A Forward-Backward Splitting Method for Monotone Inclusions Without Cocoercivity

Yura Malitsky∗ Matthew K. Tam∗

Abstract
In this work, we propose a simple modification of the forward-backward splitting method for finding a zero in the sum of two monotone operators. Our method converges under the same assumptions as Tseng’s forward-backward-forward method, namely, it does not require cocoercivity of the single-valued operator. Moreover, each iteration only uses one forward evaluation rather than two as is the case for Tseng’s method. Variants of the method incorporating a linesearch, relaxation and inertia, or a structured three operator inclusion are also discussed.

1 Introduction
In this work, we propose an algorithm for finding a zero in the sum of two monotone operators in a (real) Hilbert space \( \mathcal{H} \). Specifically, we consider the monotone inclusion problem

\[
\text{find } x \in \mathcal{H} \text{ such that } 0 \in (A + B)(x),
\]

(1)

where \( A : \mathcal{H} \rightrightarrows \mathcal{H} \) and \( B : \mathcal{H} \to \mathcal{H} \) are (maximally) monotone operators with \( B \) (locally) Lipschitz continuous such that \( (A + B)^{-1}(0) \neq \emptyset \). Inclusions of the form specified by (1) arise in numerous problems of fundamental importance in mathematical optimization, either directly or through an appropriate reformulation. In what follows, we provide some motivating examples.

Convex minimization: Consider the minimization problem

\[
\min_{x \in \mathcal{H}} f(x) + g(x),
\]

where \( f : \mathcal{H} \to (-\infty, +\infty] \) is proper, lower semicontinuous (lsc), convex and \( g : \mathcal{H} \to \mathbb{R} \) is convex with (locally) Lipschitz continuous gradient denoted \( \nabla g \). The solutions to this minimization problem are precisely the points \( x \in \mathcal{H} \) which satisfy the first order optimality condition:

\[
0 \in (\partial f + \nabla g)(x),
\]

(2)

where \( \partial f \) denotes the subdifferential of \( f \). Clearly (2) is of the form specified by (1).

General monotone inclusions: Consider the inclusion problem

\[
\text{find } x \in \mathcal{H}_1 \text{ such that } 0 \in (A + K^* B K)(x),
\]

(3)

where \( A : \mathcal{H}_1 \rightrightarrows \mathcal{H}_1 \) and \( B : \mathcal{H}_2 \rightrightarrows \mathcal{H}_2 \) are maximally monotone operators, and \( K : \mathcal{H}_1 \to \mathcal{H}_2 \) is a linear, bounded operator with adjoint \( K^* \). As was observed in [8,9], solving (3) can be equivalently cast as the following monotone inclusion posed in the product space:

\[
\text{find } \begin{pmatrix} x \\ y \end{pmatrix} \in \mathcal{H}_1 \times \mathcal{H}_2 \text{ such that } \begin{pmatrix} 0 \\ 0 \end{pmatrix} \in \left( \begin{bmatrix} A & 0 \\ 0 & B^{-1} \end{bmatrix} + \begin{bmatrix} 0 & K^* \\ -K & 0 \end{bmatrix} \right) \begin{pmatrix} x \\ y \end{pmatrix},
\]

(4)

[8] Institute for Numerical and Applied Mathematics, University of Göttingen, 37083 Göttingen, Germany. E-mail: y.malitsky@gmail.com, m.tam@math.uni-goettingen.de
Notice that the first operator in (4) is maximally monotone whereas the second is bounded and linear (in particular, it is Lipschitz continuous with full domain). Consequently, (4) is also of the form specified by (1).

Another variant of (1) is the three operator inclusion

\[
\text{find } x \in \mathcal{H} \text{ such that } 0 \in (A + B + C)(x),
\]

where the operators \( A \) and \( B \) are as before and \( C: \mathcal{H} \to \mathcal{H} \) is \( \beta \)-cocoercive. Problems with this structure have been studied in [10,14].

**Saddle point problems and variational inequalities:** Many convex optimization problems can be formulated as the *saddle point problem*

\[
\min_{x \in \mathcal{H}} \max_{y \in \mathcal{H}} g(x) + \Phi(x, y) - f(y),
\]

where \( f, g: \mathcal{H} \to (-\infty, +\infty] \) are proper, lsc, convex functions and \( \Phi: \mathcal{H} \times \mathcal{H} \to \mathbb{R} \) is a smooth convex-concave function. Problems of this form naturally arise in machine learning, statistics, etc., where the dual (maximization) problem comes from either dualizing the constraints in the primal problem or from using the Fenchel–Legendre transform to leverage a nonsmooth composite part. Through its first-order optimality condition, the saddle point problem (6) can expressed as the monotone inclusion

\[
\text{find } \begin{pmatrix} x \\ y \end{pmatrix} \in \mathcal{H} \times \mathcal{H} \text{ such that } \begin{pmatrix} 0 \\ 0 \end{pmatrix} \in \begin{pmatrix} \partial g(x) & \partial f(x) \\ -\partial y \Phi(x, y) & \partial y \Phi(x, y) \end{pmatrix},
\]

which is of the form specified by (1). By using the definitions of the respective subdifferentials, (7) can also be expressed in terms of the *variational inequality (VI)*: find \( z^* = (x^*, y^*)^\top \in \mathcal{H} \times \mathcal{H} \) such that

\[
\langle B(z^*), z - z^* \rangle + g(x) - g(x^*) - f(y) + f(y^*) \geq 0 \quad \forall z = \begin{pmatrix} x \\ y \end{pmatrix} \in \mathcal{H} \times \mathcal{H},
\]

where \( B(x, y) := (\nabla_x \Phi(x, y), -\nabla_y \Phi(x, y))^\top \).

**Splitting algorithms** are a class of methods which can be used to solve (1) by only invoking each operator individually rather than their sum directly. The individual steps within each iteration of these methods can be divided into two categories: *forward evaluations* in which the value of a single-valued operator is computed, and *backward evaluations* in which the *resolvent* of an operator computed. Recall that the resolvent of an operator \( A \) is given by \( J_A := (I + A)^{-1} \) where \( I: \mathcal{H} \to \mathcal{H} \) denotes the identity operator.

When the resolvents of both of the involved operators can be easily computed, there are various algorithms in the literature which are suitable for solving (1) with \( B \) not necessarily single-valued. The best known example of such an algorithm is the *Douglas–Rachford method* [18,27]. In practice, however, it is usually not the case that both resolvents can be readily computed and thus in order to efficiently deal with realistic problems, it is often necessary to impose further structure on the operators in (1). Splitting methods which do not require computation of two resolvents are therefore of practical interest.

The best-known splitting method for solving the inclusion (1) when \( B \) is single-valued is the *forward-backward method*, called so because each iteration combines one forward evaluation of \( B \) with one backward evaluation of \( A \). More precisely, the method generates a sequence according to

\[
x_{k+1} = J_{\lambda A}(x_k - \lambda B(x_k)) \quad \forall k \in \mathbb{N},
\]

and converges weakly to a solution provided the operator \( B: \mathcal{H} \to \mathcal{H} \) is \( 1/L \)-cocoercive and \( \lambda \in (0,2/L) \). Recall that \( B: \mathcal{H} \to \mathcal{H} \) is \( \beta \)-cocoercive if

\[
\langle x - y, B(x) - B(y) \rangle \geq \beta \|B(x) - B(y)\|^2 \quad \forall x, y \in \mathcal{H}.
\]
Cocoercivity of an operator is a stronger property than Lipschitz continuity and hence can be difficult to satisfy for general monotone inclusions. For instance, apart from the trivial case when $K = 0$, the skew-symmetric operator in (4) is never cocoercive. Furthermore, without cocoercivity, convergence of (9) can only be guaranteed in the presence of similarly strong assumptions such as strong monotonicity of $A + B$ [12], or at the cost of incorporating a backtracking strategy [6] (even when the Lipschitz constant is known).

In order to relax the cocoercivity assumption, Tseng [28] proposed a modification of the forward-backward algorithm, known as the Tseng’s method or the forward-backward-forward method, which only requires Lipschitzness of $B$ at the expense of an additional forward evaluation. Applied to (1), Tseng’s method generates sequences according to

$$
\begin{align*}
   y_k &= J_{\lambda A}(x_k - \lambda B(x_k)) \\
   x_{k+1} &= y_k - \lambda B(y_k) + \lambda B(x_k) \quad \forall k \in \mathbb{N},
\end{align*}
$$

and converges weakly provided $B$ is $L$-Lipschitz and $\lambda \in (0, 1/L)$.

In this work, we introduce and analyze a new method for solving (1) which converges under the same assumptions as Tseng’s method, but whose implementation requires only one forward evaluation per iteration instead of two. For a fixed stepsize $\lambda > 0$, the proposed scheme can be simply described as

$$
\begin{align*}
   x_{k+1} &= J_{\lambda A}(x_k - 2\lambda B(x_k) + \lambda B(x_{k-1})) \quad \forall k \in \mathbb{N},
\end{align*}
$$

and converges weakly if $B$ is $L$-Lipschitz and the stepsize is chosen to satisfy $\lambda < \frac{1}{2L}$. We refer to this scheme as the forward-reflected-backward method. It is worth noting that the analysis of our method is entirely different than existing schemes, and hence is of interest in its own right. In particular, the sequence generated by the method is not Fejér monotone. Moreover, there are relatively few fundamentally different alternatives to Tseng’s forward-backward-forward algorithm for solving inclusions in the form of (1) without cocoercivity [13,16].

We also remark that our method is of particular interest in the setting of the saddle point problem (7). Indeed, one of the first splitting techniques for solving (6) is the famous Arrow–Hurwicz algorithm [3] which suffers from the shortcoming of requiring strict assumptions to ensure convergence. This was remedied in late 70’s when various modification of the algorithm were proposed [2,17,25] which turned out to applicable not only to saddle point problems, but also to more general variational inequalities. Note also that the simplest case of (6) occurs when $\Phi$ is a bilinear form and gives rise to the popular primal-dual algorithm, first analyzed by Chambolle & Pock [11]. In a recent preprint [15], a variant of this algorithm, which can be applied when $\Phi$ is not necessarily bilinear, was considered. Such an extension is a significant improvement as it provides an approach to the saddle point problem that is different from variational inequality methods. An interesting common feature of the methods in [11,13,15,21] as well as the one presented here is that their respective iterations include a “reflection term” in which the value of an operator at the previous point is subtracted from twice its value at the current point.

The remainder of this paper is organized as follows. In Section 2, we introduce our method and prove its convergence (Theorem 2.5). In Section 2.1, this result is refined to show that convergence is linear whenever one of the operators is strongly monotone. In Section 3, we incorporate a linesearch procedure into the method (Theorem 3.4). In Section 4, we consider a relaxed inertial version (Theorem 4.3) and finally, in Section 5, we propose a variant which solves the three operator inclusion (5).

## 2 Forward-reflected-backward splitting

Recall that a set-valued operator $A : \mathcal{H} \rightrightarrows \mathcal{H}$ is monotone if

$$
(x - y, u - v) \geq 0 \quad \forall (x, u), (y, v) \in \text{gra} A,
$$

where $\text{gra} A = \{(x, y) \in \mathcal{H} \times \mathcal{H} : y \in A(x)\}$ denotes the graph of $A$. A monotone operator is maximally monotone if its graph is not properly contained in the graph of any other monotone
operator. The resolvent of a maximally monotone operator \( A: \mathcal{H} \rightrightarrows \mathcal{H} \), defined by \( J_A := (I + A)^{-1} \), is an everywhere single-valued operator \([5]\). A single-valued operator \( B: \mathcal{H} \to \mathcal{H} \) is \( L \)-Lipschitz if \( \|B(x) - B(y)\| \leq L \|x - y\| \) for all \( x, y \in \mathcal{H} \).

In this section, we consider the problem of finding a point \( x \in \mathcal{H} \) such that

\[
0 \in (A + B)(x),
\]

where \( A: \mathcal{H} \rightrightarrows \mathcal{H} \) is maximal monotone, and \( B: \mathcal{H} \to \mathcal{H} \) is monotone and \( L \)-Lipschitz. Given initial points \( x_0, x_{-1} \in \mathcal{H} \), we consider the scheme

\[
x_{k+1} = J_{\lambda_k} A(x_k - \lambda_k B(x_k)) - \lambda_k - 1(B(x_k) - B(x_{k-1})) \quad \forall k \in \mathbb{N},
\]

where \( \lambda_k \subseteq \mathbb{R}_+ \) is a sequence of step-sizes (starting with \( k = -1 \)). Note that, each iteration of this scheme requires one forward evaluation and one backward evaluation. Using the definition of the resolvent \( J_{\lambda_k} A = (I + \lambda_k A)^{-1} \), \( (13) \) can be equivalently expressed as the inclusion

\[
x_{k+1} - x_k + \lambda_k B(x_k) + \lambda_{k-1}(B(x_k) - B(x_{k-1})) \in -\lambda_k A(x_{k+1}) \quad \forall k \in \mathbb{N}.
\]

Before turning our attention to the convergence analysis of this method, we first note some special cases in which it recovers known methods.

**Remark 2.1** (Special cases of \( (13) \)). We consider three cases in which the proposed algorithm reduces or is equivalent to known methods. For simplicity, we only consider the fixed step-size case (i.e., \( \exists \lambda > 0 \) such that \( \lambda_k = \lambda \) for all \( k \)). In this case, \( (13) \) can be expressed compactly as

\[
x_{k+1} = J_{\lambda A}(x_k - 2\lambda B(x_k) + \lambda B(x_{k-1})).
\]

(a) If \( B = 0 \) then \( (15) \) simplifies to the proximal point algorithm \([26]\), that is, \( (15) \) becomes

\[
x_{k+1} = J_{\lambda A}(x_k) \quad \forall k \in \mathbb{N}.
\]

(b) If \( A = N_C \) is the normal cone to a set \( C \) and \( B \) is an affine operator then \( (15) \) can be expressed as

\[
x_{k+1} = P_C(x_k - \lambda B(2x_k - x_{k-1})) \quad \forall k \in \mathbb{N},
\]

which coincides with the projected reflected gradient method \([20]\) for VIs.

(c) If \( A = N_{\mathcal{H}} = 0 \) then the projected reflected gradient method \( (16) \) becomes

\[
x_{k+1} = x_k - \lambda B(2x_k - x_{k-1}) \quad \forall k \in \mathbb{N}.
\]

Under the change of variables \( \bar{x}_k = 2x_k - x_{k-1} \), this becomes

\[
\bar{x}_{k+1} = \bar{x}_k - 2\lambda B(\bar{x}_k) + (x_{k-1} - x_k) = \bar{x}_k - 2\lambda B(\bar{x}_k) + \lambda B(\bar{x}_k - 1) \quad \forall k \in \mathbb{N},
\]

which is precisely \( (13) \) with \( A = 0 \). Alternatively, \( (15) \) can be expressed as the two step recursion

\[
\begin{align*}
y_{k+1} &= y_k - \lambda B(x_k) \\
x_{k+1} &= y_{k+1} - \lambda B(x_k).
\end{align*}
\]

This is exactly Popov’s algorithm \([25]\) for unconstrained VIs. In this sense, the three methods coincide in this case up to a change of variable.

Before establishing convergence of the method, we require some preparatory results.

**Lemma 2.2.** Let \( (z_k) \subseteq \mathcal{H} \) be a bounded sequence and suppose \( \lim_{k \to \infty} \|z_k - z\| \) exists whenever \( z \) is a cluster point of \( (z_k) \). Then \( (z_k) \) is weakly convergent.

Equation \( (18) \) in the following proposition conforms, in particular, to our proposed method given by

\[
x_{k+1} = J_{\lambda_k} A(x_k - \lambda_k B(x_k)) - \lambda_k - 1(B(x_k) - B(x_{k-1})).
\]
Proposition 2.3. Let $F: \mathcal{H} \to \mathcal{H}$ be maximally monotone, and let $d_1, v_2, u_1, v_1, u_0 \in \mathcal{H}$ be arbitrary. Define $d_2$ as
\[
d_2 = J_F(d_1 - u_1 - (v_1 - u_0)).
\]
Then, for all $x \in \mathcal{H}$ and $u \in -F(x)$, we have
\[
\|d_2 - x\|^2 + 2 \langle v_2 - u_1, x - d_2 \rangle \leq \|d_1 - x\|^2 \quad \|v_1 - u_0, x - d_1\rangle + 2 \langle v_1 - u_0, d_1 - d_2 \rangle - \|d_1 - d_2\|^2 \quad \|v_2 - u, d_2 - x\rangle. \tag{19}
\]
Proof. By definition of the resolvent, $d_1 - u_1 - (v_1 - u_0) \in d_2 + F(d_2)$ and hence, by monotonicity of $A$,
\[
0 \leq \langle d_2 - d_1 + u_1 + (v_1 - u_0) - y, x - d_2 \rangle = \langle d_2 - d_1, x - d_2 \rangle + \langle u_1 - u, x - d_2 \rangle + \langle v_1 - u_0, x - d_2 \rangle.
\]
The first term can expressed as
\[
\langle d_2 - d_1, x - d_2 \rangle = \frac{1}{2} \big( \|d_1 - x\|^2 - \|d_2 - x\|^2 - \|d_2 - d_1\|^2 \big),
\]
and the second and third terms can be rewritten, respectively, as
\[
\langle u_1 - u, x - d_2 \rangle = \langle v_2 - u, x - d_2 \rangle + \langle u_1 - v_2, x - d_2 \rangle,
\]
\[
\langle v_1 - u_0, x - d_2 \rangle = \langle v_1 - u_0, x - d_1 \rangle + \langle v_1 - u_0, d_1 - d_2 \rangle.
\]
The claimed inequality follows by combining these expressions. \qed

Apart from using the monotonicity of $F$, the proof of Proposition 2.3 only uses simple algebraic manipulations involving $u_1, v_1, u_0, v_2, d_1, d_2$. Nevertheless, the resulting inequality (19) already provides some insight into how our subsequence analysis of (11) proceeds. For instance, the first line of (19) suggests terms for telescoping so long as the second line can be appropriately estimated.

Lemma 2.4. Let $x \in (A + B)^{-1}(0)$ and let $(x_k)$ be given by (13). Suppose $(\lambda_k) \subseteq \left[ \epsilon, \frac{1 - 2\epsilon}{2} \right]$ for some $\epsilon > 0$. Then, for all $k \in \mathbb{N}$, we have
\[
\|x_{k+1} - x\|^2 + 2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \langle \frac{1}{2} + \epsilon \rangle \|x_{k+1} - x_k\|^2
\leq \|x_k - x\|^2 + 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \frac{1}{2} \|x_k - x_{k-1}\|^2. \tag{20}
\]
Proof. By applying Proposition 2.3 with
\[
F := \lambda_k A \quad d_1 := x_k \quad u_0 := \lambda_{k-1} B(x_{k-1}) \quad v_1 := \lambda_{k-1} B(x_k)
\]
\[
u := \lambda_k B(x) \quad d_2 := x_{k+1} \quad u_1 := \lambda_k B(x_k) \quad v_2 := \lambda_k B(x_{k+1}),
\]
we obtain the inequality
\[
\|x_{k+1} - x\|^2 + 2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \|x_{k+1} - x_k\|^2
\leq \|x_k - x\|^2 + 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), x - x_k \rangle
\]
\[
+ 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), x - x_{k-1} \rangle - 2\lambda_k \langle B(x_{k+1}) - B(x_k), x_{k+1} - x \rangle.
\]
Since $B$ is monotone, the last term is nonnegative. Using Lipschitzness of $B$, the second last term can be estimated as
\[
\langle B(x_k) - B(x_{k-1}), x_k - x_{k-1} \rangle \leq L \|x_k - x_{k-1}\| \|x_k - x_{k+1}\|
\]
\[
\leq \frac{L}{2} \left( \|x_k - x_{k-1}\|^2 + \|x_k - x_{k+1}\|^2 \right). \tag{21}
\]
Thus, altogether, we obtain
\[
\|x_{k+1} - x\|^2 + 2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \langle 1 - \lambda_{k-1} L \rangle \|x_{k+1} - x_k\|^2
\leq \|x_k - x\|^2 + 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \lambda_{k-1} L \|x_k - x_{k-1}\|^2.
\]
The claimed inequality follows since $\lambda_{k-1} L < \frac{1}{2}$ and $1 - \lambda_{k-1} L \geq 1 - \frac{1 - 2\epsilon}{2} = \frac{1}{2} + \epsilon$. \qed
We are now ready for the first main result regarding convergence of the proposed method.

**Theorem 2.5.** Let $A: \mathcal{H} \rightrightarrows \mathcal{H}$ be maximally monotone, let $B: \mathcal{H} \to \mathcal{H}$ be monotone and $L$-Lipschitz, and suppose that $(A + B)^{-1}(0) \neq \emptyset$. Suppose $(\lambda_k) \subseteq \left[\varepsilon, \frac{1-2\varepsilon}{2L}\right]$ for some $\varepsilon > 0$. Given $x_0, x_{-1} \in \mathcal{H}$, define the sequence $(x_k)$ according to

$$x_{k+1} = J_{\lambda_k A}(x_k - \lambda_k B(x_k) - \lambda_{k-1}(B(x_k) - B(x_{k-1}))) \quad \forall k \in \mathbb{N}.$$ 

Then $(x_k)$ converges weakly to a point contained in $(A + B)^{-1}(0)$.

**Proof.** Let $x \in (A + B)^{-1}(0)$. By Lemma 2.4, we have

$$\|x_{k+1} - x\|^2 + 2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \left(\frac{1}{2} + \varepsilon\right)\|x_{k+1} - x_k\|^2$$

$$\leq \|x_k - x\|^2 + 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \frac{1}{2}\|x_k - x_{k-1}\|^2, \quad (22)$$

which telescopes to yield

$$\|x_{k+1} - x\|^2 + 2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \frac{1}{2}\|x_{k+1} - x_k\|^2$$

$$+ \varepsilon \sum_{i=0}^{k} \|x_{i+1} - x_i\|^2 \leq \|x_0 - x\|^2 + 2\lambda_{-1} \langle B(x_0) - B(x_{-1}), x - x_0 \rangle + \frac{1}{2}\|x_0 - x_{-1}\|^2. \quad (23)$$

Using Lipschitzness of $B$, we can estimate

$$2\lambda_k \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle \geq -2\lambda_k L \|x_{k+1} - x_k\| \|x - x_{k+1}\|$$

$$\geq -\lambda_k L \left(\|x_{k+1} - x_k\|^2 + \|x - x_{k+1}\|^2\right). \quad (24)$$

Since $\lambda_k L \leq (1 - 2\varepsilon)/2 < 1/2$, substituting the previous equation back into (23) gives

$$\frac{1}{2}\|x_{k+1} - x\|^2 + \varepsilon \sum_{i=0}^{k} \|x_{i+1} - x_i\|^2 \leq \|x_0 - x\|^2 + 2\lambda_{-1} \langle B(x_0) - B(x_{-1}), x - x_0 \rangle + \frac{1}{2}\|x_0 - x_{-1}\|^2,$$

from which we deduce that $(x_k)$ is bounded and that $\|x_k - x_{k+1}\| \to 0$.

Let $\vec{x}$ be a sequential weak cluster point of the bounded sequence $(x_k)$. From (14), $\forall k \geq 1$

$$\frac{1}{\lambda_{k-1}}(x_{k-1} - x_k + \lambda_{k-1}(B(x_k) - B(x_{k-1})) + \lambda_{k-2}(B(x_{k-2}) - B(x_{k-1}))) \in (A + B)(x_k) \quad (25)$$

Since $A + B$ is maximally monotone [5, Corollaries 24.4(i) & 20.25], its graph is demiclosed (i.e., sequentially closed in the weak-strong topology on $\mathcal{H} \times \mathcal{H}$) [5, Proposition 20.33]. Thus, by taking the limit along a subsequence of $(x_k)$ which converges to $\vec{x}$ in (25) and noting that $\lambda_k \geq \varepsilon$ for all $k \in \mathbb{N}$, we deduce that $0 \in (A + B)(\vec{x})$. To show that $(x_k)$ is weakly convergent, first note that, by combining (22) and (24), we deduce existence of the limit

$$\lim_{k \to \infty} \left(\|x_k - \vec{x}\|^2 + 2\lambda_{k-1} \langle B(x_k) - B(x_{k-1}), \vec{x} - x_k \rangle + \frac{1}{2}\|x_k - x_{k-1}\|^2\right). \quad (26)$$

Since $(x_k)$ and $(\lambda_k)$ are bounded, $\|x_k - x_{k+1}\| \to 0$, and $B$ is continuous, it then follows that the limit (26) is equal to $\lim_{k \to \infty} \|x_k - \vec{x}\|^2$. Since the cluster point $\vec{x}$ of $(x_k)$ was chosen arbitrarily, the sequence $(x_k)$ is weakly convergent by Lemma 2.2 and the proof is complete.

As an immediate consequence of Theorem 2.5, we obtain the following corollary when the stepsize sequence $(\lambda_k)$ is constant.
Corollary 2.6. Let $A: \mathcal{H} \rightrightarrows \mathcal{H}$ be maximally monotone, let $B: \mathcal{H} \to \mathcal{H}$ be monotone and $L$-Lipschitz, and suppose that $(A + B)^{-1}(0) \neq \emptyset$. Choose $\lambda \in \left(0, \frac{1}{2L} \right)$. Given $x_0, x_{-1} \in \mathcal{H}$, define the sequence $(x_k)$ according to

$$x_{k+1} = J_{\lambda A} \left( x_k - 2\lambda B(x_k) + \lambda B(x_{k-1}) \right) \quad \forall k \in \mathbb{N}.$$  

Then $(x_k)$ converges weakly to a point contained in $(A + B)^{-1}(0)$.

Remark 2.7. In practice, it can be desirable to analyze an algorithm with respect to an auxiliary metric to encourage faster convergence. This is done by considering the metric induced by the inner product $\langle \cdot, \cdot \rangle_M$ corresponding to a symmetric positive definite operator $M: \mathcal{H} \to \mathcal{H}$. In the case of saddle point problems for example, choosing the operator $M$ to be a diagonal scaling matrix gives different weights to primal and dual variables. To keep our presentation as simple and as clear as possible, we present our analysis only for the case when $M = I$. Nevertheless, the more general case can be easily obtained through a straightforward modification of the proof. In particular, instead of (13), we can consider the iteration

$$x_{k+1} = J^M_{\lambda A} \left( x_k - M^{-1} \left[ \lambda k B(x_k) + \lambda k-1 (B(x_k) - B(x_{k-1})) \right] \right) \quad \forall k \in \mathbb{N},$$

where $J^M_{\lambda A} = (I + M^{-1} A)^{-1}$ denotes the generalized resolvent of $A$.

Remark 2.8. Since the main focus of this work lies in the development and analysis of new methods, we delay a thorough comparison for future investigation. Nevertheless, the following example provides a specific problem for which the forward-reflected-backward method is faster than Tseng’s method. We make no claims about the performance of the proposed method in general.

Consider (1) with $\mathcal{H} = \mathbb{R}^n \times \mathbb{R}^n$, $A(x, y) = (0, 0)$ and $B(x, y) = (y, -x)$. Note that zero is the unique solution to this problem and that the operator $B$ is 1-Lipschitz. Let us also denote the identity operators on $\mathcal{H}$ and $\mathbb{R}^n$ by $I_\mathcal{H}$ and $I_n$, respectively. This is a classical example of a monotone inclusion, where the forward-backward method fails.

Tseng’s method \hspace{1em} By eliminating $y_k$ from (10) and using the identity $B^2 = -I_\mathcal{H}$, Tseng’s method can be expressed as

$$x_{k+1} = T(x_k) = T^k(x_0) \quad \text{where} \quad T := (1 - \lambda^2) I_\mathcal{H} - \lambda B.$$ 

The operator $T$ can be decomposed as $T = U^* \Lambda U$ where

$$U = \frac{1}{\sqrt{2}} \begin{bmatrix} i I_n & -i I_n \\ I_n & I_n \end{bmatrix}, \quad \Lambda = \begin{bmatrix} (1 - \lambda^2 + \lambda i) I_n & 0 \\ 0 & (1 - \lambda^2 - \lambda i) I_n \end{bmatrix}.$$ 

Let $\lambda \in (0, 1)$. The sequence $(x_k)$ therefore converges $Q$-linearly to zero with rate

$$\rho := |1 - \lambda^2 \pm \lambda i| = \sqrt{(1 - \lambda^2)^2 + \lambda^2} = \sqrt{1 - \lambda^2 + \lambda^4} < 1.$$ 

In fact, this shows the optimal stepsize is $\lambda = 1/\sqrt{2}$ which gives a rate of $\sqrt{3}/2$. (Note that the optimal rate does not occur for the largest possible stepsize).

FoRB splitting \hspace{1em} The forward-reflected-backward method with constant stepsize $\lambda \in (0, 1/2)$ can be expressed as

$$\begin{pmatrix} x_{k+1} \\ x_k \end{pmatrix} = T \begin{pmatrix} x_k \\ x_{k-1} \end{pmatrix} = T^k \begin{pmatrix} x_0 \\ x_{-1} \end{pmatrix} \quad \text{where} \quad T := \begin{bmatrix} I_\mathcal{H} - 2\lambda B & \lambda B \\ I_\mathcal{H} & 0 \end{bmatrix}.$$ 

The eigenvalues of $T$ are given by $\frac{1}{2} \pm \frac{1}{2} i \sqrt{8 \lambda^2 - 1 - 4i \lambda \sqrt{1 - 4 \lambda^2}}$. By choosing the stepsize $\lambda \approx 1/2$, we deduce that the rate of convergence of $(x_k)$ can be made arbitrarily close to $\left| \frac{1}{2} \pm \frac{1}{2} i \right| = \frac{1}{\sqrt{2}}$.

Since $1/\sqrt{2} < \sqrt{3}/2$, we conclude that FoRB is faster than Tseng’s method for this particular problem. Note that this comparison is in terms of the number of iterations.
2.1 Linear Convergence

In this section, we establish $R$-linear convergence of the sequence generated by the forward-reflected-backward method when $A$ is strongly monotone. Recall that $A: \mathcal{H} \rightrightarrows \mathcal{H}$ is m-strongly monotone if $m > 0$ and

$$
\langle x - y, u - v \rangle \geq m \|x - y\|^2 \quad \forall (x, u), (y, v) \in \text{gra } A.
$$

Strong monotonicity is a standard assumption for proving linear convergence of first order methods. For if $B$ is m-strongly monotone, we can always augment the operators by the identity, i.e., $A + B = (A + mI) + (B - mI)$, without destroying monotonicity and Lipschitz continuity. Notice this does not complicate computing the resolvent of $(A + mI)$, as we have $J_{A+mI}(x) = J_{A \frac{1}{1+m}}\left(\frac{x}{1+m}\right)$ for all $x \in \mathcal{H}$.

Before establishing linear convergence of our proposed method, we shall require the following preparatory lemma.

**Lemma 2.9.** Let $(a_k)$ and $(b_k)$ be two nonnegative sequences of real numbers. Suppose there exist constants $\alpha > 1$ and $\delta > 0$ such that

$$
aa_{k+1} + b_{k+1} \leq a_k + b_k \quad \text{and} \quad \delta b_k \leq a_k \quad \forall k \in \mathbb{N}.
$$

Then $(a_k)$ and $(b_k)$ converge to zero with $R$-linear rate.

*Proof.* Let $\beta \in (1, \alpha)$. Then, since $\delta b_{k+1} \leq a_{k+1}$, we have

$$
aa_{k+1} = \alpha a_{k+1} + (\alpha - \beta)a_{k+1} \geq \beta a_{k+1} + \delta(\alpha - \beta)b_{k+1}.
$$

Set $r := \min\{\beta, 1 + \delta(\alpha - \beta)\} > 1$. Combining the previous inequality with (27) gives

$$
r(a_{k+1} + b_{k+1}) \leq \beta a_{k+1} + (1 + \delta(\alpha - \beta))b_{k+1} = [\beta a_{k+1} + \delta(\alpha - \beta)b_{k+1}] + b_{k+1}

\leq aa_{k+1} + b_{k+1} \leq a_k + b_k.
$$

This implies that

$$
a_{k+1} + b_{k+1} \leq \frac{1}{r^k} (a_0 + b_0) \quad \forall k \in \mathbb{N},
$$

from which the claim follows. \hfill \Box

**Theorem 2.10.** Let $A: \mathcal{H} \rightrightarrows \mathcal{H}$ be maximally monotone and m-strongly monotone, let $B: \mathcal{H} \rightrightarrows \mathcal{H}$ monotone and L-Lipschitz, and suppose $(A + B)^{-1}(0) \neq \emptyset$. Let $\lambda \in (0, \frac{1}{2L})$. Given $x_0, x_{-1} \in \mathcal{H}$, define the sequence $(x_k)$ according to

$$
x_{k+1} = J_{LA}(x_{k} - 2\lambda B(x_k) + \lambda B(x_{k-1})) \quad \forall k \in \mathbb{N}.
$$

Then $(x_k)$ converges $R$-linearly to the unique element of $(A + B)^{-1}(0)$.

*Proof.* Let $x \in (A + B)^{-1}(0)$. Using strong monotonicity of $A$ (in place of monotonicity) in Proposition 2.3 and propagating the resulting inequality through the proof of Lemma 2.4, gives the inequality

$$
(1 + 2m\lambda) \|x_{k+1} - x\|^2 + 2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + (1 - \lambda L) \|x_{k+1} - x_k\|^2

\leq \|x_k - x\|^2 + 2\lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \frac{1}{2} \|x_k - x_{k-1}\|^2.
$$

By denoting $\alpha := 1 + 4m\lambda > 1$, this inequality implies

$$
aa_{k+1} + b_{k+1} \leq a_k + b_k,
$$

(28)
where the nonnegative sequences \((a_k)\) and \((b_k)\) are given by
\[
a_k := \frac{1}{2} \|x_k - x\|^2 \geq 0,
\]
\[
b_k := \frac{1}{2} \|x_k - x\|^2 + 2\lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \frac{1}{2} \|x_k - x_{k-1}\|^2.
\]

Using Lipschitzness of \(B\), we have
\[
b_k \geq \frac{1}{2} \|x_k - x\|^2 - 2\lambda L \|x_k - x_{k-1}\| \|x_k - x\| + \frac{1}{2} \|x_k - x_{k-1}\|^2
\]
\[
\geq \frac{1}{2} \|x_k - x\|^2 - \lambda L \left(\|x_k - x_{k-1}\|^2 + \|x_k - x\|^2\right) + \frac{1}{2} \|x_k - x_{k-1}\|^2 \geq 0.
\]

The conditions of Lemma 2.9 are thus satisfied, hence \(x_k \to x\) with \(R\)-linear rate. Since \(x\) was chosen arbitrarily from \((A + B)^{-1}(0)\), it must be unique. \(\Box\)

3 Forward-reflected-backward splitting with linesearch

The algorithm presented in the previous section required information about the single-valued operator’s Lipschitz constant in order to select an appropriate stepsize. In practice, this requirement is undesirable for several reasons. Firstly, obtaining the Lipschitz constant (or an estimate) is usually non-trivial and often a computationally expensive problem itself. Secondly, as a global constant, the (global) Lipschitz constant can often lead to an over-conservative step sizes although local properties (around the current iterate) may permit the use of larger step sizes and ultimately lead to faster convergence. Finally, when the single-valued operator is not Lipschitz continuous, any fixed step size scheme based on Lipschitz continuity will potentially failure to converge.

To address these shortcomings, most known methods can incorporate an additional procedure called linesearch (or backtracking) which is run in each iteration. It is worth noting however, that in the more restrictive context of variational inequalities, the method proposed in [21] overcomes the aforementioned difficulties without resorting to a linesearch procedure.

In what follows, we show that the forward-reflected-backward method with such a linesearch procedure converges whenever the single-valued operator is locally Lipschitz.

Algorithm 1

The forward-reflected-backward method with linesearch.

Initialization: Choose \(x_0, \tau_{-1} \in \mathcal{H}\), \(\lambda_0, \lambda_{-1} > 0\), \(\delta \in (0, 1)\), and \(\sigma \in (0, 1)\).

Iteration: Having \(x_k, \lambda_{k-1}\), and \(B(x_{k-1})\), choose \(\rho \in \{1, \sigma^{-1}\}\) and compute
\[
x_{k+1} := J_{\lambda_k A}(x_k - \lambda_k B(x_k) - \lambda_{k-1}(B(x_k) - B(x_{k-1}))),
\]
where \(\lambda_k = \rho \lambda_{k-1} \sigma^i\) with \(i\) being the smallest nonnegative integer satisfying
\[
\lambda_k \|B(x_{k+1}) - B(x_k)\| \leq \delta \|x_k - x_{k+1}\|.
\]

Remark 3.1. The parameter \(\rho\) in Algorithm 1 has been introduced to allow for greater flexibility in the choice of possible stepsizes. Indeed, there are two possible scenarios for the value of \(\lambda_k\) in the first iteration of the linesearch procedure (i.e., when \(i = 0\)): either \(\rho = \sigma^{-1}\) and \(\lambda_k = \sigma^{-1} \lambda_{k-1} > \lambda_{k-1}\), or \(\rho = 1\) and \(\lambda_k = \lambda_{k-1}\). The former, more aggressive scenario allows for the possibility of larger stepsizes at the price of a potential increase in the number of linesearch iterations.

The following lemma shows that the linesearch procedure described in Algorithm 1 is well-defined so long as the operator \(B\) is locally Lipschitz continuous.

Lemma 3.2. Suppose \(B: \mathcal{H} \to \mathcal{H}\) is locally Lipschitz. Then the linesearch procedure in (29)–(30) always terminates. i.e., \((\lambda_k)\) is well defined.
Lemma 3.2. Using Lipschitzness of \( \lambda \), the proof is exactly the same as Lemma 2.4 with the only change being that instead of using \( \lambda \), we consider the limit as \( \lambda \to 0 \) which, together with the nonexpansivity of \( J_{\lambda A} \), yields
\[
\| x_{k+1}(\lambda) - P_{\text{dom} A}(x_{k+1}(0)) \| \\
\leq \| x_{k+1}(\lambda) - J_{\lambda A}(x_{k+1}(0)) \| + \| J_{\lambda A}(x_{k+1}(0)) - P_{\text{dom} A}(x_{k+1}(0)) \| \\
\leq \lambda \| B(x_k) \| + \| J_{\lambda A}(x_{k+1}(0)) - P_{\text{dom} A}(x_{k+1}(0)) \| .
\]

By taking the limit as \( \lambda \to 0 \), we deduce that \( x_{k+1}(\lambda) \to P_{\text{dom} A}(x_{k+1}(0)) \).

Now, by way of a contradiction, suppose that the linesearch procedure in Algorithm 1 fails to terminate at the \( k \)-th iteration. Then, for all \( \lambda = \rho \lambda_{k-1} \sigma^i \) with \( i = 0, 1, \ldots \), we have
\[
\rho \lambda_{k-1} \sigma^i \| B(x_{k+1}(\lambda)) - B(x_k) \| > \frac{\delta}{2} \| x_{k+1}(\lambda) - x_k \|. \tag{31}
\]
On one hand, taking the limit as \( i \to \infty \) in (29) gives \( P_{\text{dom} A}(x_{k+1}(0)) = x_k \). On the other hand, since \( B \) is locally Lipschitz at \( x_k \), there exists \( L > 0 \) such that for \( i \) sufficiently large, we have
\[
\rho \lambda_{k-1} \sigma^i \| B(x_{k+1}(\lambda)) - B(x_k) \| > \frac{\delta}{2} \| x_{k+1}(\lambda) - x_k \| \geq \frac{\delta L}{2} \| B(x_{k+1}(\lambda)) - B(x_k) \| .
\]
Dividing both sides by \( \| B(x_{k+1}(\lambda)) - B(x_k) \| \) gives \( \delta L / 2 < \rho \lambda_{k-1} \sigma^i \). Since \( \sigma^i \to 0 \) as \( i \to \infty \), this inequality gives a contradiction which completes the proof.

The next lemma is a direct extension of Lemma 2.4.

Lemma 3.3. Let \( x \in (A + B)^{-1}(0) \) and let \( (x_k) \) be generated by Algorithm 1. Then there exists \( \varepsilon > 0 \) such that, for all \( k \in \mathbb{N} \), we have
\[
\| x_{k+1} - x \|^2 + 2 \lambda_k (B(x_{k+1}) - B(x_k), x - x_{k+1}) + \left( \frac{1}{2} + \varepsilon \right) \| x_{k+1} - x_k \|^2 \\
\leq \| x_k - x \|^2 + 2 \lambda_{k-1} (B(x_k) - B(x_{k-1}), x - x_k) + \frac{1}{2} \| x_k - x_{k-1} \|^2 . \tag{32}
\]

Proof. The proof is exactly the same as Lemma 2.4 with the only change being that instead of using Lipschitzness of \( B \) to deduce the inequality (21), we use (30), which is well-defined due to Lemma 3.2.

Theorem 3.4. Let \( \mathcal{H} \) be finite dimensional, \( A : \mathcal{H} \rightrightarrows \mathcal{H} \) be maximally monotone, \( B : \mathcal{H} \to \mathcal{H} \) be monotone and locally Lipschitz continuous, and suppose that \( (A + B)^{-1}(0) \neq \emptyset \). Then the sequence \( (x_k) \) generated by Algorithm 1 converges weakly to a point contained in \( (A + B)^{-1}(0) \).

Proof. We argue similarly to Theorem 2.5 but using Lemma 3.3 in place of Lemma 2.4, and (30) in place of Lipschitzness of \( B \). This yields (24) from which we deduce that \( (x_k) \) is bounded and \( \| x_k - x_{k+1} \| \to 0 \). As a locally Lipschitz operator on finite dimensional space, \( B \) is Lipschitz on bounded sets. Thus, since \( (x_k) \) is bounded, there exists a constant \( L > 0 \) such that
\[
\| B(x_{k+1}) - B(x_k) \| \leq L \| x_{k+1} - x_k \| \quad \forall k \in \mathbb{N} . \tag{33}
\]
By combining (30) and (33), we see that \( (\lambda_k) \) is bounded away from zero. The remainder of the proof is the same as Theorem 2.5.

4 Relaxed inertial forward-reflected-backward splitting

In this section, we consider a relaxed inertial variant of the forward-reflected-backward splitting algorithm. Such variants are of interest in practice because they have the potential to improve performance as well as the range of admissible stepsizes. A treatment of a relaxed inertial variant of the forward-backward method with \( B \) cocoercive can be found in [4].
Consider the monotone inclusion

\[ \text{find } x \in \mathcal{H} \text{ such that } 0 \in (A + B)(x), \]

where \( A : \mathcal{H} \rightharpoonup \mathcal{H} \) is maximally monotone, and \( B : \mathcal{H} \to \mathcal{H} \) is either monotone and \( L\)-Lipschitz continuous or \( 1/L\)-cocoercive. The relaxed inertial algorithm is given by

\[
\begin{align*}
\begin{cases}
    z_{k+1} := J_{\lambda A}(x_k - \lambda B(x_k) - \frac{\lambda}{\beta}(B(x_k) - B(x_{k-1})) + \frac{\alpha}{\beta}(x_k - x_{k-1})) \\
x_{k+1} := (1 - \beta)x_k + \beta z_{k+1}
\end{cases}
\end{align*}
\]

(34)

for all \( k \in \mathbb{N} \) and for appropriately chosen parameters \( \alpha \geq 0 \) and \( \beta, \lambda > 0 \) whose precise form depends on the properties of \( B \). By denoting \( B' := B - \frac{\rho}{L}I \), the scheme can be expressed as

\[
\begin{align*}
\begin{cases}
    \hat{z}_{k+1} := J_{\lambda A}(x_k - \lambda B(x_k) - \frac{\lambda}{\beta}(B'(x_k) - B'(x_{k-1}))) \\
    \hat{x}_{k+1} := (1 - \beta)x_k + \beta \hat{z}_{k+1}
\end{cases}
\end{align*}
\]

\( \forall k \in \mathbb{N} \). (35)

To prove convergence of this scheme, we first prove two lemmas.

**Lemma 4.1.** Suppose \( B : \mathcal{H} \to \mathcal{H} \) is monotone and \( \rho \geq 0 \). Then the operator \( B' := B - \rho I \) is \( L'\)-Lipschitz with \( L' \) given by

\[
L' := \begin{cases} 
  L + \rho & \text{if } B \text{ is } L\text{-Lipschitz}, \\
  L - \rho & \text{if } B \text{ is } 1/L\text{-cocoercive and } \rho \leq \frac{L}{2}, \\
  \rho & \text{if } B \text{ is } 1/L\text{-cocoercive and } \rho > \frac{L}{2}.
\end{cases}
\]

(36)

**Proof.** Let \( x, y \in \mathcal{H} \). When \( B \) is \( L\)-Lipschitz, we have

\[
\|(B - \rho I)x - (B - \rho I)y\| \leq \|Bx - By\| + \rho \|x - y\| \leq (L + \rho) \|x - y\|,
\]

which establishes the first case. For the second and third cases, first observe that \( 1/L\)-cocoercivity of \( B \) yields

\[
\|(B - \rho I)x - (B - \rho I)y\|^2 = \|Bx - By\|^2 - 2\rho \langle Bx - By, x - y \rangle + \rho^2 \|x - y\|^2 \\
\leq \left(1 - \frac{2\rho}{L}\right) \|Bx - By\|^2 + \rho^2 \|x - y\|^2.
\]

One one hand, if \( \rho > \frac{L}{2} \) then \( 1 - \frac{2\rho}{L} < 0 \) and \( \rho\)-Lipschitzness of \( B' \) follows. On the other hand, if \( \rho \leq \frac{L}{2} \) then

\[
\|(B - \rho I)x - (B - \rho I)y\|^2 \leq \left(L^2 - 2\frac{\rho}{L} L^2 + \rho^2\right) \|x - y\|^2 = (L - \rho)^2 \|x - y\|^2,
\]

which shows that \( B' \) is \( (L - \rho)\)-Lipschitz. The proof is now complete. \( \square \)

Note that it is possible to slightly improve the estimate of \( L' \) in the case when \( B \) is \( L\)-Lipschitz and monotone to \( L' = \sqrt{L^2 + \rho^2} \). However, the benefits of using a new bound are minimal since, in our case \( \rho \), will take small values relatively to \( L \).

In the following lemma, we use the following form of (19) from Proposition 2.3.

\[
\|d_2 - x\|^2 + 2 \langle u - u_1, x - d_2 \rangle \leq \|d_1 - x\|^2 + 2 \langle v_1 - u_0, x - d_1 \rangle \\
+ 2 \langle v_1 - u_0, d_1 - d_2 \rangle - \|d_1 - d_2\|^2.
\]

(37)

**Lemma 4.2.** Let \( x \in (A + B)^{-1}(0) \), let \( (x_k) \) be given by (35) and consider constants \( \alpha \geq 0 \) and \( \beta, \lambda > 0 \). Then

\[
(1 - \alpha) \|x_{k+1} - x\|^2 + 2\lambda \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + b_{k+1} \leq (1 - \alpha) \|x_k - x\|^2 + 2\lambda \langle B'(x_k) - B'(x_{k-1}), x - x_k \rangle + b_k \\
+ \frac{\lambda L'}{\beta} \|x_k - x_{k-1}\|^2 - \left(2 - \beta - \frac{\lambda L'}{\beta} - \alpha\right) \|x_{k+1} - x_k\|^2.
\]

where \( b_k := 2\lambda \langle B(x) - B(x_k), x - x_k \rangle \geq 0 \) and \( L' \) is the Lipschitz constant of \( B' \).
Proof. Let \( u := \lambda B(x) \). As \( u \in -\lambda A(x) \), applying (37) with

\[
F := \lambda A \quad d_1 := x_k \quad u_0 := (\lambda/\beta)B'(x_{k-1}) \\
u_1 := \lambda B(x_k) \quad d_2 := z_{k+1} \quad v_1 := (\lambda/\beta)B'(x_k)
\]
yields the inequality

\[
\|z_{k+1} - x\|^2 + 2\lambda \langle B(x) - B(x_k), x - z_{k+1} \rangle \leq \|x_k - x\|^2 - \|x_k - z_{k+1}\|^2 + \frac{2\lambda}{\beta} \langle B'(x_k) - B'(x_{k-1}), x - x_k \rangle + \frac{2\lambda}{\beta} \langle B'(x_k) - B'(x_{k-1}), x_k - z_{k+1} \rangle. \tag{38}
\]

Using the identity \( z_{k+1} = (x_{k+1} - (1 - \beta)x_k)/\beta \) and the definition of \( B' \), the second term in (38) can be expressed as

\[
2\lambda \langle B(x) - B(x_k), x - z_{k+1} \rangle + \frac{1 - \beta}{\beta} b_k - \frac{1}{\beta} b_{k+1}
\]

\[
= \frac{2\lambda}{\beta} \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + \frac{2\alpha}{\beta} (x_{k+1} - x_k, x - x_{k+1})
\]

\[
= \frac{2\lambda}{\beta} \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + \frac{\alpha}{\beta} (\|x_k - x\|^2 - \|x_{k+1} - x_k\|^2 - \|x_{k+1} - x\|^2).
\]

Substituting this back into (38) and using \( z_{k+1} - x_k = (x_{k+1} - x_k)/\beta \) gives

\[
\|z_{k+1} - x\|^2 - \frac{\alpha}{\beta} \|x_{k+1} - x\|^2 + \frac{2\lambda}{\beta} \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + \frac{1 - \beta}{\beta} b_k
\]

\[
\leq \left(1 - \frac{\alpha}{\beta}\right) \|x_k - x\|^2 + \frac{2\lambda}{\beta} \langle B'(x_k) - B'(x_{k-1}), x - x_k \rangle + \frac{1 - \beta}{\beta} b_k
\]

\[
+ \frac{2\lambda}{\beta} \langle B'(x_k) - B'(x_{k-1}), x_k - z_{k+1} \rangle + \left(\frac{\alpha}{\beta} - \frac{1}{\beta^2}\right) \|x_{k+1} - x_k\|^2. \tag{39}
\]

By using the identity

\[
\|z_{k+1} - x\|^2 = \frac{1}{\beta} \|x_{k+1} - x\|^2 - \frac{1 - \beta}{\beta} \|x_k - x\|^2 + \frac{1 - \beta}{\beta^2} \|x_{k+1} - x_k\|^2
\]

in (39) and multiplying both sides by \( \beta \), we obtain

\[
(1 - \alpha) \|x_{k+1} - x\|^2 + 2\lambda \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + b_{k+1}
\]

\[
\leq (1 - \alpha) \|x_k - x\|^2 + 2\lambda \langle B'(x_k) - B'(x_{k-1}), x - x_k \rangle + (1 - \beta) b_k
\]

\[
+ 2\lambda \langle B'(x_k) - B'(x_{k-1}), x_k - z_{k+1} \rangle - \left(\frac{2 - \beta}{\beta} - \alpha\right) \|x_{k+1} - x_k\|^2. \tag{40}
\]

Since \( B' \) is \( L' \)-Lipschitz, the second last term can be estimated by

\[
2\lambda \langle B'(x_k) - B'(x_{k-1}), x_k - z_{k+1} \rangle = \frac{2\lambda}{\beta} \langle B'(x_k) - B'(x_{k-1}), x_{k+1} - x_k \rangle
\]

\[
\leq \frac{\lambda L'}{\beta} \left(\|x_k - x_{k-1}\|^2 + \|x_{k+1} - x_k\|^2\right).
\]

The claimed inequality follows by substituting this estimate back into (40). \( \square \)

**Theorem 4.3.** Let \( A: \mathcal{H} \rightrightarrows \mathcal{H} \) be maximally monotone and let \( B: \mathcal{H} \to \mathcal{H} \) be monotone with \((A + B)^{-1}(0) \neq \emptyset\). Suppose \( \alpha \in [0, 1), \beta \in (0, 1], \lambda > 0 \) and either

(a) \( B \) is \( L \)-Lipschitz and

\[
\lambda < \min \left\{ \frac{2 - \beta - \alpha \beta - 2\alpha}{2L}, \frac{1 - \alpha - \alpha \beta}{\beta L} \right\}, \quad \text{or} \tag{41}
\]
(b) $B$ is $(1/L)$-cocoercive, $\alpha < \frac{2-\beta}{2+\beta}$ and
\[
\lambda < \min\left\{ \frac{2-\beta - \alpha \beta + 2\alpha}{2L}, \frac{1-\alpha + \alpha \beta}{\beta L} \right\}. \tag{42}
\]

Given $x_0, x_{-1} \in \mathcal{H}$, define the sequences $(x_k)$ and $(z_k)$ according to (34). Then $(x_k)$ converges weakly to a point in $(A + B)^{-1}(0)$.

Proof. Let $L'$ denote the Lipschitz constant of $B' := B - \frac{\alpha}{\lambda} I$. By combining Lemma 4.1 with the assumptions in each of respective cases, we obtain
\[
\varepsilon := \min\left\{ \frac{2-\beta(1+\alpha)}{2}, \frac{1-\alpha}{\beta} \right\} - \lambda L' > 0. \tag{43}
\]
Then Lemma 35 together with (43) gives
\[
(1 - \alpha) \|x_{k+1} - x\|^2 + 2\lambda \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + b_{k+1}
\leq (1 - \alpha) \|x_k - x\|^2 + 2\lambda \langle B'(x_k) - B'(x_{k-1}), x - x_k \rangle + b_k
\quad + \frac{\lambda L'}{\beta} \|x_k - x_{k-1}\|^2 - \left( \frac{\lambda L'}{\beta} + \varepsilon \right) \|x_{k+1} - x_k\|^2,
\]
which telescopes to yield
\[
(1 - \alpha) \|x_{k+1} - x\|^2 + 2\lambda \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle + b_{k+1}
\leq (1 - \alpha) \|x_0 - x\|^2 + 2\lambda \langle B'(x_0) - B'(x_{-1}), x - x_0 \rangle + b_0
\quad + \frac{\lambda L'}{\beta} \|x_0 - x_{-1}\|^2 - \frac{\lambda L'}{\beta} \|x_{k+1} - x_k\|^2 - \varepsilon \sum_{i=1}^{k} \|x_{i+1} - x_i\|^2. \tag{44}
\]
The $L'$-Lipschitz continuity of $B'$ together with (43) gives
\[
2\lambda \langle B'(x_{k+1}) - B'(x_k), x - x_{k+1} \rangle \geq -2\lambda L' \|x_{k+1} - x_k\| \|x_{k+1} - x\|
\geq -\frac{\lambda L'}{\beta} \|x_{k+1} - x_k\|^2 - \beta \lambda L' \|x_{k+1} - x\|^2
\geq -\frac{\lambda L'}{\beta} \|x_{k+1} - x_k\|^2 - (1 - \alpha - \varepsilon) \|x_{k+1} - x\|^2.
\]
This, together with (44) and the fact that $b_{k+1} \geq 0$, yields the inequality
\[
\varepsilon \|x_{k+1} - x\|^2 + \varepsilon \sum_{i=1}^{k} \|x_{i+1} - x_i\|^2 \\
\leq (1 - \alpha)\|x_0 - x\|^2 + 2\lambda \langle B'(x_0) - B'(x_{-1}), x - x_0 \rangle + b_0 + \frac{\lambda L'}{\beta} \|x_0 - x_{-1}\|^2 ,
\]
which shows that $(x_k)$ is bounded and $\|x_k - x_{k+1}\| \to 0$. The remainder of the proof follows a similar argument to Theorem 2.5.

The admissible values of $\alpha$ and $\beta$ for the two cases in Theorem 4.3 are shown in Figure 1. By setting $\beta = 1$ in Theorem 4.3, we obtain the following inertial algorithm.

**Corollary 4.4.** Let $A: \mathcal{H} \rightrightarrows \mathcal{H}$ be maximally monotone and let $B: \mathcal{H} \to \mathcal{H}$ be monotone with $(A + B)^{-1}(0) \neq \emptyset$. Suppose $\alpha \in [0, 1/3)$, $\lambda > 0$ and either

(a) $B$ is $L$-Lipschitz and $\lambda < \frac{1 - 3\alpha}{2L}$.

(b) $B$ is $(1/L)$-cocoercive and $\lambda < \frac{1 + \alpha}{2L}$.

Given $x_0, x_{-1} \in \mathcal{H}$, define the sequence $(x_k)$ according to
\[
x_{k+1} := J_{\lambda A}(x_k - 2\lambda B(x_k) + \lambda B(x_{k-1}) + \alpha(x_k - x_{k-1})) \tag{45}
\]
Then $(x_k)$ converges weakly to a point contained in $(A + B)^{-1}(0)$.

**Remark 4.5.** Although Corollary 4.4 establishes that inertia increases the range of admissible step-sizes when $B$ is cocoercive, it has the opposite effect when $B$ is merely monotone. A similar phenomena with Tseng’s method was observed in [7].

**Remark 4.6.** By setting $B = 0$ in Corollary 4.4, the scheme (45) reduces to the classical inertial proximal algorithm first considered in [1]. It is interesting to note that the proof presented here does not follow the technique from [1], which is used in the analysis of most other first order inertial operator splitting methods [7,19,22].

## 5 Three operator splitting

In this section, we consider a structured three operator monotone inclusion. Specifically, we consider the inclusion
\[
\text{find } x \in \mathcal{H} \text{ such that } 0 \in (A + B + C)(x), \tag{46}
\]
where $A: \mathcal{H} \rightrightarrows \mathcal{H}$ is maximal monotone, $B: \mathcal{H} \rightrightarrows \mathcal{H}$ is monotone and $L_1$-Lipschitz, and $C: \mathcal{H} \rightrightarrows \mathcal{H}$ is $1/L_2$-cocoercive. This problem could be solved using the two operator splitting algorithm in Section 2 applied to $A$ and $(B + C)$, where we note that $(B + C)$ is $L$-Lipschitz continuous with $L = L_1 + L_2$. Consequently, to apply Theorem 2.5, the stepsize $\lambda$ should satisfy
\[
\lambda < \frac{1}{2L} = \frac{1}{2L_1 + 2L_2}.
\]

In this section, we show that this can be improved by exploiting the additional structure in (46). Indeed, we propose a modification which only requires $\lambda > 0$ to satisfy
\[
\lambda < \frac{2}{4L_1 + L_2} = \frac{1}{2L_1 + \frac{1}{2}L_2}.
\]

Given initial points $x_0, x_{-1} \in \mathcal{H}$, our modified scheme is given by
\[
x_{k+1} = J_{\lambda A}(x_k - 2\lambda B(x_k) + \lambda B(x_{k-1}) - \lambda C(x_k)) \quad \forall k \in \mathbb{N} \tag{47}
\]
In other words, the algorithm only uses a standard forward step of the operator $C$, as is employed in the forward-backward method (9).

We begin our analysis with the three operator analogue of Lemma 2.4.
Lemma 5.1. Let \( x \in (A + B + C)^{-1}(0) \) and let the sequence \( (x_k) \) be given by (47). Suppose \( \lambda \in \left(0, \frac{2}{4L_1 + L_2}\right) \). Then there exists an \( \varepsilon > 0 \) such that, for all \( k \in \mathbb{N} \), we have

\[
\|x_{k+1} - x\|^2 + 2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + (\lambda L_1 + \varepsilon) \|x_{k+1} - x_k\|^2 \\
\leq \|x_k - x\|^2 + 2\lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \lambda L_1 \|x_k - x_{k-1}\|^2.
\]

Proof. Since \( 0 \in (A + B + C)(x) \), we have \(- (B + C)(x) \in A(x)\). Combined with the monotonicity of \( A \), this gives

\[
0 \leq \langle x_{k+1} - x_k + \lambda (B + C)(x_k) + \lambda (B(x_k) - B(x_{k-1})) - \lambda (B + C)(x), x - x_{k+1} \rangle,
\]

which we rewrite as

\[
0 \leq \langle x_{k+1} - x_k, x - x_{k+1} \rangle + \lambda \langle B(x_k) - B(x), x - x_{k+1} \rangle \\
+ \lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \lambda \langle B(x_k) - B(x_{k-1}), x - x_{k+1} \rangle \\
+ \lambda \langle C(x_k) - C(x), x - x_k \rangle + \lambda \langle C(x_k) - C(x), x - x_{k+1} \rangle.
\]

The first through fourth terms can be estimated as in Lemma 2.4. Using \( 1/L_2 \)-cocoercivity of \( C \), the fifth term can be estimated as

\[
\langle C(x_k) - C(x), x - x_k \rangle \leq - \frac{1}{L_2} \|C(x_k) - C(x)\|^2,
\]

and the final term can estimated as

\[
\langle C(x_k) - C(x), x_k - x_{k+1} \rangle \leq \|C(x_k) - C(x)\| \|x_{k+1} - x_k\| \\
\leq \frac{1}{L_2} \|C(x_k) - C(x)\|^2 + \frac{L_2}{4} \|x_{k+1} - x_k\|^2.
\]

Thus, altogether, (48) implies that

\[
0 \leq \|x_k - x\|^2 - \|x_{k+1} - x\|^2 - \|x_{k+1} - x\|^2 - 2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle \\
+ 2\lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \lambda L_1 \left( \|x_k - x_{k-1}\|^2 + \|x_{k+1} - x_k\|^2 \right) \\
- \frac{2\lambda}{L_2} \|C(x_k) - C(x)\|^2 + \lambda \left( \frac{2}{L_2} \|C(x_k) - C(x)\|^2 + \frac{L_2}{2} \|x_{k+1} - x_k\|^2 \right),
\]

which, on rearranging, gives

\[
\|x_{k+1} - x\|^2 + 2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \left( 1 - \lambda L_1 - \frac{\lambda L_2}{2} \right) \|x_{k+1} - x_k\|^2 \\
\leq \|x_k - x\|^2 + 2\lambda \langle B(x_k) - B(x_{k-1}), x - x_k \rangle + \lambda L_1 \|x_k - x_{k-1}\|^2.
\]

The claimed inequality follows with \( \varepsilon := \left( 1 - \lambda L_1 - \frac{\lambda L_2}{2} \right) - \lambda L_1 = 1 - 2\lambda L_1 - \frac{\lambda L_2}{2} > 0 \).

The following theorem is our main result regarding convergence of the three operator splitting scheme.

Theorem 5.2. Let \( A : \mathcal{H} \rightrightarrows \mathcal{H} \) be maximally monotone, let \( B : \mathcal{H} \rightrightarrows \mathcal{H} \) be monotone and \( L_1 \)-Lipschitz, and let \( C : \mathcal{H} \rightrightarrows \mathcal{H} \) be \( 1/L_2 \)-cocoercive. Suppose that \( (A + B + C)^{-1}(0) \neq \emptyset \) and \( \lambda \in \left(0, \frac{2}{4L_1 + L_2}\right) \). Given \( x_0, x_{-1} \in \mathcal{H} \), define the sequence \( (x_k) \) according to

\[
x_{k+1} = J_{\lambda A} (x_k - 2\lambda B(x_k) + \lambda B(x_{k-1}) - \lambda C(x_k)) \quad \forall k \in \mathbb{N}.
\]

Then \( (x_k) \) converges weakly to a point contained in \((A + B + C)^{-1}(0)\).
Proof. The proof is more or less the same as Theorem 2.5 but uses Lemma 5.1 in place of Lemma 2.4. The only other thing to check is that

\[
\|x_{k+1} - x\|^2 + 2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle + \lambda L_1 \|x_{k+1} - x_k\|^2
\]

is bounded from below by zero. To see this, observe that

\[
2\lambda \langle B(x_{k+1}) - B(x_k), x - x_{k+1} \rangle \geq -2\lambda L_1 \|x_{k+1} - x_k\| \|x_{k+1} - x\| \\
\geq -\lambda L_1 \left( \|x_{k+1} - x_k\|^2 + \|x_{k+1} - x\|^2 \right),
\]

and \(1 - \lambda L_1 > 0\) since \(\lambda < \frac{2}{4L_1 + L_2} < \frac{1}{L_1}\).

6 Concluding remarks

In this work, we have proposed a modification of the forward-backward algorithm for finding a zero in the sum of two monotone operators which does not require cocoercivity. To conclude, we outline three possible directions for further research into the method.

**Fixed point interpretations:** As the proof of the forward-reflected-backward method does not conform to the usual Krasnoselskii–Mann framework, it would be interesting to see if the method can be analyzed from the perspective of fixed point theory. To this end, consider the two operators \(M, T : \mathcal{H} \times \mathcal{H} \rightarrow \mathcal{H} \times \mathcal{H}\) given by

\[
M := \begin{bmatrix} J_{\lambda A} & 0 \\ 0 & I \end{bmatrix}, \quad T := \begin{bmatrix} I - 2\lambda B & \lambda I \\ B & 0 \end{bmatrix}.
\]

By introducing the auxiliary variable \(u_{k+1} := B(x_k)\), it is easy to see that (15) may be expressed as the fixed point iteration in \(\mathcal{H} \times \mathcal{H}\) given by

\[
\begin{pmatrix} x_{k+1} \\ u_{k+1} \end{pmatrix} = (M \circ T) \begin{pmatrix} x_k \\ u_k \end{pmatrix}.
\]

From the perspective of fixed point theory, it is not clear what properties the operator \(M \circ T\) posses which can be used to deduce convergence. For instance, although \(M\) is firmly nonexpansive, the operator \(T\) need not be. A similar question regarding interpretations of the golden ratio algorithm, for which the operator \(M\) is of the same form, was posed in [21].

**Stochastic and coordinate extensions:** In large-scale problems, it is not always possible to evaluate the operator \(B\) owing to its high computational cost. Two possibilities for reducing the computational requirements are stochastic approximations of \(B(x_k)\) and block coordinate variants of the algorithm. Both approaches work by employing low-cost approximation of \(B(x_k)\) in each iteration. It would be interesting to consider stochastic and coordinate extensions of the method proposed here.

**Acceleration schemes:** As was explained in Section 1, the forward-reflected-backward method can be specialized to solve a minimization problem involving the sum of two convex functions, one of which is smooth. In 2007, in [23], Nesterov exploited his original idea from [24] to derive accelerated proximal gradient methods that enjoy better complexity rates than the standard forward-backward method. It therefore seems reasonable that the forward-reflected-backward method could be adapted to incorporate a Nesterov-type acceleration.
