Inner approximation algorithm for solving linear multiobjective optimization problems

Laszlo Csirmaz

Dedicated to the memory of Fantisek Matúš

Abstract—Benson’s outer approximation algorithm and its variants are the most frequently used methods for solving linear multiobjective optimization problems. These algorithms have two intertwined constituents: one-dimensional linear optimization one one hand, and a combinatorial part closely related to vertex enumeration on the other. Their separation provides a deeper insight into Benson’s algorithm, and points toward a dual approach different from the one defined by Ehrgott, Löhne and Shan [7]. Two skeletal algorithms are defined and instantiated with different separation oracles to yield a sequential convex hull algorithm, a new version of Benson’s algorithm with the theoretically best possible iteration count, and the new algorithm. The new algorithm has several advantages. First, the corresponding one-dimensional optimization problem uses the original constraints without adding any extra variables or constraints. Second, its iteration count meets the theoretically best possible one. As a dual algorithm, it is sequential: in each iteration it produces an extremal solution, thus can be aborted when a satisfactory solution is found. The Pareto front can be “probed” or “scanned” from several directions at any moment without adversely affecting the efficiency. Finally, it is well suited to handle highly degenerate problems where there are many linear dependencies among the constraints. On problems with 20 or more objectives the implementation shows a more than 10-fold increase in efficiency compared to Benson – due to the reduced number of iterations and the improved combinatorial handling.

I. INTRODUCTION

Our notation is standard and mainly follows that of [7], [10]. The transpose of the matrix \( M \) is denoted by \( M^T \). Vectors are usually denoted by small letters and are considered as single column matrices. For two vectors \( x \) and \( y \) of the same dimension, \( xy \) denotes their inner product, which is the same as the matrix product \( x^T y \). The \( i \)-th coordinate of \( x \) is denoted by \( x_i \), and \( x \leq y \) means that for every coordinate \( i \), \( x_i \leq y_i \). The non-negative orthant \( \mathbb{R}_+^n \) is the collection of vectors \( x \in \mathbb{R}^n \) with \( x \geq 0 \), that is, vectors whose coordinates are non-negative numbers.

For an introduction to higher dimensional polytopes see [14], and for a description of the double description method and its variants, consult [2]. Linear multiobjective optimization problems, methods, and algorithms are discussed in [7] and the references therein.

A. The MOLP problem

Given positive integers \( n, m, \) and \( p \), the \( m \times n \) matrix \( A \) maps the problem space \( \mathbb{R}^n \) to \( \mathbb{R}^m \), and the \( p \times n \) matrix \( P \) maps the problem space \( \mathbb{R}^n \) to the objective space \( \mathbb{R}^p \). For better clarity we use \( x \) to denote points of the problem space \( \mathbb{R}^n \), while \( y \) denotes points in the objective space \( \mathbb{R}^p \). In the problem space a convex closed polytope \( A \) is specified by a collection of linear constraints. For simplicity we assume that the constraints are given in the following special format. This format will only be used in Section V.

\[
A = \{ x \in \mathbb{R}^n : Ax = c, x \geq 0 \},
\]

where \( c \in \mathbb{R}^m \) is a fixed vector. The \( p \)-dimensional linear projection of \( A \) is given by the \( p \times n \) matrix \( P \)

\[
Q = PA = \{ Px : x \in A \}.
\]

Using this notation, the multiobjective linear optimization problem can be cast as follows:

\[
\text{find } \min_y \{ y : y \in Q \}, \quad \text{MOLP}
\]

where minimization is understood with respect to the coordinate-wise ordering of \( \mathbb{R}^p \). The point \( \hat{y} \in Q \) is non-dominated or Pareto optimal, if no \( y \leq \hat{y} \) different from \( \hat{y} \) is in \( Q \), and it is weakly non-dominated if no \( y < \hat{y} \) is in \( Q \). Solving the multiobjective optimization problem is to find (a description of) all non-dominated vectors.

Let \( Q^+ = Q + \mathbb{R}_+^p \), the Minkowski sum of \( Q \) and the non-negative orthant of \( \mathbb{R}^p \), see [14]. It follows easily from the definitions, but see also [6], [7], [12], that non-dominated points of \( Q \) and of \( Q^+ \) are the same. The weakly non-dominated points of \( Q^+ \) form its Pareto frontier. Figure 1 illustrates non-dominated (solid line), and weakly non-dominated points (dashed line) of \( Q^+ \) when a) all objectives are bounded from below, and when b) the first objective is not bounded. \( Q^+ \) is the unbounded light gray area extending \( Q \).

B. Facial structure of polytopes

Let us recall some facts concerning the facial structure of \( n \)-dimensional convex closed polytopes. A face of such a polytope \( B \subset \mathbb{R}^n \) is a non-empty intersection of \( B \) and some closed halfspace. Faces of dimension one, two, \( n-2 \), and \( n-1 \) are called vertex, edge, ridge, and facet, respectively. All hyperplanes are oriented, thus have positive and negative side. In particular, facets of the polytope \( B \) are hyperplanes containing \( B \) on their non-negative side. The hyperplane is supporting if the polytope is on its non-negative side and contains a boundary point of \( B \). A supporting plane intersects
the expense of computing the extreme rays of $Q$ from below. From this it follows immediately that neither $Q$ nor solutions are the bounded faces (of dimension $B$ of the ideal plane. Thus in theoretical considerations, without postponing to Section VI, where we also extend our results to the software package Bensolve [11]. Further discussions are postponed to Section VI, where we also extend our results to the case where the ordering is given by some cone different from $\mathbb{R}_\geq^p$.

**Assumption.** The optimization problem (MOLP) satisfies the following conditions:

1. the $n$-dimensional polytope $\mathcal{A}$ defined in (1) is not empty;
2. each objective in $Q$ is bounded from below; in particular
3. $Q^+$ does not contain a complete line.

In other words, Assumption 1 says that the (scalar) LP problem (1) has a feasible solution. Consequently, the projection $Q = PA$ is non-empty either, and then $Q^+ = Q + \mathbb{R}_\geq^p$ is full dimensional. According to Assumption 2, $Q$ and $Q^+$ is contained in $y + \mathbb{R}_\geq^p$ for some (real) vector $y \in \mathbb{R}^p$. Thus $Q^+$ has exactly $p$ ideal vertices, namely the positive endpoints of the coordinate axes, and these ideal vertices lie on the single ideal facet.

### E. Benson’s algorithm revisited

The solution of the MOLP problem can be recovered from a description of the Pareto frontier of $Q^+$, which, in turn, is specified by the list of its vertices and (non-ideal) facets. Indeed, the Pareto optimal points are just the convex linear combination of (non-ideal) vertices lying on the same facet. Thus solving MOLP means find all vertices and facets of the polytope $Q^+$.

Benson’s “outer approximation algorithm” and its variants [6], [7], [10], [11], [12] do exactly this, working in the (low dimensional) objective space. These algorithms have two intertwined constituents: scalar optimization on one hand, and a combinatorial part on the other. Their separation provides a deeper insight how these algorithms work, and points toward a dual approach giving the title of this paper.

Benson’s algorithm works in stages by maintaining a “double description” of an approximation of the final polytope $Q^+$. A convex polytope is uniquely determined by the list of its vertices as well as by the list of its facets. The “double description” label refers to the technique keeping and maintaining both lists simultaneously. The iterative algorithm stops when the last approximation equals $Q^+$. At this stage both the vertices and facets of $Q^+$ are computed, thus the MOLP problem has been solved.

During the algorithm a new facet is added to the approximating polytope in each iteration. The new facet is determined by solving a smartly chosen scalar LP problem (specified from the description of the actual approximation). Then the combinatorial step is executed: the new facet is merged to the approximation by updating the facet and vertex lists. This step is very similar to that of incremental vertex enumeration [1], [2], [9], [15], and can be parallelized.

Section II defines black box algorithms which, on each call, provide data the combinatorial part can work on. The first one is called point separating oracle indicating that it separates a point from the (otherwise unknown) polytope $Q^+$ by a hyperplane. The plane separating oracle is its dual: the input is a hyperplane, and the oracle provides a point of $Q^+$ on the negative side of the hyperplane.

Two general enumeration algorithms using these oracles are specified in Section III. It is proved that they terminate with a double description of their corresponding target polytopes. Instantiating with specific initial polytopes and oracles are a convex hull algorithm, a (variant of) Benson’s algorithm, and the new inner approximating algorithm.

Aspects of the combinatorial part are discussed in Section IV. Section V explains how the oracles in these algorithms can be realized. Finally, Section VI discusses other implementation details, limitations and possible generalizations.
F. Our contribution

The first skeletal algorithm in Section III-A is the abstract versions of Benson’s outer approximation algorithm and its variants, where the combinatorial part (vertex enumeration) and the scalar LP part has been separated; the latter one is modeled as an inquiry to a separating oracle which, on each call, provides the data the combinatorial part can work on. Instantiating with one of the point separation oracles of Section V-A, one can recover, e.g., Algorithm 1 of [7]. The running time estimate in Theorem 8 is the same (with the same proof) as the estimate in [7, Theorem 4.6].

The other skeleton algorithm is the dual of the outer approximation one, but in a different sense of duality that used in [7]. Their Algorithm 2, called “dual variant of Benson’s outer approximation algorithm” can be transformed to an instantiation of our inner approximation skeletal algorithm using a weak hyperplane separating oracle different from the one in Section V-C. It would be interesting to see a more detailed comparison of the two approaches.

Studying skeletal algorithms made possible to clarify the role of the initial approximation, and prove general terminating conditions. While not every separating oracle guarantees termination, it is not clear what are the (interesting and realizable) sufficient conditions. Benson’s outer approximation algorithm is recovered by the first separation oracle defined in Section V-A. Other two separation oracles have stronger termination guarantees, yielding the first version which is guaranteed to take only the theoretically minimal number of iterations. Oracles in Section V-C are particularly efficient and contribute significantly to the excellent performance of the inner approximation algorithm.

It is almost trivial to turn any of the skeletal algorithms to an incremental vertex (or facet) enumeration algorithm. Such algorithms have been studied extensively, and have severe limitations. Typically there is a blow-up in the size of the intermediate approximation; there are examples where even the last but one approximation has size $\Omega(mv^2/p^2)$ where $m$ is the final number of facets (or vertices) [3]. The blow-up can be significant when the number of objectives is 6 or more, and is an unavoidable consequence of the used combinatorial method.

An interesting extension to the traditional scalar LP have been identified and used, called here as “multi-goal LP”. In this case not one but several goals are specified. Optimization is done for the first goal, then within the solution space the second goal is optimized, that is, in the second optimization there is an additional constraint specifying that the first goal has optimal value. Then within this solution space the third goal is optimized, etc. Section V-B sketches how existing LP solvers can be patched to become an efficient multi-goal solver. We expect more interesting applications for this type of solvers.

II. SEPARATING ORACLES

In this and in the following section $\mathcal{B} \subset \mathbb{R}^p$ is some bounded, closed, convex polytope with non-empty interior. As discussed in Section I-C, the condition that $\mathcal{B}$ is bounded can be replaced by the weaker assumption that $\mathcal{B}$ does not contain a complete line.

A $p$-dimensional hyperplane $H$ is specified by the equation $\{y \in \mathbb{R}^p : yh - M = 0\}$, where $h \in \mathbb{R}^p$ is a non-null vector (normal), and $M$ is a scalar (intercept). The positive side of $H$ is the open half-space $\{y \in \mathbb{R}^p : yh - M > 0\}$. The negative side is defined similarly. A facet of $\mathcal{B}$ is specified as a hyperplane so that $\mathcal{B}$ is on its non-negative side. A point is in $\mathcal{B}$ if and only if it is on the non-negative side of each facet of $\mathcal{B}$.

**Definition 1.** The point separating oracle $\mathrm{ptO}(\mathcal{B})$ for the polytope $\mathcal{B} \subset \mathbb{R}^p$ is a black box algorithm with the following input/output behavior:

- input: a point $v \in \mathbb{R}^p$;
- output: “inside” if $v \in \mathcal{B}$; otherwise a facet $H$ of $\mathcal{B}$ such that $v$ is on the negative side of $H$.

**Definition 2.** The plane separating oracle $\mathrm{hpO}(\mathcal{B})$ for the polytope $\mathcal{B} \subset \mathbb{R}^p$ is a black box algorithm with the following input/output behavior:

- input: a $p$-dimensional hyperplane $H$;
- output: “inside” if $\mathcal{B}$ is on the non-negative side of $H$; otherwise a vertex $v$ of $\mathcal{B}$ on the negative side of $H$.

The main point is that in the enumeration algorithms of Section III only the oracle uses the polytope $\mathcal{B}$, which is not necessarily defined by a collection of linear constraints. In particular, this happens when the algorithm is used to solve the multiobjective problem, where the polytope passed to the oracle is $\mathcal{Q} \cup \mathcal{Q}^+$.

The two oracles are dual in the sense that if $\mathcal{B}^*$ is the geometric dual of the convex polytope $\mathcal{B}$ with the usual point versus hyperplane correspondence [14], then $\mathrm{ptO}(\mathcal{B})$ and $\mathrm{hpO}(\mathcal{B}^*)$ are equivalent: when a point is asked from oracle $\mathrm{ptO}(\mathcal{B})$, ask the dual of this point from $\mathrm{hpO}(\mathcal{B}^*)$, and return the dual of the answer.

The object returned by a weak separating oracle is not required to be a facet (or vertex), but only a supporting hyperplane (or a boundary point) separating the input from the polytope. The returned separating object, however, cannot be arbitrary, must have some structural property. Algorithms of Section III work with the weaker separating oracles defined below, but the performance guarantees are exponentially worse. On the other hand such weak oracles can be realized easier: no additional probabilistic assumption is required, and there is no need to modify the underlying scalar LP solver. Actually, strong separating oracles in Section V are implemented as tweaked weak oracles.

**Definition 3.** The weak point separating oracle $\mathrm{ptO}^*(\mathcal{B})$ for polytope $\mathcal{B}$ is a black box algorithm which works as follows. It fixes an internal point $o \in \mathcal{B}$.

- input: a point $v \in \mathbb{R}^p$;
- output: “inside” if $v \in \mathcal{B}$; otherwise connect $v$ to the fixed internal point $o$, compute where this line segment intersects the boundary of $\mathcal{B}$, and return a supporting hyperplane $H$ of $\mathcal{B}$ at that point (this $H$ separates $v$ and $\mathcal{B}$).
Definition 4. The weak plane separating oracle \( \text{hpO}^+(B) \) for polytope \( B \) is a black box algorithm which works as follows.

- **input:** a hyperplane \( H \);
- **output:** “inside” if \( B \) is on the non-negative side of \( H \);
- otherwise a boundary point \( v \) of \( B \) which is farthest away from \( H \) on its negative side.

A strong oracle is not necessarily a weak one (e.g., a \( \text{hpO} \) can return any vertex on the negative side of \( H \), not only the one which is farthest away from it), but can always give a response which is consistent with being a weak oracle. Similarly, there is always a valid response of a weak oracle which qualifies as correct answer for the corresponding strong oracle.

While strong oracles are clearly dual of each other, it is not clear whether the weak oracles are dual, and if yes, in what sense of duality.

III. APPROXIMATING ALGORITHMS

The skeletal algorithms below are called outer and inner approximations. The outer name reflects the fact that the algorithm approximates the target polytope from outside, while the inner does it from inside. The outer algorithm is an abstract version of Benson’s algorithm where the computational and combinatorial parts are separated.

A. Skeletal algorithms

On input both algorithms require two convex polytopes: \( S \) and \( B \). The polytope \( S \) is the initial approximation; it is specified by double description: by the list of its vertices and facets. The polytope \( B \) is passed to the oracle, and is specified according to the oracle’s requirements. Both \( S \) and \( B \) are assumed to be closed, convex polytopes with non-empty interior. For this exposition they are also assumed to be bounded; this condition can (and will) be relaxed to the weaker condition that none of them contains a complete line.

**Algorithm 1** (Outer approximation). Set \( S_0 = S \) as the initial approximation. In each approximating polytope certain vertices will be marked as “final.” Initially this set is empty.

Consider the \( i \)-th approximation \( S_i \). If all vertices of \( S_i \) are marked final, then stop, the result is \( R = S_i \). Otherwise pick a non-final vertex \( v_i \in S_i \), and call the (weak) plane separating oracle with point \( v_i \). If the oracle returns “inside,” then mark \( v_i \) as “final,” repeat. Otherwise the oracle returns the equation of a hyperplane \( H \). Let \( S_{i+1} \) be the intersection of \( S_i \) and the non-negative side of \( H \). Keep the “final” flag on previous vertices. (Actually, all final vertices of \( S_i \) will be vertices of \( S_{i+1} \)). Repeat.

**Theorem 5.** The outer approximation algorithm using the \( \text{ptO}(B) \) oracle terminates with the polytope \( R = B \cap S \). The algorithm makes at most \( v + f \) oracle calls, where \( v \) is the number of vertices of \( R \), and \( f \) is the number of facets of \( B \).

**Proof.** First we show that if the algorithm terminates then the result is \( B \cap S \). Each approximating polytope is an intersection of certain facets of \( B \) (as \( \text{ptO}(B) \) returns facets of \( B \)), and all facets of \( S_0 \) thus \( B \cap S \subseteq S_i \).

If \( B \cap S \) is a proper subset of \( S_i \), then \( S_i \) has a vertex \( v_i \) not in \( B \cap S \). This vertex \( v_i \) cannot be marked “final” as final vertices are always points of \( B \cap S \). (All vertices of \( S_i \) are points of \( S \), and when the oracle returns “inside,” the queried point is in \( B \).) Thus the algorithm cannot stop at \( S_i \).

Second, the algorithm stops after making at most \( v + f \) oracle calls. Indeed, there are at most \( v \) oracle calls which return “inside” (as a final vertex is never asked from the oracle). Moreover, the oracle cannot return the same facet \( H \) of \( B \) twice. Suppose \( H \) is returned at the \( i \)-th step. Then \( S_{i+1} = S_i \cap \{H \geq 0 \} \). If \( j > i \) and \( v_j \) is a vertex of \( S_j \subseteq S_{i+1} \), then \( v_j \) is on the non-negative side of \( H \), i.e., the oracle cannot return \( H \) for the query \( v_j \).

From the discussion above it follows that vertices marked as “final” are vertices of \( B \cap S \), thus they are vertices of all subsequent approximations. This justifies the sentence in parentheses in the description of the algorithm.

**Theorem 6.** The outer approximation algorithm using the weak \( \text{ptO}^+(B) \) oracle terminates with the polytope \( R = B \cap S \). The algorithm makes at most \( v + 2f \) oracle calls, where \( v \) is the number of vertices of \( R \), and \( f \) is the number of facets of \( B \).

**Proof.** Similarly to the previous proof, for each iteration we have \( B \cap S \subseteq S_i \), as each \( H \) is a supporting hyperplane to \( B \). If \( B \cap S \) is a proper subset of \( S_i \), then \( S_i \) has a vertex \( v_i \) not in \( B \cap S \), thus not marked as “final”, and the algorithm cannot stop at this iteration.

To show that the algorithm eventually stops, we bound the number of oracle calls. If for the query \( v_i \), the response is “inside,” then \( v_i \) is a vertex of \( R \), and \( v_i \) will not be asked again. This happens at most as many times as many vertices \( R \) has.

Otherwise the oracle’s response is a supporting hyperplane \( H_i \) which touches \( B \) at the point where the segment \( v_{i-1} o \) intersects the boundary of \( B \). This boundary point is either a vertex of \( B \), or otherwise it is in the relative interior of a unique face of \( B \). Let \( F_i \) be this face or vertex. Observe that the supporting hyperplane \( H_i \) contains all points of \( F_i \). It means that if an internal point of the line segment \( v_{i-1} o \) intersects this face \( F_i \), then \( v_j \) is on the negative side of \( H_i \). As \( S_{i+1} \) and all subsequent approximations are on the non-negative side of \( H_i \), \( v_{j} o \) cannot intersect \( F_i \), thus the face \( F_i \) necessarily differs from the face \( F_i \). Thus there can be no more iterations than the number of faces of \( B \). As each face is the intersection of some facets, this number is at most \( 2^f \).

Now we turn to the dual of outer approximation.

**Algorithm 2** (Inner approximation). Set \( S_0 = S \) as the initial approximation. In each approximation certain facets will be marked as “final.” Initially this set is empty.

Consider the \( i \)-th approximation \( S_i \). If all facets of \( S_i \) are marked final, then stop, the result is \( R = S_i \). Otherwise pick a non-final facet \( F_i \subseteq S_i \), and call the (weak) plane separating oracle with facet \( F_i \). If the oracle returns “inside,” then mark \( F_i \) as “final,” and repeat. Otherwise the oracle returns a boundary point \( v_i \) of \( B \) on the negative side of \( H_i \). Let \( S_{i+1} \) be the convex hull of \( S_i \) and \( v_i \). Keep the “final” flag on previous...
 facets. (Actually, all final facets of $S_i$ will be facets of $S_{i+1}$.)

Repeat.

**Theorem 7.** The inner approximation algorithm using the hpO($B$) oracle terminates with $R = \text{conv}(B \cup S)$, the convex hull of $B$ and $S$. The algorithm makes at most $v + f$ oracle calls, where $v$ is the number of vertices of $B$, and $f$ is the number of facets of $R$.

**Proof.** This algorithm is the dual of Algorithm 1 above. The claims can be proved along the proof of Theorem 5 by replacing notions by their dual: vertices by facets, intersection by convex hull, calls to ptO by calls to hpO, etc. Details are left to the interested reader.

**Theorem 8.** The inner approximation algorithm using the weak hpO$^*$($B$) oracle terminates with $R = \text{conv}(B \cup S)$. The algorithm makes at most $2^v + f$ oracle calls, where $v$ is the number of vertices of $B$, and $f$ is the number of facets of $R$.

**Proof.** As weak oracles are not dual, the proof is not as straightforward as it was for the previous theorem. First, if the algorithm stops, it computes the convex hull. Indeed, $S_i \subseteq R$, and if they differ, then $S_i$ has a facet $H$ and a vertex of $B$ is on its negative side. This facet cannot be final, thus the algorithm did not stop.

To show termination, observe that at most $f$ oracle calls return “inside”. In other calls the query was the hyperplane $H_i$, and the oracle returned $v_i$ from the boundary of $B$ such that the distance between $v_i$ and $H_i$ is maximal. Consider the face $F_i$ of $B$ which contains $v_i$ in its relative interior, or set $F_i = v_i$ if $v_i$ is a vertex. We claim that the same $F_i$ cannot occur for any subsequent query. Indeed, all points of $F_i$ are exactly the same (negative) distance from $H_i$, $v_i \in F_i$, $v_i$ is a point of $S_{i+1}$ and all subsequent approximations. If $j > i$, $H_j$ is a facet of $S_j$, then $v_i$ is on the non-negative side of $H_j$. Consequently $v_i$ is not an element of the face $F_j$, and then $F_i$ and $F_j$ differ.

Thus the number of such queries cannot be more than the number of faces in $B$, which is at most $2^v$.

**B. A convex hull algorithm**

These skeleton algorithms can be instantiated with different oracles and initial polytopes. As an easy application we present an algorithm computing the convex hull of a point set $V \subseteq \mathbb{R}^p$. In this case $B = \text{conv}(V)$, the convex hull of $V$. If the initial approximation $S$ is inside this convex hull, then Algorithm 2 (inner approximation) just returns the convex hull $B$.

**Algorithm 3 (Convex hull).** On input a point set $V \subseteq \mathbb{R}^p$ construct the $p$-dimensional simplex $S$ as described in (3.1); then execute Algorithm 2 with the hpO oracle defined in (3.2).

(3.1) Let $\bar{v} \in \mathbb{R}^p$ be the average of $V$, and choose $\varepsilon$ be a small positive number (say, smaller than all the positive distances $|v_i - \bar{v}|$ for $v_i \in V$). Let $S$ be the $p$ dimensional simplex with vertices $v$ and $v + \varepsilon e_i$, where $e_i$ is the $i$-th coordinate vector. The $p + 1$ facets of $S$ can be computed easily.

(3.2) The input of the hpO oracle is the hyperplane $H$, the output should be a vertex of the convex hull. For each $v \in V$ compute the distance of $v$ from the hyperplane $H$. If none of the distances is negative, then return “inside”. Otherwise let $V'$ be the set of all points where the distances are minimal. The lexicographically minimal element of $V'$ will be a vertex of $\text{conv}(V)$.

Instead of returning the lexicographically minimal element (which makes the oracle hpO, we can return any element of $V'$, which makes it a weak hpO$^*$. The convex hull algorithm would work equally well but with possibly more iterations.

**C. Algorithms solving multiobjective linear optimization problems**

Let us now turn to the problem of solving the multiobjective linear optimization problem. As discussed in Section I-E, this means that we have to find a double description of the (unbounded) polytope $Q^+$. To achieve this, both skeletal algorithms from Section III-A can be used. Algorithm 4 below is (a variant of) Benson’s original outer approximation algorithm [7], while Algorithm 5, announced in the title of this paper, uses inner approximation. The second algorithm has several features which makes it better suited for problems with large number (at least six) of objectives, especially when $Q^+$ has relatively few vertices.

As $Q^+$ is unbounded, both instantiating use ideal elements from the extended ordered projective space $\mathbb{RP}$ as elaborated in [5]. Elements of $\mathbb{RP}$ can be implemented using homogeneous coordinates. For $1 \leq i \leq p$ the ideal point at the positive end of the $i$-th coordinate axis $e_i$ is denoted by $e_i \in \mathbb{RP}$. For a (non-ideal) point $v \in \mathbb{RP}$ the $p$-dimensional simplex with vertices $v$ and $\{e_i : 1 \leq i \leq p\}$ is denoted by $v + E$. One facet of $v + E$ is the ideal hyperplane containing all ideal points; the other $p$ facets have equation $(y - v)e_i = 0$ as $v + E$ is on the non-negative side of these hyperplanes. The description of how the oracles in Algorithms 4 and 5 are implemented is postponed to Section V.

The input of Algorithms 4 and 5 are the $n$-dimensional polytope $A$ as in (1), and the $p \times n$ projection matrix $P$ defining the objectives, as in (2). The output of both algorithms is a double description of $Q^+$.

**Algorithm 4 (Benson’s outer algorithm).** Construct the initial polytope $S \subseteq Q^+$ as described in (4.1). Then execute Algorithm 1 with the oracle ptO($Q^+$), or ptO$^*$($Q^+$), defined in Section V-A.

(4.1) Pick $v \in \mathbb{RP}$ so that for all $1 \leq i \leq p$, $v_i$ is a lower bound for the $i$-th objective $P_i$, the $i$-th row of $P$. The initial outer approximation $S$ is the simplex $v + E$. The coordinate $v_i$ can be found, e.g., by solving the scalar LP

$$
 v_i = \min_x \{ P_i x : x \in A \}.
$$

By Theorems 5 and 6 this algorithm terminates with $Q^+$, as required. When creating the initial polytope $S$ in step 4.1, the scalar LP must have a feasible solution (otherwise $A$ is empty), and should not be unbounded (as otherwise the $i$-th objective is unbounded from below), contradicting the assumptions about
the MOLP problem. After \( S \) has been created successfully we know that its ideal vertices are also vertices of \( Q^+ \), thus they can be marked as “final”. As these are the only ideal vertices of \( Q^+ \), no further ideal point will be asked from the oracle at all. These facts can be used to simplify the oracle implementation.

**Algorithm 5** (Inner algorithm). Construct the initial approximation \( S \) as described in (5.1). Then execute Algorithm 2 with the oracle \( hpO(Q) \), or \( hpO^+(Q) \) described in Section V-C. (5.1) Pick a point \( v \in Q \); the initial polytope \( S \) is the simplex \( v + \mathcal{E} \). This \( v \) can be found as \( v = Px \in \mathbb{R}^p \) for any feasible solution \( x \in \mathbb{R}^n \) of the scalar LP in (1); or \( v \) could be the answer of the oracle to the hyperplane query \( \{ y \in \mathbb{R}^p : ye - M = 0 \} \), where \( e \in \mathbb{R}^p \) is the all-one vector, and \( M \) is a very large scalar.

Theorems 7 and 8 claim that this algorithm computes a double description of \( Q^+ \), as the convex hull of \( Q \) and \( S \) is just \( Q^+ \). Observe that in this case the oracle answers questions about the polytope \( Q \), and not about \( Q^+ \), which latter one has a more complicated description. The ideal facet of \( S \) is the (only) ideal facet of \( Q^+ \), thus it can be marked as “final” and then it won’t be asked from the oracle. No ideal point should ever be returned by the oracle.

To simplify the generation of the initial approximation \( S \), the oracle may accept any vector \( h \in \mathbb{R}^p \) as a query, and return a (non-ideal) vertex (or boundary point) \( v \) of \( Q \) which minimizes the scalar product \( hv \), and leave it to the caller to decide whether the whole \( Q \) is on the non-negative side of the hyperplane \( \{ y \in \mathbb{R}^p : ye - M = 0 \} \). (This happens when \( vh - M \geq 0 \) for the returned point \( v \).) As can be seen in the proof of Theorems 7 and 8, the algorithm only asks oracle questions where the answer is either on the hyperplane, or on its negative side. Thus the additional work the oracle has to do not knowing that the computation can be aborted when the answer is “inside” should have no, or negligible, effect on the overall performance.

Unlike the oracle implementation for the outer algorithm 4 where \( Q^+ \) is guaranteed to be non-empty and bounded from below, the oracle implementation of this algorithm should handle cases when \( Q \) is empty, or is not bounded in some objective direction.

**IV. VERTEX AND FACET ENUMERATION**

This section discusses the combinatorial part of the skeleton Algorithms 1 and 2 in some detail. For a more thorough exposition of this topic please consult [1], [2], [8]. At each step of these algorithms the approximation \( S_i \) is updated by adding a new facet (outer algorithm) or a new vertex (inner algorithm). To maintain the double description, we need to update both the list of vertices and the list of facets. In the first case the new facet can be easily added to the list, but the vertex list might change significantly. In the second case it is the other way around: the vertex list grows by one, and the facet list changes substantially. As adding a facet and updating the vertex list is at the heart of incremental vertex enumeration [9], [15], it will be discussed first.

Suppose \( S_i \) is to be intersected by the (new) facet \( H \). Vertices of \( S_i \) can be partitioned as \( V^+ \cup V^- \cup V^0 \); those which are on the positive side, on the negative side, and those which are on \( H \). As the algorithm proceeds, \( H \) always cuts \( S_i \) properly, thus neither \( V^+ \) nor \( V^- \) is empty; however \( V^0 \) can be empty. Vertices in \( V^+ \) and in \( V^- \) remain vertices of \( S_{i+1} \); vertices in \( V^- \) will not be vertices of \( S_{i+1} \) any more, and should be discarded. The new vertices of \( S_{i+1} \) are the points where \( H \) intersects the edges of \( S_i \) in some internal point. Such an edge must have one endpoint in \( V^+ \), and the other endpoint in \( V^- \). To compute the new vertices, for each pair \( v_1 v_2 \) with \( v_1 \in V^+ \) and \( v_2 \in V^- \) we must decide whether \( v_1 v_2 \) is an edge of \( S_i \) or not. This can be done using the well-known and popular necessary and sufficient combinatorial test stated in Proposition 9 b) below. (As computing this test is really time consuming, the faster necessary condition a) is checked first which filters out numerous non-edges. A proof for the correctness of the tests can be found, e.g., in [8].)

**Proposition 9.** a) If \( v_1 v_2 \) is an edge, then there must be at least \( p - 1 \) different facets containing both \( v_1 \) and \( v_2 \).

b) \( v_1 v_2 \) is an edge if and only if for every other vertex \( v_3 \) there is a facet \( H \) which contains \( v_1 \) and \( v_2 \) but not \( v_3 \).

Both conditions can be checked using the vertex–facet adjacency matrix, which must also be updated in each iteration. In practice the adjacency matrix is stored twice: using the bit vector \( H_v \) for each vertex \( v \) (indexed by the facets), and the bit vector \( V_H \) for each facet \( H \) (indexed by the vertices). The vector \( H_v \) at position \( H \) contains 1 if and only if \( v \) is on the facet \( H \); similarly for the vector \( V_H \). Condition a) can be expressed as the intersection \( H_{v_1} \land H_{v_2} \) has at least \( p - 1 \) ones. Condition b) is the same as the bit vector

\[
\bigwedge \{ V_H : H \in H_{v_1} \land H_{v_2} \}
\]

contains only zeros except for positions \( v_1 \) and \( v_2 \). Bit operations are quite fast and is done on several (typically 32 or 64) bits simultaneously. Checking which vertex pairs in \( V^+ \times V^- \) are edges, and when such a pair is an edge computing the coordinates of the new vertex, can be done in parallel. Almost the complete execution time of vertex enumeration is taken by this edge checking procedure. Using multiple threads the total work can be evenly distributed among the threads with very little overhead, practically dividing the execution time by the number of the available threads. See Section VI-D for further remarks.

Along updating the vertex and facet lists, the adjacency vectors must be updated as well. In each step we have one more facet, thus vectors \( H_v \) grow by one bit. The size of facet adjacency vectors change more erratically. We have chosen a lazy update heuristics: there is an upper limit on this size. Until the list size does not exceed this limit, newly added vertices are assigned a new slot, and positions corresponding to deleted vertices are put on a “spare indices” pool. When no more new slots are available, the whole list is compressed, and the upper limit is expanded if necessary.

In Inner Algorithm 2 the sequence of intermediate polytopes \( S_i \) grows by adding a new vertex rather than cutting it by a
new facet. In this case the facet list is to be updated. As this is the dual of the procedure above, only the main points are highlighted.

Let \( v \) be the new vertex to be added to the polytope \( S_t \). Partition the facets of \( S_t \) as \( H^+ \cup H^- \cup H^0 \) such that \( v \) is on the positive side of facets in \( H^+ \), on the negative side of facets in \( H^- \), and is on the facets in \( H^0 \). The new facets of \( S_{t+1} \) are facets in \( H^+ \) and \( H^0 \), plus facets determined by \( v \) and a ridge (a \((p-2)\)-dimensional face) which is an intersection of one facet from \( H^+ \) and one facet from \( H^- \). One can use the dual of Proposition 9 to check whether the intersection of two facets is a ridge or not. We state this condition explicitly as this dual version seems not to be known.

**Proposition 10.** a) If the intersection of facets \( H_1 \) and \( H_2 \) is a ridge, then they share at least \( p-1 \) vertices in common.

b) \( H_1 \cap H_2 \) is a ridge if and only if for every other facet \( H_3 \) there is a vertex \( v \in H_1 \cap H_2 \) which is not in \( H_3 \).

Using the adjacency bit vectors \( H_v \) and \( V_H \), these conditions can be expressed as a) \( V_{H_1} \cap V_{H_2} \) has at least \( p-1 \) ones; b) the bit vector

\[
\bigwedge \{ H_v : v \in V_{H_1} \cap V_{H_2} \}
\]

contains only zeros except for positions \( H_1 \) and \( H_2 \). Remarks about parallel execution and the bitmaps update are the same as above.

V. REALIZING ORACLE CALLS

This section describes how the oracles in Algorithms 4 and 5 can be realized. In both cases a weak separating oracle is defined first, and the we show how can it be tweaked to become a strong oracle. The solutions are not completely satisfactory. Either the hyperplane returned by the point separating oracle for Benson’s algorithm 4 will be a facet with “high probability” only, or the oracle requires a non-standard feature from the underlying scalar LP solver. Fortunately weak oracles work as well, thus the improbable but possible failure of the “probability” oracle is not fatal: it might add further iterations but neither the correctness nor termination is affected. (Numerical stability is another issue.) In Section V-B we describe how a special class of scalar LP solvers – including the GLPK solver [13] used in the implementation of Bensolve [11] and Inner – can be patched to find the lexicographically minimal element in the solution space.

The polytopes on which the oracles work are defined by the \( m \times n \) and \( p \times n \) matrices \( A \) and \( P \), respectively, and by the vector \( c \in \mathbb{R}^m \) as follows:

\[
A = \{ x \in \mathbb{R}^n : Ax = c, \quad x \geq 0 \},
\]

\[
Q = PA = \{ Px : x \in A \},
\]

\[
Q^+ = Q + \mathbb{R}^p_+ = \{ y + z : y \in Q, \quad z \in \mathbb{R}^p_+ \}.
\]

The next two sections describe how the weak and strong oracles required by Algorithms 4 and 5 can be realized.

A. Point separation oracle

The oracle’s input is a point \( v \in \mathbb{R}^p \), and the response should be a supporting hyperplane (weak oracle) or a facet (strong oracle) of \( Q^+ \) which separates \( v \) and \( Q^+ \). As discussed in Section III-C, several simplifying assumptions can be made, namely

- \( Q \) is not empty and bounded from below in each objective direction;
- \( v \) is not an ideal point;
- if \( v \) is in \( Q^+ \), then it is a boundary point.

Let us consider first the weak oracle. According to Definition 3 the \( \text{ptO}'(Q^+) \) must choose a fixed internal point \( o \in Q^+ \). The vertices of the ideal facet of \( Q^+ \) are the positive endpoints of the coordinate axes. If all coordinates of \( e^* \in \mathbb{R}^p \) are positive, then the ideal point corresponding to this vector is in the relative interior of the ideal facet. Fix this vector \( e^* \), and let \( o \) be the ideal point corresponding to \( e^* \). While \( o \) is not an internal point of \( Q^+ \), this choice works as no ideal point is ever asked from the oracle according to the assumptions above. Thus let us fix \( o \) this way.

Given the query point \( v \), the “segment” \( vo \) is the ray \( \{ v - \lambda e^* : \lambda < 0 \} \). The \( vo \) line intersects the boundary of \( Q^+ \) at the point \( \hat{v} = v - \lambda e^* \), where \( \lambda \) is the solution of the scalar LP problem

\[
\hat{\lambda} = \max_{\lambda, x} \{ \lambda : Px \leq v - \lambda e^*, \ Ax = c, \ x \geq 0 \}.
\]

Indeed, this problem just searches for the largest \( \lambda \) for which \( v - \lambda e^* \in Q^+ \). By the assumptions above \( P(v, e^*) \) always has an optimal solution.

Now the line \( vo \) intersects \( Q^+ \) in the ray \( \hat{v}o \). Thus \( v \in Q^+ \) if \( \hat{\lambda} \geq 0 \); in this case the oracle returns “inside”. In the \( \hat{\lambda} < 0 \) case the oracle should find a supporting hyperplane \( H \) to \( Q^+ \) at the boundary point \( \hat{v} \). Interestingly, the normal of these supporting hyperplanes can be read off from the solution space of the dual of \( P(v, e^*) \), where the dual variables are \( s \in \mathbb{R}^p \) and \( t \in \mathbb{R}^m \):

\[
\min_{s, t} \{ s^T v + t^T c : s^T P + t^T A \geq 0, \ s^T e^* = 1, \ s \geq 0 \}.
\]

As the primal \( P(v, e^*) \) has an optimal solution, the strong duality theorem says that the dual \( D(v, e^*) \) has the same optimum \( \lambda \).

**Proposition 11.** The problem \( D(v, e^*) \) takes its optimal value \( \hat{\lambda} \) at \( s \in \mathbb{R}^p \) (together with some \( t \in \mathbb{R}^m \)) if and only if \( s \) is a normal of a supporting hyperplane to \( Q^+ \) at \( \hat{v} \).

**Proof.** By definition \( s \) is a normal of a supporting hyperplane to \( Q^+ \) at \( \hat{v} \) if and only if \( s(y - \hat{v}) \geq 0 \) for all \( y \in Q^+ \). From here it follows that \( s \geq 0 \) (as otherwise \( sy \) is not bounded from below for some large enough \( y \in Q^+ \)), and as \( e^* \) has all positive coordinates, \( s \) can be normalized by assuming \( s^T e^* = 1 \).

Knowing that \( s \geq 0 \), if \( sy \geq s\hat{v} \) holds for some \( y \in \mathbb{R}^p \), then it also holds for every \( y' \geq y \). Thus it is enough to require \( sy \geq s\hat{v} \) for all \( y \in Q \) only, that is,

\[
s^T(Px) \geq s^T \hat{v} \quad \text{for all} \ x \in A.
\]
The polytope \( A \) is non-empty. According to the strong duality theorem, all \( x \in A \) satisfies a linear inequality if and only if it is a linear combination of the defining (in)equalities of \( A \). Thus (3) holds if and only if there is a vector \((-t) \in \mathbb{R}^m\) such that
\[
s^T P \geq -t^T A, \quad \text{and} \quad s^T \hat{v} = -t^T c.
\]
Plugging in \( \hat{v} = v - \lambda e^* \) and using \( s^T e^* = 1 \) we get that \( s \) is a normal of a supporting hyperplane of \( Q^+ \) at \( \hat{v} \) if and only if
\[
s^T P + t^T A \geq 0, \quad \text{and} \quad s^T v + t^T c = \hat{\lambda},
\]
namely \((s, t)\) is in the solution space of \( D(v, e^*)\).

Proposition 11 indicates immediately how to define a weak separating oracle.

Oracle 12 (weak \( p\)O\((Q^+)\)). Fix the vector \( e^* \in \mathbb{R}^p \) with all positive coordinates. On input \( v \in \mathbb{R}^p \), solve \( D(v, e^*)\). Let the minimum be \( \hat{\lambda} \), and the place where the minimum is attained be \((\hat{s}, \hat{t})\). If \( \hat{\lambda} \geq 0 \), then return “inside”. Otherwise let \( \hat{v} = v - \lambda e^* \), and the supporting hyperplane to \( Q^+ \) at \( \hat{v} \) is
\[
\{ y \in \mathbb{R}^p : \hat{y} - \hat{v} = 0 \}.
\]
The oracle works with any positive \( e^* \). Choosing \( e^* \) to be the all one vector is a good choice when numerical stability (or simplicity) is a concern. This choice has been made by Bensolve and other variants. Choosing other vectors can be advantageous. Observe that the supporting plane will be a facet if the boundary point is not in any \((p-2)\)-dimensional face. Given any point \( v \in Q^+ \), the directions \( e^* \) for which \( v - \lambda e^* \) hits \( Q^+ \) in such a low-dimensional face has measure zero (in the usual Lebesgue sense). Thus choosing \( e^* \) “randomly” all returned hyperplanes will be facets with probability one.

Oracle 13 (probabilistic \( p\)O\((Q^+)\)). Choose each coordinate of \( e^* \) randomly, say uniformly and independently from \([1, 2]\). Then execute Oracle 12 using this random vector \( e^* \).

While there is no guarantee that Oracle 13 always returns a facet (the “random” choice is only pseudorandom with limited granularity, and events with zero probability might occur, the LP solver might run into numerical instability, etc.) such a failure is not fatal, as the oracle still acts as a weak one. In such an exceptional case further iterations might be necessary, but neither the correctness not the termination of the algorithm is affected.

Proposition 11 suggests another way to extract a facet among the supporting hyperplanes. The solution space of \( D(v, e^*) \) in the first \( p \) variables spans the (convex polyhedral) space of the normals of the supporting hyperplanes. Facet normals are the extremes among them. Pinpointing a single extreme among them is easy. As in the case of the convex hull algorithm in Section III-B, choose its lexicographically minimal element: this will be the normal of a facet.

Oracle 14 (strong \( p\)O\((Q^+)\)). Fix the vector \( e^* \in \mathbb{R}^p \) with all positive coordinates, e.g., take the all one vector. On input \( v \in \mathbb{R}^p \) solve \( D(v, e^*) \). The LP solver must return the minimum, and the lexicographically minimal \( s \in \mathbb{R}^p \) from the solution space. Proceed as in Oracle 12. 

The question how to find the lexicographically minimal element in the solution space is addressed in the next section.

B. A “multi-goal” scalar LP solver

Scalar LP solvers typically stop when the optimum value is reached, and report the optimum, the value of the structural variables, and optionally the value of the dual variables. The lexicographically minimal vector from the solution space can be computed by solving additional (scalar) LP problems by adding more and more constraints which restrict the solution space. For Oracle 14 this sequence could be

\[
\hat{\lambda} = \min_{s,t} \{ s^T v + t^T c : \text{original constraints} \},
\]
\[
\hat{s}_1 = \min_{s,t} \{ s_1 : s^T v + t^T c = \hat{\lambda} + \text{original constraints} \},
\]
\[
\hat{s}_2 = \min_{s,t} \{ s_2 : 1 = \hat{s}_1, \ s^T v + t^T c = \hat{\lambda} + \text{original constraints} \},
\]
\[
\hat{s}_3 = \min_{s,t} \{ s_3 : 2 = \hat{s}_2, \ 1 = \hat{s}_1, \ s^T v + t^T c = \hat{\lambda} + \text{original constraints} \},
\]
etc.

The first LP solves \( D(v, e^*) \). The second one fixes this solution and searches for the minimal \( s_1 \) within the solution space, etc. Fortunately, certain simplex LP solvers – including GLPK [13] – can be patched to do this task more efficiently. Let us first define what do we mean by a “multi-goal” LP solver, show how it can be used to realize the strong Oracle 14, and then indicate an efficient implementation.

Definition 15. A multi-goal LP solver accepts as input a set of linear constraints and several goal vectors, and returns a feasible solution after minimizing for all goals in sequence:

**Constraints**: a collection of linear constraints.

**Goals**: real vectors \( g_1, g_2, \ldots, g_k \).

**Result**: let \( A_0 = \{ x : x \text{ satisfies the given constraints} \} \); for \( 1 \leq j \leq k \) let \( x \in A_j \) if \( g_j x \) is minimal among \( x \in A_{j-1} \). Return any vector \( x \) from the last set \( A_k \), or report failure if any of \( A_j \) is empty (including the case when \( g_j x \) is not bounded from below).

Oracle 14 can be realized by such a multi-goal LP solver. Fix \( e^* \in \mathbb{R}^p \). We need the lexicographically minimal \( s \in \mathbb{R}^p \) from the solution space of \( D(v, e^*) \). Let \( e_i \in \mathbb{R}^{p+m} \) be the coordinate vector with 1 in position \( i \). Call the multi-goal LP solver as follows:

**Constraints**: \( s^T P + t^T A \geq 0, \ s^T e^* = 1, \ s \geq 0 \).

**Goals**: the \( p+m \) dimensional vectors \( (v, c), e_1, e_2, \ldots, e_p \).

Parse the \( p+m \) dimensional output as \((\hat{s}, \hat{t})\), and compute \( \hat{\lambda} = \hat{s}^T v + \hat{t}^T c, \ \hat{v} = v - \lambda e^* \). Return “inside” if \( \hat{\lambda} \geq 0 \), and return the facet equation \( \hat{s}(y - \hat{v}) = 0 \) otherwise.

In the rest of the section we indicate how GLPK [13] can be patched to become an efficient multi-goal LP solver. After parsing the constraints, GLPK internally transforms them to the form

\[
Ax = c, \ a \leq x \leq b.
\]
Here \( x \in \mathbb{R}^n \) is the vector of all variables, \( A \) is some \( m \times n \) matrix, \( m \leq n \), \( c \in \mathbb{R}^m \) is a constant vector, and \( a, b \in \mathbb{R}^m \) are the lower and upper bounds, respectively. The lower bound \( a_i \) can be \(-\infty\) and the upper bound \( b_i \) can be \(+\infty\) meaning that the variable \( x_i \) is not bounded in that direction. The two bounds can be equal, but \( a_i \leq b_i \) must always hold (otherwise the problem has no feasible solution). The function to be minimized is \( g^x \) for some fixed goal vector \( g \in \mathbb{R}^n \). (During this preparation only slack and auxiliary variables are added, thus \( g \) can be got from the original goal vector by padding it with zeroes.)

GLPK implements the simplex method by maintaining a set of \( m \) base variables, an invertible \( m \times m \) matrix \( M \) so that the product \( MA \) contains the permutation of a unit matrix at column positions corresponding to the base variables. Furthermore, for each non-base variable \( x_i \) there is a flag indicating whether it takes its lower bound \( a_i \) or upper bound \( b_i \). Fixing the value of non-base variables according to these flags, the value of base variables can be computed from the equation \( MAx = Mc \). If the values of the computed base variables fall between the corresponding lower and upper bounds, then the arrangement (base, \( M \), flags) is primal feasible.1

The simplex method works by changing one feasible arrangement to another one while improving the goal \( g^x \). Suppose we are at a feasible arrangement where \( gx \) cannot decrease. Let \( \phi \in \mathbb{R}^m \) be a vector such that \( g^\prime = g - \phi^T(MA) \) contains zeros at indices corresponding to base variables. As \( MA \) contains a unit matrix at these positions, computing this \( \phi \) is trivial. Now \( g^\prime x = gx - \phi^T(MA)x = gx - \phi^TMc \), thus \( g^\prime x \) is minimal as well. By simple inspection \( g^\prime x \) cannot be decreased if and only if for each non-base variable \( x_i \) one of the following three possibilities hold:

1. \( g^\prime_i = 0; \)
2. \( g^\prime_i > 0 \) and \( x_i \) is on its upper limit;
3. \( g^\prime_i < 0 \) and \( x_i \) is on its lower limit.

When this condition is met, the optimum is reached. At this point, instead of terminating the solver, let us change the bounds \( a_i \leq b_i \) to \( a_i^\prime \leq b_i^\prime \) as follows. For base variables \( x_i \), and when \( g^\prime_i = 0 \) keep the old bounds: \( a_i^\prime = a_i, b_i^\prime = b_i \). If \( g^\prime_i > 0 \) then set \( a_i^\prime = b_i^\prime = b_i \) (shrink it to the upper limit), and if \( g^\prime_i < 0 \) then set \( a_i^\prime = b_i^\prime = a_i \) (shrink it to the lower limit).

**Proposition 16.** The solution space of the scalar LP

\[
\min_x \{ g^x : Ax = c, a \leq x \leq b \}
\]

is the collection of all \( x \in \mathbb{R}^n \) which satisfy

\[
\{ Ax = c, a^\prime \leq x \leq b^\prime \}.
\]

**Proof.** From the discussion above it is clear that if \( g^x \) is optimal then \( x \) must satisfy \( a^\prime \leq x \leq b^\prime \), otherwise \( g^x \) can decrease.

This indicates how GLPK can be patched. When the optimum is reached, change the bounds \((a, b)\) to \((a^\prime, b^\prime)\). After this change all feasible solutions are optimal solutions for the first goal. Change the goal function to the next one and resume execution. The last arrangement remains feasible, thus there is no overhead, no additional work is required, just continue the usual simplex iteration. Experience shows that each additional goal adds only a few or no iterations at all. The performance loss over returning after the first minimization is really small.

**C. Plane separation oracle**

The plane separation oracles used in the Inner algorithm 5 can be implemented as indicated at the end of Section III-C. The oracle’s input is a vector \( h \in \mathbb{R}^m \) and an intercept \( M \in \mathbb{R} \). The oracle should return a point \( v \in \mathbb{R}^m \) on the boundary of \( Q \) (weak oracle), or a vertex of \( Q \) (strong oracle) for which the scalar product \( hv \) is the smallest possible. Both the oracle (and the procedure calling the oracle) should be prepared for cases when \( Q \) is empty, or when \{\( hv : v \in Q \)\} is not bounded from below.

**Oracle 17 (weak \( hpO^\ast(Q) \)).** On input \( h \in \mathbb{R}^p \) and intercept \( M \in \mathbb{R} \) find any \( \hat{x} \in \mathbb{R}^m \) where the scalar LP problem

\[
\min_x \{ h^T Px, \ Ax = c, x \geq 0 \}
\]

takes its minimum. If the LP fails, return failure. Otherwise compute \( v = P\hat{x} \in \mathbb{R}^p \). Return “inside” if \( M \) is specified and \( hv \geq M \), otherwise return \( v \).

The scalar LP problem \( P(h) \) searches for a point of \( Q \) which is farthest away in the direction of \( h \). As all oracle calls specify a normal \( h \geq 0 \), the LP can fail only when some of the assumptions on the MOLP problem in Section I-D does not hold. In such a case the MOLP solver can report the problem and abort.

The very first oracle call can be used to find a boundary point of \( Q \) Algorithm 5 starts with. In this case the oracle is called without the intercept. This first oracle call will complain when the the polytope \( \mathcal{A} \) is empty, but might not detect if \( Q \) is not bounded from below in some objective direction. The input to subsequent oracle calls is the facet equation of the approximating polytope, thus have both normal and intercept.

To guarantee that the oracle returns a vertex of \( Q \), and not an arbitrary point on its boundary at maximal distance, the multi-goal scalar LP solver from Section V-B can be invoked.

**Oracle 18 (strong \( hpO(Q) \)).** On input \( h \in \mathbb{R}^p \) and intercept \( M \in \mathbb{R}^p \) call the multi-goal LP solver as follows:

**Constraints:** \( Ax = c, x \geq 0 \).

**Goals:** \( h^T Px, P_1x, P_2x, \ldots, P_px \),

where \( P_i \) is the \( i \)-the row of the objective matrix \( P \). The solver returns \( \hat{x} \). Compute \( \hat{v} = P\hat{x} \). Return “inside” if \( M \) is specified and \( h\hat{v} \geq M \), otherwise return \( \hat{v} \).

The point \( \hat{v} \) is lexicographically minimal among the boundary points of \( Q \) which are farthest away from the specified hyperplane, thus – assuming the oracle did not fail – it is a vertex.

Observe that the plane separating oracles in this section work directly on the polytope \( \mathcal{A} \) without modifying or adding
any further constraints. Thus the constraints and all but the first goal in the invocations of the multi-goal LP solver are the same. Consequently the server could use a “warm boot” further improving the efficiency of the algorithm.

VI. REMARKS

A. Using different ordering cone

In a more general setting the minimization in the MOLP problem

$$\text{find } \min_y \{ y : y \in \mathcal{Q} \}$$

MOLP

is understood with respect to the partial ordering on $\mathbb{R}^p$ defined by the (convex, closed, pointed, and polyhedral) ordering cone $\mathcal{C}$. In this case the solution of the MOLP problem is the list of facets and vertices of the Minkowski sum $\mathcal{Q}^+ = \mathcal{Q} + \mathcal{C}$. The MOLP problem is $\mathcal{C}$-bounded just in case the ideal points of $\mathcal{Q}^+$ are the extremal rays of $\mathcal{C}$. In this case the Inner algorithm 5 works with the same plane separating oracles $\maxhpO(\mathcal{Q})$ and $\maxhpO^*(\mathcal{Q})$ as defined in Section V-C whenever the vertices of the initial approximation $\mathcal{S}$ are just these extremal ideal points and some point $v \in \mathcal{Q}$. Indeed, in this case we have $\mathcal{Q}^+_C = \text{conv}(\mathcal{Q} \cup \mathcal{S})$, and the algorithm terminates with a double description of just this polytope.

When using the outer approximation algorithm, the point separating oracle is invoked with the polytope $\mathcal{Q}^+_C$. The vector $e^*$ should be chosen to be an internal ray in $\mathcal{C}$, and the scalar $\lambda$ for each facet $\mathcal{C}$ is

$$\hat{\lambda} = \max_{\lambda, x, z} \{ \lambda : v - \lambda e^* = P x + z, Ax = c, x \geq 0, z \in \mathcal{C} \},$$

see Section V-A. The analog of Proposition 11 can be used to realize the oracles $\minptO(\mathcal{Q}^+_C)$ and $\minptO^*(\mathcal{Q}^+_C)$. The base of the initial bounding $\mathcal{S}$ is formed by the ideal vertices at the end of the extremal rays of $\mathcal{C}$, as above. The top vertex can be generated by computing a $H$-minimal point of $\mathcal{Q}$ for each facet $H$ of $\mathcal{C}$.

B. Relaxing the condition on boundedness

When the boundedness assumption in Section I-D does not hold, then the ideal points of $\mathcal{Q}^+$ (or the polytope $\mathcal{Q}^+_C$ above) are not known in advance. As the initial approximation of the Outer algorithm 4 must contain $\mathcal{Q}^+$, these ideal points should be computed first. For the Inner algorithm 5 there are two possibilities. One can start from the same initial polytope $\mathcal{S}$, but then the oracle can return ideal points (and the oracle and the calling procedure must handle these cases). Or, as above, the initial approximation could contain all ideal points, and then all points returned by the oracle (which could just be $\maxhpO(\mathcal{Q})$ or $\maxhpO^*(\mathcal{Q})$) are normal points.

The ideal points of $\mathcal{Q}^+$ (or $\mathcal{Q}^+_C$) are the convex hull of the ideal points of $\mathcal{Q}$ and that of the positive orthant $\mathbb{R}^p_+$ (or the ordering cone $\mathcal{C}$). To find all the ideal vertices the Inner algorithm 5 can be called recursively for this $(p - 1)$-dimensional problem.

C. The order of oracle inputs

The skeletal algorithms 1 and 2 do not specify which non-final vertex (facet) should be passed to the oracle; as far as the algorithm is concerned, any choice is good. But the actual choice can have a significant effect on the overall performance: it can affect the size (number of vertices and facets) of the subsequent approximating polytopes, and, which is equally important, numerical stability. There are no theoretical results which would recommend any particular choice. Bremner in [3] gave an example where any choice leads to a blow-up in the approximating polytope.

The implementation of the Inner algorithm 2 offers three possibilities for choosing which vertex is to be added to the approximation polytope.

1) Ask the oracle the facets in the order they were created (first facets from the initial approximation $\mathcal{S} = \mathcal{S}_0$, then facets from $\mathcal{S}_1$, etc.), and then use the returned vertex to create the next approximation.

2) Pick a non-final facet from the current approximation randomly with (roughly) equal probability, and ask this facet from the oracle.

3) Keep a fixed number of candidate vertices in a “pool”. (The pool size can be set between 10 and 100.) Fill the pool by asking the oracle non-final facets randomly, checking that the same vertex enters the pool only once. Give a score for each vertex in the pool and choose the vertex with the best score.

The following heuristics gave consistently the best result: choose the vertex which is to be added to the approximation polytope.

D. Parallelizing

While the simplex algorithm solving scalar LP problems is inherently serial, the most time-consuming part of vertex enumeration – the ridge test – can be done in parallel. There are LP intensive problems – especially when the number of variables and constraints are high and there are only a few objectives – where almost the total execution time is spent by the LP solver; and there are combinatorial intensive problems – typically when the number of objectives is very high, 20 or more – where the LP solver takes negligible time. In the latter cases the average number of ridge tests per iteration can be as high as $10^7 – 10^9$ and can take hours to complete serially on a decent processor. Doing it in parallel can reduce the execution time significantly as explained in Section IV.

In a multithread environment each thread is assigned a set of facet pairs on which it executes the ridge test as defined in Proposition 10, and computes the coordinates of the new facet if the pair passes the test. Every thread uses the current facet
and vertex bitmaps with total size up to $10^8 – 10^9$ byte, while every thread requires a relative small private memory around $10^5$ byte. Run on a single processor the algorithm scales well with the number of assigned threads. On supercomputers with hundreds of threads (and processors) memory latency can be an issue [4].
