivity was measured using the van der Pauw method [52, 53] with ac-current ($I = 0.005$ mA, $f = 18.3$ and 21.3 Hz) parallel to the [111] plane and a magnetic field was applied perpendicular to the current plane. A miniature diamond anvil cell [54], with 300 $\mu$m culets, was used to generate the pressure for the resistivity measurement and KCl powder was used as a pressure transmitting medium. The temperature gradient between the dilution refrigerator thermometer and sensor positioned on miniature diamond anvil cell close to the anvils was evaluated in a separate experiment and was found negligible with the protocol of the measurement used in this work. Single crystals with a typical dimension of $80 \times 80 \times 20 \, \mu$m$^3$ were loaded into the sample chamber with an inner diameter of 130 $\mu$m made out of a cubic BN gasket. Pressure was applied at room temperature and ruby fluorescence, at 300 K was used to determine the pressure[55].

**RESULTS AND DISCUSSION**

Temperature dependent resistivity measurements on three different samples of YbFe$_2$Zn$_{20}$ under pressures up to 26.4 GPa are shown in Fig. 1. For each pressure, resistivity values are normalized to the lowest pressure, 300 K resistivity value of each sample. For sample 1, when increasing the pressure, the 300 K resistivity, $\rho_{300K}$, is monotonically suppressed, which is similar to Ref. 46. For sample 2 and 3, as indicated in Figs. 1 (b) and (c), $\rho_{300K}$ shows a non-monotonic dependence on pressure when higher pressure values are achieved. However, for $p \lesssim 18$ GPa, $\rho_{300K}$ shows relatively small variation with pressure, while for $p \gtrsim 18$ GPa, $\rho_{300K}$ systematically increases with pressure. Fig. 2 presents the pressure evolution of the normalized $\rho_{300K}$ with pressure. As indicated in the figure, $\rho_{300K}$ stays relatively flat for $p \lesssim 18$ GPa and continuously increases for $p \gtrsim 18$ GPa. Fig. 3 presents a low temperature expanded view of the data presented in Fig. 1. In addition to the increased $\rho_{300K}$ for $p \gtrsim 18$ GPa there is also the clear onset of a relatively sharp, low temperature feature (Fig. 3) for $p \gtrsim 20$ GPa. Whereas these are qualitative changes we will now examine these data quantitatively.
For all measured pressures, for $T > 50$ K, the resistivity data show a nearly linear temperature dependence (Fig. 1). It is worth noting that the high-temperature slope ($250$ K $< T < 300$ K) of the resistivity decreases with increasing pressure up to about $10$ GPa and then remains constant for higher pressures. Below $50$ K, there is a broad shoulder in the resistivity data for $p < 3.4$ GPa that changes into a broad maximum ($T_{\text{max}}$) with pressure increasing above $3.6$ GPa. The value of $T_{\text{max}}$ usually scales with the Kondo temperature, $T_K$. It moves to lower temperatures with increasing pressure up to about $20$ GPa and then shows a sudden increment for $p > 20$ GPa. The behavior of pressure dependence of the $T_{\text{max}}$ (for $p < 9.6$ GPa) is consistent with the previous work [46].

The total resistivity of the YbFe$_2$Zn$_{20}$ can be expressed as a combination of normal metallic behavior and a magnetic contribution. As mentioned above, the high-temperature resistivity shows a nearly linear temperature dependence, indicating that phonon scattering is dominant in the high temperature range. Normal metallic behavior can be approximated by considering the temperature dependent resistivity of non-magnetic LuFe$_2$Zn$_{20}$. Therefore, the magnetic contribution to the resistivity of YbFe$_2$Zn$_{20}$ can be estimated by subtracting the LuFe$_2$Zn$_{20}$ resistivity data from YbFe$_2$Zn$_{20}$ data. Since the residual resistivity values of our samples show non-monotonic increments, first we have to subtract their residual resistivity values for each data set and then normalize the high temperature ($T > 275$ K) slope of the resistivity to that of LuFe$_2$Zn$_{20}$. This can be written as

$$\rho_{\text{mag}}(T) = (\rho_{\text{Yb}} - \rho_{\text{Yb},0}) \frac{d\rho_{\text{Yb},0}}{dT} \mid_{275K} - (\rho_{\text{Lu}} - \rho_{\text{Lu},0}) \mid_{275K}$$  (1)

Similar analysis has been used to determine the $\rho_{\text{mag}}(T)$ in Ref. 33, $\rho_{\text{mag}}(T)$ data for samples 2 and 3 are shown in Figs. 4 (a) and (b) respectively. For both samples, $T_{\text{max1}}$ decreases with increasing pressure up to about $20$ GPa and then shows a sudden change (jump up in temperature) for higher pressures. $T_{\text{max2}}$ is the temperature corresponding to this higher pressure, broad, maximum in the $\rho_{\text{mag}}(T)$ low temperature data. The solid black triangles and open red squares indicate the $T_{\text{max1}}$ and $T_{\text{max2}}$ respectively.

The evolution of the low temperature resistivity for samples 2 and 3 are shown in Figs. 5 (a) and (b) respectively. For $T < T_{\text{max}}$ and $p < 18.2$ GPa, the resistivity of both samples decreases with decreasing temperature and there is no pronounced anomaly down to $50$ mK.
When the pressure exceeds $p_c = 18.2 \pm 0.8$ GPa, the resistivity shows a kink/sharp drop, suggesting a loss of spin-disorder-scattering and magnetic ordering at $T_M$. The peak in the temperature derivative of the resistivity $d\rho/dT$ is used to determine the ordering temperature, $T_M$, as shown in Figs. 5 (c) and (d). As can be seen, the peak position does not change with the pressure and remains essentially the same up to 26 GPa. From the resistivity measurements, we cannot determine the nature of the magnetic transition, however, as shown in Fig. 6, application of magnetic field broadens the kink/sharp drop of the resistivity and moves it to higher temperatures, which suggests that this is not a structural phase transition. Instead, this is typical behavior for a ferromagnetic transition.

A pressure-temperature phase diagram can be constructed and shown in Fig. 7 using the data from Figs. 4 and 5 as well as data from Ref. 46. Black solid triangles and red open squares represent the data obtained from Fig. 4. The $T_{\text{max}}$ obtained from Ref. 46 is represented by open green triangles.

Figs. 7 and 2 demonstrate three changes that take place as pressure increases through $p \sim 20$ GPa. At low temperatures ($\sim 1$ K) there is the sudden appearance of a transition that is arguably ferromagnetic. At intermediate temperatures there is the disappearance of an $\sim 10$ K resistive maximum associated with the Kondo effect and the appearance of an 30-40 K resistive feature that is most likely associated with CEF splitting [56, 57]. At higher temperatures, all the way up to room temperature, there is a marked increase in resistivity that starts around 15 GPa and appears to saturate by $\sim 25$ GPa. Taking these three observations together, our results strongly suggest that by $\sim 20$ GPa there is a band structure change associated with the dropping of the Yb-4$f$-levels below the Fermi level. As a result, the Yb-4$f$-levels stop being hybridized and the system enters the magnetic regime in the Doniach phase diagram.

These results can be put in the context of the RFecZn$_{30}$ ($R = \text{Gd-Tm}$) series which shows a clear de Gennes scaling of its ferromagnetic ordering temperature [33, 50]. According to the de Gennes scaling, if Yb$^{3+}$ were to be
purely local-moment-like, YbFe2Zn20 would order ferromagnetically at about 1 K. This is essentially what we find for \( p > p_c \). The suggested pressure-induced ferromagnetic ordering in YbFe2Zn20 is not too surprising, if we look at other intermetallic compounds in \( RT_2Zn_{20} \) family\[31, 33\]. Taking Gd\( T_2Zn_{20} \) series for example, ferromagnetic ordered ground state is found for members in the iron column (\( T = Fe, Ru \) and Os) while antiferromagnetic ordered ground state in the cobalt column (\( T = Co, Rh \) and Ir)\[31\]. Moreover, the pressure-induced ordered states in YbCo\( 2Zn_{20} \) and YbIr\( 2Zn_{20} \) have also been suggested as AFM ordering\[39, 44\]. Taking YbFe\( 2Zn_{20} \) in this study together, \( RT_2Zn_{20} \) family seems to follow the rule that for the iron column members, ferromagnetic ordering is expected, while for the cobalt column members, antiferromagnetic ordering is expected.

\( T_M \) appears to abruptly develop above \( p_c \), suggesting the first-order nature of the quantum phase transition at \( p_c \). This is consistent with the growing number of examples of avoided quantum criticality in ferromagnetic metals\[58–61\]. According to the current theoretical understanding, a continuous PM to FM transition is not possible at \( T = 0 \) K, when suppressing the FM phase with a clean parameter such as pressure\[62\]. Two possibilities have been proposed\[63, 64\]: either the transition becomes of the first order\[59, 65–67\] or the modulated magnetic phase appears to replace the ferromagnetic one\[58, 68, 69\]. In order to check for hysteresis effects (first order transition), the resistivity measurements were carried out with both increasing and decreasing temperatures at 26.4 GPa (see Fig. 8). However, no hysteretic behavior is observed. This could be due to a weak-first-order transition, where the hysteresis is small and may not be detected experimentally. Also, it could be due to 26.4 GPa being higher than the pressure that corresponds to the tricritical point, so that, at 26.4 GPa, the transition is second order in temperature.

FIG. 6. (Color online) Temperature dependence of the resistivity at various magnetic fields for (a) \( p = 22.6 \) GPa and (b) \( p = 26.4 \) GPa.

FIG. 7. (Color online) Temperature-pressure phase diagram of YbFe\( 2Zn_{20} \) as determined from resistivity measurement. \( T_M, T_{\text{max}1} \) and \( T_{\text{max}2} \) are obtained using the criteria described in Fig. 4 and 5. The green open triangles are obtained from Ref. 46. Vertical arrow represents the critical pressure \( p_c = 18.2 \pm 0.8 \) GPa for ferromagnetic transition as well as 4f-localization. The error bars of \( p \) are determined by performing ruby fluorescence on several locations inside the sample space. The error bars of temperature are determined as half the data spacing.

FIG. 8. (Color online) (a) Temperature dependence of the resistivity at 26.4 GPa for increasing (red solid squares) and decreasing (blue solid circles) temperature. (b) Temperature derivative of \( \rho \) for both increasing (red solid squares) and decreasing (blue solid circles) temperature.

Let’s consider more details about the temperature variation of the resistivity. Figs 9 (a)-(c) show the \( \rho - \rho_0 \) versus \( T \) for sample 1, 2 and 3 to emphasize the low-temperature exponent, \( n \), which appears as the slope on a log-log scale. At low-pressures (in Fig. 9 (a) \( p < 3.4 \) GPa), \( \rho - \rho_0 \) obeys
FIG. 9. (Color online) $\rho - p$ vs $T$ for (a) sample 1 (b) sample 2 and (c) sample 3 in log-log scale for selected pressures. The Red, green and blue dashed lines are guides showing slopes for various low-temperature exponents, $n = 1, 1.5$ and 2 respectively. (d) Evolution of $n$ as a function of pressure. Corresponding $n$ is obtained by fitting (a)-(c) with $\rho - p_0 = AT^n$. For $p > p_c$, fitting was done for $T < T_M$. $T^2$ and for the intermediate pressures ($p \sim 6$ GPa) it follows $T^{1.5}$. For higher pressures ($9$ GPa $< p < 18$ GPa), $\rho - p_0$ shows linear $T$ dependence over a wide range of temperature. A $T$-linear resistance has been observed in several compounds, such as; CeCoIn$_5$ [70], CeRhIn$_5$ [71, 72], YbRh$_2$Si$_2$ [73–75], YbAgGe[9, 76] and CeNi$_2$Ge$_2$ [77]. Evolution of the temperature power-law exponent $n$ with pressure is summarized in Fig. 9 (d). The value of $n$ is obtained from a sliding window fit to $\rho - p_0 = AT^n$, where $\rho_0$ is obtained from the fit at the lowest temperature. Since the data have been taken down to 0.05 K, the value of $\rho_0$ can be obtained more accurately than was possible for Ref. 46. As can be seen, $n$ is clearly deviating from 2 for higher pressures. Power-law analysis from Ref. 46 indicates $n = 2$ even at $p \sim 8$ GPa (see Figs. 5 and 9 in Ref. 46). This most likely led to the low estimated value of $p_c$ based on the divergence of $\Delta$-coefficient in Ref. 46. For $p > p_c$ the low temperature loss of spin disorder feature has $\propto T^n$ behavior most likely associated with spin excitation scattering not too far below $T_c$. As indicated in Fig. 9 (d), as pressure is increased above $p_c$, $n$ quickly deviates from 1.

From the constructed $p - T$ phase diagram (Fig. 7), it is shown that for YbFe$_2$Zn$_{20}$, at the low temperature region, the associated Kondo temperature $T_{\text{max}1}$ is first suppressed with increasing pressure. At $p_c$, a possibly ferromagnetic transition $T_M$ suddenly appears at $\sim 1$ K and stays unchanged with further increasing pressure. This suggests that for YbFe$_2$Zn$_{20}$, the quantum criticality is avoided by going through a first-order QPT under pressure, which is in contrast to the YbCo$_2$Zn$_{20}$ and YbIr$_2$Zn$_{20}$, where they enter AFM ordered states through QCP[26, 39, 44]. At high temperature, a continuously increase of the resistivity with pressure was observed for $p > p_c$ (Fig. 2), suggesting that the suppressing of hybridization and developing of the Yb$^{3+}$ local moment is more continuous in nature.

CONCLUSIONS

In summary, we have measured the resistivity of YbFe$_2$Zn$_{20}$ up to $\sim 26$ GPa and down to 50 mK. Above a critical pressure, $p_c = 18.2 \pm 0.8$ GPa, we observed the resistivity anomaly at $T_{\text{M}} \sim 1$ K, which remains constant with increasing pressure. This anomaly appears to correspond to a ferromagnetic transition, since the application of magnetic field broadened the transition and moved it to higher temperature. Increasing pressure drives the $T_{\text{max}}$, the associated Kondo temperature, to lower values and flattening at pressures up to $p_c$ indicating a decrease of the hybridization strength. Above $p_c$, $T_{\text{max}}$ abruptly increases with pressure. In this pressure range $T_{\text{max}}$ can be attributed to the crystal electric field effects. In heavy fermion non-magnetic phase, the low temperature power law exponent is deviated from the Fermi liquid behavior for $p > 3.4$ GPa and reached $n = 1$ for 9 GPa $< p < p_c$. 
The reason for this unusual exponent value, \( n = 1 \), over large range of pressure is not clear so far. Additionally, our data suggests that at \( \sim p_c \) there is a band structure change associated with the dropping of 4f-levels below the Fermi level.
