Version 1.3

Abstract

This paper uses deep learning to value derivatives. The approach is broadly applicable, and we use a call option on a basket of stocks as an example. We show that the deep learning model is accurate and very fast, capable of producing valuations a million times faster than traditional models. We also develop a methodology to randomly generate appropriate training data and explore the impact of layer width and depth on neural network performance.

1 Introduction

1.1 The need for speed

The case for fast derivative valuations is already well established in contexts like CVA, where derivatives models are repeatedly called within a Monte Carlo simulation (see for example Green [2015]). Newer valuation adjustments (XVAs) such as KVA and MVA are likely to require the calculation of even more valuations, further increasing requirements on computational performance.

This challenge is not unique to XVA. The new market risk capital (FRTB) rules will require up to 63 expected shortfall (ES) calculations to be applied to the Trading Book. Furthermore, some applications such as KVA on FRTB-CVA will require an approximation for future CVA and its sensitivities to be available within the Monte Carlo simulation.

While XVA and FRTB are currently driving the need for high performance valuations, faster valuations have always been sought after. Desks have long been constrained by their computing resources, and have had to weigh the benefits of increased accuracy versus the number sensitivities, stress tests, etc they could calculate. For example, increasing the number of Monte Carlo simulations increases accuracy at the expense of compute time, and a trading desk will need to decide whether it prefers a small number of accurate sensitivities or larger number of less accurate sensitivities.

An important aspect of quantitative finance research is the development of new techniques that deliver more accuracy with the same computational effort or similar levels of accuracy with much lower computational effort. Monte Carlo variance reduction techniques

are an example. Other work includes approximations to computationally expensive valuation functions such as Longstaff-Schwartz regression (see for example Cesari et al. 2009) and lattice interpolation using PDE or tree-based valuation models. These techniques are commonly applied in XVA models. Chebyshev interpolation techniques have been applied in the context of XVA and more generally (Zeron and Ruiz 2017; Gaß et al. 2015).

Deep Neural Networks bring some major benefits to the approximation of functions:

- Deep Neural Networks (DNNs) bifurcate accuracy and valuation time. The catch is that computation time must be invested upfront in training the neural networks.
- DNNs do not suffer from the curse of dimensionality. The techniques developed in the paper can be applied to valuation models with hundreds of input parameters.
- DNNs are broadly applicable. They can be trained by a wide variety of traditional models that employ Monte Carlo simulation, finite differences, binomial trees, etc. as their underlying framework.

Neural networks are perhaps best known in finance in the context of predictive algorithms for use as trading strategies (see for example Tenti 1996). Credit scoring and bankruptcy prediction also have also seen application of neural network models. Neural networks have recently been applied to CVA, alongside other machine learning techniques, where a classifier approach has been used to map CDS to illiquid counterparties (Brummelhuis and Luo 2017). Neural networks previously have been applied to the approximation of derivative valuations. Hutchinson et al. (1994) applied neural networks to the Black-Scholes model in an early financial application. More recently, Culkin and Das (2017) applied Deep Neural Networks to the same problem.

1.2 Applying Deep Learning to Derivatives Valuation

This paper makes the following contributions:

1. Demonstrates the use of deep neural network models as approximations to derivative valuation routines and provides a basket option as an example.
2. Develops a training methodology for neural network models, where the training and test set are generated using Monte Carlo simulation.
3. Explores a range of geometries for neural network models.
4. Provides an assessment of computational performance, while making use of CPU and GPU parallelism during training set generation and network parameter fitting.

The remainder of this paper is organised as follows. In Section 2 we provide a brief overview of deep neural network models and the associated fitting algorithm. In Section 3 we describe the application of deep neural networks to valuing derivatives by using a call option on a basket of stocks as an example. The example is used to demonstrate the accuracy and performance of various deep learning models. Section 4 concludes with applications and future work.

2 Deep Neural Networks

2.1 Introducing Neural Networks

An artificial neural network consists of a series of layers of artificial neurons. Each neuron takes a vector of inputs from the previous layer, \( a_{j}^{[l-1]} \) and applies a weight vector, \( W_{l,j}^{[l]} \) and

A bias $b^{[l]}_j$ so that

$$Z^{[l]}_j = W^{[l]}_j a^{[l-1]} + b^{[l]}_j$$

(1)

or in matrix notation

$$Z^{[l]} = W^{[l]} a^{[l-1]} + b^{[l]}.$$  

(2)

The result from layer $l$ is then given by applying a non-linear activation function $g(Z)$,

$$a^{[l]} = g(Z^{[l]}).$$  

(3)

A number of different activation functions can be used and the main types are listed in Table 2. In order to produce non-linear outputs it is necessary that a non-linear function be used. All neurons in the same layer use the same activation function but different layers often use different activation functions. Equations (2) and (3) together describe how the input $a^{[0]} = x$ vector is forward propagated through the network to give the final output $a^{[L]} = y$.

The number of inputs to the model is dictated by the number of input features, while the number of neurons in the output layer is determined by the problem. For a regression problem with one real-valued output, as described in this paper, there will be a single node in the output layer. If a neural network model is used in a classifier problem with multiple classes, there will be one neuron per class. The number of layers in the model, $L$ and the number of neurons in each layer can be considered hyperparameters and these are normally set using hyperparameter tuning over a portion of the training data set, as described in Section 2.3. Models with many hidden layers are known as deep neural networks. A example neural network geometry is illustrated in Figure 1.
2.2 Training the Model and Back Propagation

During the training phase, the weights and bias parameters of the model are systematically updated to minimize the error between the training data and estimates generated by the model. A set of \( m_{\text{train}} \) training examples is used and the error is given by a cost function \( J \),

\[
J(W^{[l]}, b^{[l]}) = \sum_{i} L(\hat{y}^{(i)}, y^{(i)}) = \mathcal{L}(\hat{y}, y),
\]

where the function \( \mathcal{L} \), depends on the choice of loss measure. A number of choices are available for the loss measure including the L2 or L1 norm.

The minimum is found using an optimization procedure. The standard approach uses batch gradient descent or a variant such as mini-batch gradient descent. Such optimization procedures require the gradients of the cost function,

\[
dW^{[l]} = \frac{\partial J}{\partial W^{[l]}},
\]

\[
db^{[l]} = \frac{\partial J}{\partial b^{[l]}},
\]

which are used to update the weights,

\[
W^{[l]} = W^{[l]} - \alpha dW^{[l]}
\]

\[
   b^{[l]} = b^{[l]} - \alpha db^{[l]}
\]

To obtain the gradients a specialised type of algorithmic differentiation is used, known as backpropagation. This algorithm recursively applies the chain rule to propagate derivatives back through the computational graph of the neural network model. Beginning with the output layer, the derivative \( da^{[L]} \) is defined by

\[
da^{[L]} = \nabla_{a^{[L]}} = g(L(\hat{y}, y)).
\]

The derivative \( dZ^{[L]} \) is then given by,

\[
dZ^{[L]} = da^{[L]} \odot g'(Z^{[L]}).
\]

\(^3\)In this paper we use mini-batch gradient descent where the size of each mini-batch is a hyperparameter.
Hence the derivatives of the weights for layer $L$ are given by,

$$dW^{[L]} = \frac{1}{m}dZ^{[L]}a^{[L-1]}$$  \hspace{1cm} (11)$$

$$db^{[L]} = \frac{1}{m}dZ^{[L]}.$$  \hspace{1cm} (12)$$

The derivative $da^{[L-1]}$ for the next layer are then given by,

$$da^{[L-1]} = (W^{[L]})^TdZ^{[L]},$$  \hspace{1cm} (13)$$

and hence the derivatives can be propagated backwards through the network to obtain all the $dW^{[l]}$ and $db^{[l]}$. Forward and backward propagation are illustrated in Figure 2.

To train the model, $m$ training examples are used. Typically the input data set of $m$ examples is divided into three independent groups, $m_{\text{train}}$, which is used to train the network, $m_{\text{test}}$ which is used to test the trained network and $m_{\text{dev}}$ which is used to develop or cross-validate the hyperparameters of the model. The fraction of data divided into each group depends on how much training data is available, with $m_{\text{test}}$ and $m_{\text{dev}}$ forming a relatively larger proportion if $m$ is relatively small. The training stops after a fixed number of iterations, or when the loss function is no longer decreasing.

The weights are initialized using a pseudo-random number generator, with samples drawn either from the uniform distribution or the standard normal distribution. One common procedure with the ReLU activation function initializes the weights in layer $l$ using a standard normal distribution with mean zero and variance $2/n^{[l]}$.

2.3 Hyperparameter Tuning

While the weights, $W$ and the bias parameters, $b$, are defined during training, other parameters such as the learning rate $\alpha$ and the topology of the neural network are hyperparameters that are not directly trained. The hyperparameters could be specified exogenously, however, in general their optimal values are not known a priori. Hence hyperparameters are optimised by assessing model performance, once trained, on a separate independent set of samples.

In this paper we focus on two axes of hyperparameter tuning by varying the number of neurons per hidden layer and the number of hidden layers. We demonstrate the impact these hyperparameters have on accuracy and performance.
3 Derivatives Valuation and Deep Learning

A derivatives valuation model is ultimately just a function which maps inputs, consisting of market data and deal specific terms, to a single output representing the value. That function may have an known analytic form, though frequently numerical approaches including Monte Carlo simulation, binomial trees or finite difference techniques must be used. For simple European stock options, there are just five inputs while for a more complex product like a Bermudan swaption the number of inputs is significantly larger, involving all the properties of the underlying swap and option exercise schedule. The number of parameters could be in the hundreds or thousands for such complex products. Having a large number of inputs to a neural network model is certainly feasible and many current practical applications have inputs of a similar order of magnitude. For example, an image recognition application might use images 64 x 64 pixels in size with 3 colours, which corresponds to an input vector of length 12280. However, the dimensionality of the input does have an impact on the generation of training data as will be seen in the next section. Large neural network models are also prone to over-fitting the training data so there is a need for caution.

We can choose to fit all the parameters of the valuation model or only some of them, creating respectively domain approximations or conditional domain approximations. A domain approximation will generate a neural network model that can fully replace the underlying function. A conditional domain approximation is more bespoke and could, for example, be used to replicate the behaviour of a single option. In the case of a Bermudan swaption we may choose to condition on the properties of a specific trade and then fit only the value of this option against a variety of input market data scenarios. Given the reduction in size of the parameter space, the models will be smaller and their training requirements such as the size of training data set, the amount of time spent training, etc lower.

It is also important to note that the model can only be trusted to approximate the function well over the parameter ranges that were used to train it. Should inputs move outside of these ranges then it is unlikely the approximation will perform well. It is prudent to monitor the use of the model and retrain should inputs move outside the training range.

In this paper we fit all the input parameters of both example pricing models and leave the generation of conditional domain approximations for future work.

3.1 Derivatives Pricing Example: Basket Options

To demonstrate how a network can learn a derivative valuation model we trained a network to price a European call option on a worst-of basket with six underlying stocks. This option is commonly valued using a Monte Carlo simulation with each of the stocks following a geometric Brownian motion. This example was selected for four reasons: First the dimensionality of the function is moderate, with the number of input parameters equal to $\frac{1}{2}n(n + 3) + 1$, which equals 28 for a basket with six underlying stocks. Second, the use of a Monte Carlo explores the use of deep learning with a computationally intensive valuation routine. Third, it will be easy to scale up the dimensionality of this problem by adding more stocks to the basket. Fourth, the use of a numerical method like Monte Carlo means that the function to be replicated has numerical noise.

To fit a neural network model we need to generate a set of training examples $(x^{(i)}, y^{(i)})$, with the $x^{(i)}$ being input model parameters and the $y^{(i)}$ being the output value. To generate the training data we use Monte Carlo simulation to generate random sets of inputs within appropriate ranges selected for each parameter. In the context of this example all parameters were generated independently with the distribution selected individually for each parameter. The choice of sampling distribution is important and should be made on a case by case basis. For example, there is little point in generating a large volume of examples which yield zero option value. Hence we anticipate that different choices of sampling distribution, where the parameters are not independent will be needed for some derivative models. In other

cases, stratification or importance sampling may be appropriate but we leave this for further research.

Once a random set of parameter values is created, the function to be replicated is called to generate a value. In this way a large number of training examples can be created. This can be computationally intensive as the derivative valuation function is called many times. However, this process needs only be done once for the initial training of the model. Given all training examples are independent it can also be readily parallelized.

### 3.2 Training for Basket Options

For our basket option example, we reduced the number of input parameters by assuming flat implied volatility surfaces for each of the stocks in the basket. Further simplification was made by assuming both zero interest rates and dividends. For the case of six underlying stocks we have the parameter breakdown as shown in Table 3.

The parameters were sampled randomly and independently, with the exception of correlation matrices which were handled separately. Stock prices were generated using $100 \times \exp(z)$, with $z \sim N(0.5, 0.25)$. The correlation matrices were generated using the C-vine method of Lewandowski et al. (2009).

A neural network model will try to minimize the error between its estimates and that of the training data that it is presented, it is important to choose a representative data set. Another consideration when developing training data is the nature of the function being learned. Areas of rapidly changing function value need to be assigned more training data. We generated more data for short maturities since the convexity of the basket option valuation function is greatest for at the money short dated options.

The sample distributions of the inputs are illustrated in Figure 3.

We used QuantLib (2000) to generate our training data. Our training data consisted of 3.7 million sets of randomly generated market data and the resultant option valuation calculated by Quantlib’s MCEuropeanBasketEngine. Using 1 million Monte Carlo simulations, Quantlib took on average 7 seconds to calculate each valuation on an AMD Epyc 7401P. The average standard error estimated by QuantLib was 2 cents. By running 48 threads in parallel, we generated approximately 500k training samples per day.

One powerful aspect of using neural networks is that accuracy and inference time are bifurcated. We can increase the number of Monte Carlo simulations to 10 million to improve QuantLib’s accuracy at the cost of taking longer to generate the training set. However, once trained, computational cost per inference will be the same.

### 3.3 Results

#### 3.3.1 Learning Capacity: Varying the number of neurons per layer

Five different models, each with six hidden layers were trained with 20, 50, 100, 200 and 500 neurons per layer. Each hidden layer used ReLU activation functions with the final output layer a simple linear function to give a real valued output.

The models were trained over 20k minibatches, with a minibatch size of 1% of the total training set. The test set used 1% of the overall dataset and was drawn at random from
Figure 3: Sample distributions of input variables used in the basket option training and test sets. Given there are six input assets to the basket and the sampling was independent, only one representative example is illustrated for stock, volatility, and correlation. The individual figures illustrate (a) maturity (in days), (b) correlation between stock A and stock B, (c) stock price A, (d) volatility of stocks, and (e) option value.
the total population of examples and used only for testing. All models were trained using an Adam optimizer (Kingma and Ba, 2014) with the learning rate set to 1e-3, $\beta_1 = 0.9$ and $\beta_2 = 0.999$.

Figure 4 illustrates the learning capacity as a function of the number of mini-batch iterations for each of the five models. Two curves are presented for each model, giving the learning curve for the test and training sets. The curves represent the minimum loss from each iteration of the Adam optimizer. A steady improvement is seen when increasing the number of nodes per layer up to 200 nodes per layer. The 500 nodes per layer case shows a significantly lower loss from the training set versus the test set, indicating that in this case the model has been overtrained with test set performance similar to the 200 node per layer case.

3.3.2 Learning Capacity: Varying the number of layers

Figure 5 illustrates the minimum loss a function of mini-batch iteration for nine models each with 300 nodes per layer but varying depth from one to nine hidden layers. Steady improvement is observed for the models with up to four hidden layers. For the remaining models, there is little improvement in test set performance indicating that four to five hidden layers have sufficient learning capacity for this example. Further discussion of learning capacity can be found in Guss and Salakhutdinov (2018).

3.3.3 Accuracy

The distribution of errors derived from the test set is shown in Figure 6 which illustrates the probability density of the differences between the Monte Carlo result and the neural network model estimation. A high degree of accuracy has been achieved across the test set showing that the neural network has approximated the QuantLib basket valuation model well.

We investigated the samples in the tails of the histogram as they often came from the edges of the training distribution. A plot of the model prices as a function of one underlying stock price for two separate volatility values, 10% and 40%, is shown in Figure 7. The remaining stocks were all held at a fixed value of 200. The correlations were all set at 0.6 and the maturity of the selected option was 0.4 years. The DNN shows good agreement with the Monte Carlo model for both volatilities, except for high value of the stock price. There

were few training examples where all the stocks had high values and this resulted in lower accuracy fits in this part of the parameter space.

3.3.4 Speed

The overall performance can be broken down into the three key phases, generation of the training set, training the neural network and the final inference step. To generate the approximately 3.7 million training examples, the underlying model was called repeatedly at a cost of 7 seconds per valuation, equating to 3,600 CPU core-hours. The use of a small farm of servers with multi-core processors brought the overall time down to a total of a few days. Neural network model training is a function of both the number of layers as well as the neurons per layer. The examples above were taken from a model with 6 hidden layers each containing 300 neurons. This network took approximately 9350 seconds to train through 20,000 minibatch iterations each consisting of 37,000 training samples using a NVIDIA GeForce GTX 1070 graphics processing unit. That is more than 75,000 valuations and backpropagations per second. Once training is complete and the backpropagation stage no longer necessary, the model can compute 20,000 valuations in parallel in less than 50 microseconds on modest hardware. The training time as a function of the number of hidden layers and as a function of the number of neurons per layer is shown in Figure 8.

4 Conclusions and Opportunities for Future Work

In this paper we have demonstrated that deep neural networks can be used to provide highly accurate derivatives valuations using a basket option example. These models compute valuations approximately 1 million times faster than traditional Monte Carlo models. We have developed a successful methodology to generate a set of training data, which can be adapted to suit other valuation models. A variety of different neural network geometries were tried and we concluded that for a basket option with 28 input parameters, a training set size of 3.7 million samples and a model with four to five layers with 300 neurons in each accurately reproduced the derivative valuation function.

We are actively investigating several areas:

1. Scaling the dimensionality of the derivatives pricing model. Some models require many hundreds of inputs across market data and trade specifics.
2. Scaling of training dataset size. In this study we used 3.7mm samples in our training set since that was manageable in short order. Larger neural networks (500 nodes per layer) were overfitted with only 3.7mm training samples. As we generate more training data, we see if we can train larger models to give more accurate function approximations.

3. Providing risk sensitivities through back propagation of neural networks as an alternative or complement to algorithmic differentiation.

4. Using DNNs to approximate both valuation model and model calibration steps independently as a pipeline.

5. Applying transfer learning to accelerate the training of related derivative products.

6. Using DNNs in practice to accelerate derivative valuations for XVA.
