Abstract

Wagering mechanisms are one-shot betting mechanisms that elicit agents’ predictions of an event. For deterministic wagering mechanisms, an existing impossibility result has shown incompatibility of some desirable theoretical properties. In particular, Pareto optimality (no profitable side bet before allocation) can not be achieved together with weak incentive compatibility, weak budget balance and individual rationality. In this paper, we expand the design space of wagering mechanisms to allow randomization and ask whether there are randomized wagering mechanisms that can achieve all previously considered desirable properties, including Pareto optimality. We answer this question positively with two classes of randomized wagering mechanisms: i) one simple randomized lottery-type implementation of existing deterministic wagering mechanisms, and ii) another family of simple and randomized wagering mechanisms which we call surrogate wagering mechanisms, which are robust to noisy ground truth. This family of mechanisms builds on the idea of learning with noisy labels [1] as well as a recent extension of this idea to the information elicitation without verification setting [2]. We show that a broad family of randomized wagering mechanisms satisfy all desirable theoretical properties.

1 Introduction

Wagering mechanisms [3, 4, 5, 6, 7] are one-shot betting mechanisms that allow a principal to elicit participating agents’ beliefs about an event of interest without paying out of pocket or incurring a risk. Compared with prediction-market-type of dynamic elicitation mechanisms, one-shot wagering maybe preferred due to its simplicity. It is particularly designed for agents with immutable beliefs who “agree to disagree” and who do not update their beliefs. In a wagering mechanism, each agent submits a prediction for the event and specifies a wager, which is the maximum amount of money that the agent is willing to lose. Then after the event outcome is revealed, the total wagered money will be redistributed among the participants. Researchers have developed wagering mechanisms with various theoretical properties. In particular, [3, 4] proposed a class of weighted score wagering mechanisms (WSWM) that satisfy a set of desirable properties, including budget balance, individual rationality, incentive compatibility, sybilproofness, among some others. [5] later proposed a no-arbitrage wagering mechanism (NAWM) that removes the opportunities for participating agents to risklessly profit.

1Precise definitions can be found in Section 4.
However, in both WSWM and NAWM, it has been observed that a participant only loses a very small fraction of his total wager even in the worst case. This seems to be undesirable in practice as it is against the “spirit” of betting and a wager effectively loses its meaning as a budget. [6] first formalized this observation by indicating that these mechanisms are not Pareto optimal, where Pareto optimality requires that there is no profitable side bet among participants before the allocation of a wagering mechanism. Unfortunately, Pareto optimality is not compatible with individual rationality, weak budget balance and weak incentive compatibility, as shown by [6]. A double clinching auction (DCA) wagering mechanism [6] is proposed to improve Pareto efficiency, and parimutuel consensus mechanism (PCM) is shown to satisfy Pareto optimal [7], but violating incentive compatibility.

This paper is another quest of wagering mechanisms with better theoretical properties. We expand the design space of wagering mechanisms to allow randomization on agent payoffs and ask whether we can achieve all aforementioned desirable properties, including Pareto optimality. We give a positive answer to this question: Our randomized wagering mechanisms are the first ones to achieve Pareto optimality along with other properties.

We first show that a simple randomized lottery type of implementation of existing mechanisms (Lottery Wagering Mechanisms (LWM)) satisfy all desirable properties. The idea of LWM is, instead of receiving re-allocated money from a deterministic wagering mechanism, each agent will receive a number of lottery tickets proportional to their payoff from the deterministic wagering mechanism. Then each of the agents will have a chance of winning the entire amount of wagered money (collected from all participants) with a chance being proportional to his number of lottery tickets.

We then study another family of randomized mechanisms which we name as Surrogate Wagering Mechanisms (SWM), that bring insights from learning with noisy data [1] to wagering mechanism design. The idea is to first generate a “surrogate outcome” for each agent according to the true event outcome. His reported prediction will then be evaluated using this surrogate but biased outcome; a bias removal procedure is applied to this score such that in expectation the agent will receive a score that is as if evaluated against the ground truth. That is, though being randomized, SWM preserve the incentive properties of a deterministic wagering mechanism. We show that certain SWM satisfy all desired properties of a wagering mechanism. Notably, SWM are robust to the case when there is only access to a noisy copy of the ground truth - this property is due to the fact that we borrow the machineries from the literature of learning with noisy data. We believe this is another unique contribution to the literature of wagering mechanism design. Most of the presentations of SWM focus on binary outcome events but we do show how to extend the results to multi-outcome (> 2) settings.

The rest of this paper is organized as follows. We discuss relevant literature in the Section 2. Section 3 introduces some preliminaries. We define randomized wagering mechanisms as well as desirable theoretical properties for them in Section 4. Section 5 presents a family of lottery-based wagering mechanisms. A family of surrogate wagering mechanisms are introduced in Section 6. We extend surrogate wagering mechanisms on NAWM and on the multi-outcome event settings in Section 7. Extensive simulations are presented in Section 8 to demonstrate the advantages of randomized wagering mechanisms. Section 9 concludes this paper.

2 Related works

The ability to elicit information, in particular predictions and forecasts about future events, is crucial for many application settings and has been studied extensively in the literature. Proper scoring rules have been designed [9] [10] [11] [12] [13] for this purpose, where each agent is rewarded by how well their reported forecasts predicted the true realized outcome (after the outcome is resolved). Later, competitive scoring rule [14] and a parimutuel Kelly probability scoring rule [15] adapt proper scoring rules to group competitive
betting. Both mechanisms are budget balanced so that the principal doesn’t need to pay any participant. These spur the further development of the previously discussed wagering mechanisms \cite{3, 4, 5, 6, 7} and the examination of their theoretical properties.

Our method used in lottery wagering mechanisms to transfer an arbitrary deterministic wagering mechanism into a randomized one, while maintaining the properties, is inspired by the method proposed in \cite{16}. The paper studies the incentive compatible forecasting competition and it transfers scores of multiple predictions into the odds of winning to maintain properties of the scoring rules. \cite{3} proposed a randomization method based on WSWM via randomly selecting strictly proper scoring rules and proper scoring rules with extreme values to increase the stake. However, this method does not generalize to other deterministic wagering mechanisms. \cite{17} proposed to apply differential privacy technology to randomize the payoff of wagering mechanisms in order to preserve the privacy of each agent’s belief. However, their method does not maintain budget balance (in ex-post).

The idea of using randomization in wagering mechanism design is not entirely new, but not thoroughly studied. Both \cite{3, 17} proposed certain types of randomized wagering mechanisms, but neither of the mechanisms satisfies Pareto optimality. The randomized wagering mechanisms first appeared in \cite{3}. There, the randomization is restricted to randomly selecting different scoring rules used in WSWM. It introduced this randomization in order to alleviate the the problem that in WSWM, agents only lose a small fraction of their wagers regardless of the event outcome. However, even with this randomization, an agent won’t lose all his wager in the worst when the number of agents is finite. \cite{17} applied differential privacy technology to randomize the payoff of wagering mechanisms. Its goal is to preserve the privacy of agents’ beliefs.

Our specific ideas of adding randomness as in the lottery-like wagering mechanisms are inspired by recent works on forecasting competition \cite{16}. Our ideas of surrogate wagering mechanisms are inspired by surrogate scoring rules \cite{2}, and the literature on learning with noisy labels \cite{18, 1, 8}.

## 3 Preliminaries

In this section, we explain the scenario where a wagering mechanism applies and formally introduce the deterministic wagering mechanisms. Consider a scenario where a principal is interested in eliciting subjective beliefs from a set of agents \(\mathcal{N} = \{1, 2, ..., N\}\) about a random variable (event) \(X\), which takes a value (outcome) in set \(\mathcal{X} = \{0, 1, ..., M - 1\}\), \(M \geq 2\). The belief of each agent \(i\) is private, denoted as a vector of occurrence probabilities of each outcome \(\hat{p}_i = (\hat{p}_i^j)_{j \in \mathcal{X}} \in \Delta^{M-1}\). Following the previous work on wagering mechanism, this paper continues to adopt an immutable belief model for agents. Unlike in a Bayesian model, agents with immutable beliefs do not update their beliefs. The immutable belief model and the Bayesian model are two extremes of agent modeling for information elicitation, with the reality lies in between and arguably closer to the immutable belief side as people do “agree to disagree.” Moreover, \cite{4} showed that while WSWM was designed for agents with immutable beliefs, it continued to perform well for Bayesian agents who have some innate utility for trading.

The principal uses a wagering mechanism to elicit the private beliefs of agents. In a wagering mechanism, each agent reports a probability vector \(\hat{p}_i \in \Delta^{M-1}\), capturing his belief, and wager \(w_i \in \mathbb{R}_+\). Similar to \cite{3}, we assume that wagers are exogenously determined for each agent and are not a strategic consideration. We use \(\hat{p}\) and \(w\) to denote the reports and the wagers of all agents respectively, and use \(\hat{p}_{-i}\) and \(w_{-i}\) to denote the reports and wagers of all agents other than agent \(i\). Besides, we use \(W_S\) to denote \(\sum_{i \in S} w_i\) for any set of agents \(S \subseteq \mathcal{N}\). After an event outcome \(x \in \mathcal{X}\) is realized, the wagering mechanism redistributes all the wagers collected from agents according to \(\hat{p}, w, x\). The net-payoff of agent \(i\) is defined as the payoff or the money that agent \(i\) receives from the redistribution minus his wager. The wagering mechanism defines a net-payoff function \(\Pi_i(\hat{p}; w; x)\) for each agent \(i\) with wager constraint \(\Pi_i(\hat{p}; w; x) \geq -w_i\) and constraint \(\Pi_i(\hat{p}; w; x) = 0\) whenever \(w_i = 0\). The two constraints ensure that no agent can lose more than his wager.
and no agent with zero wager can gain.

3.1 Strictly proper scoring rules and weighted score wagering mechanisms

Strictly proper scoring rules [13] are scoring functions proposed and developed to truthfully elicit beliefs from risk-neutral agents. They are building blocks of many incentive compatible wagering mechanisms, such as WSWM and NAWM. A strictly proper scoring rule solely rewards a prediction $\hat{p}_i$ by a score $s_x(\hat{p}_i)$, according to the realization $x$ of the random variable $X$. The scoring function $s_x(\cdot)$ is designed such that the expected payoff of truthful reporting is strictly larger than that of any other report, i.e., $\mathbb{E}_{X \sim p_i}[s_X(\hat{p}_i)] > \mathbb{E}_{X \sim p_i}[s_X(p_j)]$, $\forall \hat{p}_i \neq p_j$.

There is a rich family of strictly proper scoring functions, including Brier scores (for binary outcome events, $s_x(\hat{p}_i) = 1 - (\hat{p}_i - x)^2$, where $\hat{p}_i$ is agent $i$’s report of $\mathbb{P}(X = 1)$), logarithmic and spherical scoring functions. Strictly proper scoring rules are closed under positive affine transformations.

WSWM [3] rewards an agent according to his wager and the accuracy of his prediction relative to that of other agents’ predictions. The net-payoff of agent $i$ in WSWM, is formally defined as

$$\Pi_i^{WS} (\bar{p}; w; x) = \frac{w_i W_{N \setminus \{i\}}}{W_N} \left( s_x(\hat{p}_i) - \sum_{j \in N \setminus \{i\}} \frac{w_j}{W_{N \setminus \{i\}}} s_x(\hat{p}_j) \right),$$

(1)

where $s_x(\cdot)$ is any strictly proper scoring rule bounded within $[0, 1]$. Notice that WSWM strictly encourages truthful report of predictions, because the net-payoff of agent $i$ is a strictly proper scoring rule of his prediction. Besides, $\sum_{i \in N} \Pi_i^{WS}$ is always zero by the form of the net-payoff formula, no matter what $s_x(\cdot)$ is. That is the budget balance property of Eqn. (1) doesn’t depend on the form of the scoring function. The budget balance result of our randomized wagering mechanisms is also due to this property.

4 Randomized wagering mechanisms

We introduce randomized wagering mechanisms as extensions of deterministic wagering mechanisms. Similar to deterministic wagering mechanisms, the net-payoff of an agent depends on all agents’ predictions $\bar{p}$ and wagers $w$, as well as the realized outcome $x$. But different from deterministic wagering mechanisms, the net-payoffs are now random variables. For notational simplicity, we now use $\Pi_i (\bar{p}; w; x)$ to represent the random variable of agent $i$’s net-payoff in a randomized wagering mechanism. We use $\pi_i (\bar{p}; w; x)$ to represent the realization of $\Pi_i (\bar{p}; w; x)$. We use $\Pi_i$ and $\pi_i$ as abbreviations when $\bar{p}; w; x$ are clear in the context. We denote the maximum/minimum possible value of a random variable $X$ by $\bar{X}/\underline{X}$. We denote the joint distribution of $\Pi_i (\bar{p}; w; x)$, $i \in N$ by $D(\bar{p}; w; x)$ and the marginal distribution of $\Pi_i (\bar{p}; w; x)$ by $D_i (\bar{p}; w; x)$.

Definition 1. Given the reports $\bar{p}$ and wagers $w$ of agents and the event outcome $x$, a randomized wagering mechanism defines a joint distribution $D(\bar{p}; w; x)$, and pays each agent $i$ by a net-payoff $\Pi_i (\bar{p}; w; x)$, where $\Pi_i (\bar{p}; w; x)$, $i \in N$ are jointly drawn from $D(\bar{p}; w; x)$. Meanwhile, $\Pi_i (\bar{p}; w; x) \geq -w_i$ and $\Pi_i (\bar{p}; w; x) = 0$ whenever $w_i = 0$.

A deterministic wagering mechanism is a special case of randomized wagering mechanisms when $D_i (\bar{p}; w; x)$ is a point distribution for all agent $i \in N$.

4.1 Desirable properties

In the literature, several desirable properties of wagering mechanisms have been proposed in the deterministic context. [3] introduced (a) individual rationality, (b) incentive compatibility, (c) budget balance, (d)
sybilproofness, (e) anonymity, (f) neutrality. [5] introduced (g) no arbitrage property. [6] introduced (h) Pareto optimality. We extend these properties to the randomized context. These new properties reduce to the properties defined in the literature for the special case of deterministic wagering mechanisms.

(a) **Individual rationality** requires that each agent has nothing to lose in expectation by participating.

**Definition 2.** A randomized wagering mechanism is **individually rational (IR)** if \( \forall i, p_i, w, \) and \( \hat{p}_{-i}, \) there exists \( \hat{p}_i \) such that

\[
\mathbb{E}_{X \sim p_i, \Pi \sim D_i(\hat{p}_i, \hat{p}_{-i}; w; X)} \left[ \Pi_i(\hat{p}_i, \hat{p}_{-i}; w; X) \right] \geq 0.
\]

(b) **Incentive compatibility** requires that an agent’s expected net-payoff is maximized when he reports honestly, regardless of other agents’ reports and wagers.

**Definition 3.** A randomized wagering mechanism is **weakly incentive compatible (WIC)** if \( \forall i, p_i, \hat{p}_i \neq p_i, \hat{p}_{-i}, w : \)

\[
\mathbb{E}_{X \sim p_i, \Pi \sim D_i(\hat{p}_i, \hat{p}_{-i}; w; X)} \left[ \Pi_i(p_i, \hat{p}_{-i}; w; X) \right] \geq \mathbb{E}_{X \sim p_i, \Pi \sim D_i(\hat{p}; w; X)} \left[ \Pi_i(\hat{p}; w; X) \right].
\]

A randomized wagering mechanism is **strictly incentive compatible (SIC)** if the inequality is strict.

(c) **Ex-post budget balance** requires the principal not losing money after the net-payoffs are realized.

**Definition 4.** A randomized wagering mechanism is **weakly ex-post budget-balanced (WEBB)** if \( \forall \hat{p}, w, x : \sum_{i \in N} \pi_i(\hat{p}, w, x) \leq 0 \) for any realization of \((\pi_i)_{i \in N}\) drawn from the joint distribution \( D(\hat{p}, w, x) \). A randomized wagering mechanism is **ex-post budget-balanced (EBB)** if the equality always holds.

(d) **Sybilproofness** requires that no agent can increase its expected net-payoff by creating fake identities and splitting his wager, regardless of other agents’ reports and wagers.

**Definition 5.** A randomized wagering mechanism is **sybilproof** if \( \forall i, \hat{p}_i, w_i, \hat{p}_{-i}, w_{-i}, x, \forall k \in \mathbb{N}, \hat{p}_i, ..., \hat{p}_k (\hat{p}_i = \hat{p}, l = 1, ..., k), w_i, ..., w_k \in \mathbb{R}_+ \left( \sum_{i=1}^k w_i = w_i \right) \) and \( \hat{p}' = (\hat{p}_1, ..., \hat{p}_i, \hat{p}_1, ..., \hat{p}_{i-1}, \hat{p}_{i+1}, ..., \hat{p}_N) \), \( w' = (w_{i1}, ..., w_{i1}, w_1, ..., w_{i-1}, w_{i+1}, ..., w_N) \) and \( \Pi' = (\Pi_{i1}, ..., \Pi_{i1}, \Pi_1, ..., \Pi_{i-1}, \Pi_{i+1}, ..., \Pi_N) \), we have

\[
\mathbb{E}_{\Pi_i \sim D_i(\hat{p}; w; x)} \left[ \Pi_i(\hat{p}; w; x) \right] \geq \mathbb{E}_{\Pi' \sim D(\hat{p}'; w'; x)} \left[ \sum_{l=1}^i \Pi_{l0}(\hat{p}'; w'; x) \right].
\]

(e) **Anonymity** requires that agents’ identities do not affect their net-payoffs. Let \( \sigma_N \) be a permutation of the set of agents \( N \), and denote \( \hat{p}_{\sigma_N}, w_{\sigma_N} \) the reports and wagers of agents after applying the permutation respectively. Denote \( D_{\sigma_N} \) the joint distribution of net-payoffs of agents in \( N \) after applying the permutation on agents.

**Definition 6.** A randomized wagering mechanism is **anonymous** if \( \forall \sigma_N, \hat{p}, w, x : D(\hat{p}; w; x) = D_{\sigma_N}(\hat{p}_{\sigma_N}; w_{\sigma_N}; x) \)

(f) **Neutrality** requires that the net-payoffs do not depend on the labeling of the event outcomes. Let \( \sigma_M \) be a permutation of the set of outcomes \( M \). Denote by \( \hat{p}_{i, \sigma_M} \) the reported prediction of agent \( i \) after we relabel the outcomes according to permutation \( \sigma_M \), and denote by \( \sigma_M(x) \) the new label of an outcome \( x \in M \).

**Definition 7.** A randomized wagering mechanism is **neutral** if \( \forall \sigma_M, \hat{p}, w, x : \)

\[
D(\hat{p}; w; x) = D(\hat{p}_{1, \sigma_M}, ..., \hat{p}_{N, \sigma_M}, w; \sigma_M(x)).
\]

(g) **No arbitrage** requires that no agent can risklessly make profits.
Definition 8. A randomized wagering mechanism has no arbitrage if \( \forall i, \hat{p}, w, \exists x \) such that \( \prod_i (\hat{p}, w, x) < 0 \).

(h) Pareto optimality in economics refers to an efficient situation where no trade can be made to improve an agent’s payoff without harming any other’s payoff. In an IR wagering mechanism, agents with different beliefs can always form a profitable wagering game for each of them if they all have a positive budget. \( [6] \) defined Pareto optimality of a wagering mechanism as a property that agents with different beliefs will always lose all of their own wagers under at least one of the event outcomes (this “worst case” outcome might be different for different agents). Thus, no agent can commit to secure part of his wager from the mechanism before the event outcome is realized. Thus, before the event outcome is realized, no additional profitable wagering game can be made. We define Pareto optimality for randomized wagering mechanisms in a similar spirit: no agents with different beliefs can commit to secure part of their wagers before the event outcome is realized.

Definition 9. A randomized wagering mechanism is Pareto optimal (PO) if \( \forall \hat{p}, w, \forall i, j \in \mathcal{N} (\hat{p}_i \neq \hat{p}_j), \exists l \in \{i, j\}, \exists x, \Pi_l (\hat{p}, w, x) = -w_l. \)

Properties of existing wagering mechanisms We summarize the properties of existing wagering mechanisms and ours in Table 1. To emphasize, no existing mechanism satisfies all properties (a)-(h). Moreover, \( [6] \) showed an impossibility result for deterministic wagering mechanisms that it is impossible to achieve properties IR, WIC, WEBB, and PO simultaneously. For existing randomized wagering mechanisms, the randomized WSWM in \( [3] \) only satisfies PO in the limit of large population of participants, and the private WSWM \( [17] \) does not satisfy WEBB and PO.

5 Lottery wagering mechanisms

In this section we introduce a class of randomized wagering mechanisms, namely lottery wagering mechanisms, which extend arbitrary deterministic wagering mechanisms into randomized wagering mechanisms. We are going to show that this set of mechanisms can easily preserve the randomized version of the properties of the underlying deterministic wagering mechanisms, while maintaining Pareto optimality, overcoming the impossibility result.

\( ^2 \)WSWM, NAWM, DCA, PCM, randomized WSWM \( [3] \), private WSWM \( [17] \)
In lottery wagering mechanisms, each agent receives a number of lottery tickets in proportion to the payoff he gets under a deterministic wagering mechanism, and a winner is drawn from all the lottery tickets to win the whole pool of wagers. The mechanisms are designed in a way such that the expected payoff of each agent is the same as that in the deterministic wagering mechanism and each agent has a positive probability to lose all his wager. Hence, no profitable side bet exists and the mechanisms are Pareto optimal. We formally present the lottery wagering mechanism that extends an arbitrary deterministic wagering mechanism DET in Mechanism 1. To distinguish the payoff from the net-payoff, we denote the payoff by $\pi'_i$ of agent $i$.

### Mechanism 1 Lottery Wagering Mechanisms

1: Compute the payoff of each agent $i$ under a DET: $\pi'_i \leftarrow w_i + \Pi_i(\hat{p}; w; x)$.
2: Each agent has winning probability $\frac{\pi'_i}{\sum_{i \in N} \pi'_j}$. Draw a lottery winner $i^* \in N$.
3: Winner $i^*$ is assigned a net-payoff $\sum_{i \in N \setminus \{i^*\}} w_i$ and any agent $j \neq i^*$ has a net-payoff $-w_j$.

Lottery wagering mechanisms are powerful in obtaining desirable theoretical properties. We show in Theorem 1 that the lottery wagering mechanism that extends the WSWM, denoted as LWS, satisfies all properties (a)-(h).

**Theorem 1.** LWS satisfy all properties (a) - (h).

However, we notice that an agent either loses all his wager or wins the entire pool of wagers, resulting in a high variance in each agent’s payoff. Besides, an agent has a large probability of losing money even if his prediction is much more accurate than the others’. Consider the following example: when agents have uniform wagers, in the WSWM mechanism, no agent can have a net-payoff that is more than his wager. Consequently, in the LWS mechanism, each agent has at least $\frac{N-2}{N}$ chance of losing all his wager no matter what predictions other agents report. Ideally, we prefer a randomized wagering mechanism with moderate payoff variance and high probability of winning money for accurate agents. To alleviate these two shortcomings of the LWM, we can always mix a deterministic wagering mechanism with LWM by assigning each of them a probability to be executed. This probabilistic mixture provides us the flexibility of adjusting the variance of payoff and the probability of winning money.

## 6 Surrogate wagering mechanisms

In this section, we propose the **surrogate wagering mechanisms** (SWM). We first introduce the general SWM, then variants of SWM which obtain desirable properties and have moderate variance in payoffs and a large probability of winning for accurate predictions. We then notice that randomization opens up the possibility of dealing with situations where only noisy ground truth is available. We discuss how to extend our results to this noisy setting.

### 6.1 Generic surrogate wagering mechanisms

A surrogate wagering mechanism consists of three main steps: (1) the SWM generates a surrogate event outcome for each agent based on the true event outcome and a randomization device; (2) the SWM evaluates each agent’s prediction according to the surrogate event outcome using a designed scoring function such that the score is an unbiased estimate of the score derived by applying a strictly proper scoring rule to the ground truth outcome; (3) the SWM applies WSWM to the scores based on the surrogate event outcome to determine the final net-payoff of each agent. Next, we explain the three steps in details. For clarity and
simplicity of exposition, we consider only binary events, i.e., $\mathcal{X} = \{0, 1\}$, in this section. We will use $\hat{p}_i$ to denote agent $i$'s report for $\mathbb{P}(X = 1)$, which fully describes $\hat{p}_i$ for binary events.

**Step 1. Surrogate event outcomes** A SWM generates a surrogate event outcome $\hat{X}_i$ for each agent $i \in \mathcal{N}$. Denote $\hat{X} = (\hat{X}_1, \hat{X}_2, ..., \hat{X}_N)$. $\hat{X}_i$s are drawn independently conditional on $X$, and are specified by the SWM. The conditional marginal distribution $\mathbb{P}(\hat{X}_i | X)$, $i \in \mathcal{N}$ can be expressed by two parameters, the error rates of the surrogate outcome: $e_0^i = \mathbb{P}(\hat{X}_i = 0 | X = 1)$ and $e_1^i = \mathbb{P}(\hat{X}_i = 1 | X = 0)$. The conditional marginal distribution $\mathbb{P}(\hat{X}_i | X)$ can be any distribution satisfying $\forall i \in \mathcal{N}: e_1^i + e_0^i \neq 1$. We use $\bar{x}$ and $\tilde{x}_i$ to denote the realization of $\bar{X}$ and $\tilde{X}_i$ respectively.

**Step 2. Computing unbiased scores** Given a strictly proper scoring rule $s_x(\cdot)$ within $[0,1]$, the SWM computes the score of an agent $i$ as $\phi \circ s_{\bar{x}}(\hat{p}_i)$, where

$$
\varphi \circ s_{\bar{x}}(\hat{p}_i) = \frac{(1 - e_1^i - \bar{x}_i) s_{\bar{x}}(\hat{p}_i) - e_2^i, s_{1-\bar{x}}(\hat{p}_i)}{1 - e_0^i - e_1^i}.
$$

$\tilde{x}_i$ is the realized surrogate event outcome for agent $i$. Lemma 1 shows that $\phi$ is an unbiased operator on the score $s_{\bar{x}}(\hat{p}_i)$ in the sense that $\mathbb{E}_{\hat{X}_i|x}[\varphi \circ s_{\bar{x}}(\hat{p}_i)] = s_x(\hat{p}_i)$.

**Lemma 1 (Lemma 3.4 of [2]).** $\forall x \in \{0, 1\}, \forall \hat{p}_i, e_0^i, e_1^i \in [0, 1](e_0^i + e_1^i \neq 1)$, we have $\mathbb{E}_{\hat{X}_i | x}[\varphi \circ s_{\bar{x}}(\hat{p}_i)] = s_x(\hat{p}_i)$.

We express Lemma 1 in our setting more explicitly in Corollary 1:

**Corollary 1.** Given an event $X$, a prediction $\hat{p}$, a strictly proper scoring rule $s_x(\cdot)$, error rates $e_0, e_1 \in [0, 1]$ where $e_0 + e_1 \neq 1$ and a surrogate event $\bar{X}$ randomly generated in a way that $\mathbb{P}(\bar{X} = 0 | X = 1) = e_1$ and $\mathbb{P}(\bar{X} = 1 | X = 0) = e_0$, the scoring rule given by $\varphi \circ s_{\bar{x}}(\hat{p}_i)$ is a strictly proper scoring rule in expectation in the sense that $\forall x, \hat{p}_i \in \mathbb{E}_{\hat{X}_i | x}[\varphi \circ s_{\bar{x}}(\hat{p}_i)] = s_x(\hat{p}_i)$.

**Step 3. Computing net-payoffs** In the final step, the SWM computes the net-payoff of agent $i$ using WSWM and the unbiased score of agent $i$, i.e., replacing score $s_{\bar{x}}(\hat{p}_i)$ in Eqn. (1) by score $\varphi \circ s_{\bar{x}}(\hat{p}_i)$. Formally, we have

$$
\Pi_{i}^{SWWM}(\hat{p}, w, x) = \frac{w_i \mathbb{E}_{\hat{X}_i | x}[\varphi \circ s_{\bar{x}}(\hat{p}_i)] - \sum_{j \in \mathcal{N}\setminus \{i\}} w_j \mathbb{E}_{\hat{X}_i | x}[\varphi \circ s_{\bar{x}}(\hat{p}_j)]}{W_N},
$$

and $x$ and $\tilde{x}_i, i \in \mathcal{N}$ are the event outcome and the surrogate event outcome for each agent $i$ respectively.

**Mechanism 2 Surrogate Wagering Mechanisms**

1. Collect the predictions $\hat{p}$ and wagers $w$.
2. Select error rate $e_0^i, e_1^i \in [0, 1](e_0^i + e_1^i \neq 1), \forall i$.
3. Generate surrogate outcome $\tilde{X}_i, \forall i$ such that $\mathbb{P}(\tilde{X}_i = 1 | X = 0) = e_1^i, \mathbb{P}(\tilde{X}_i = 0 | X = 1) = e_0^i$.
4. Score each agent $i \in \mathcal{N}$ according to Eqn. (3).
5. Pay each agent $i \in \mathcal{N}$ a net-payoff using Eqn. (3).

We formally present SWM in Mechanism 2. According to our Corollary 1 (applying to each score terms), we have $\forall i, x, \hat{p}, w : \mathbb{E}_{\Pi_{i}^{SWWM}(\hat{p}; w, x)}[\Pi_{i}^{SWWM}(\hat{p}; w; x)] = \Pi_{i}^{WSWM}(\hat{p}; w; x)$. Because the deterministic WSWM satisfies properties ((a)-(f)) SWM also satisfies these properties. Meanwhile, a realization of the score $\phi \circ s_{\bar{x}}(\hat{p}_i)$ can be larger than 1, offering a chance for agent $i$ to lose (or win) more than the money he can lose (or win) in deterministic WSWM. However, we also notice that for some extreme values of error rates, the constraint $\Pi_{i}(\hat{p}; w; x) \geq -w_i$ can be violated, i.e., an agent may lose more than he wagers, which makes SWM invalid. In the next section, we show that by selecting error rates in a subtle way, we can obtain all the properties (a)-(h) without violating the wager constraint $\Pi_{i}(\hat{p}; w; x) \geq -w_i$.  

\footnote{Extension to multi-outcome events can be found in our supplemental materials.}

\footnote{For example, in a wagering game, two agents both wager 1 and report 1 and 0, respectively. Let $s_{\bar{x}}(\hat{p}_i) = 1 - (x - \hat{p}_i)^2, e^i_0 = 0.4, i = 1, 2, j = 0, 1$. In the worst case of agent 1, the surrogate outcomes are realized as $\tilde{x}_1 = 0, \tilde{x}_2 = 1$. Then, $\pi_1 = -5 < -1$.}
6.2 SWM with Error rate selection (SWME) and random partition SWME (RP-SWME)

We notice that according to Corollary 1, no matter which error rates $e_0$, $e_1$ are chosen, the unbiasedness property of SWM holds, i.e., $\mathbb{E}_{\hat{\pi} \sim D(\hat{\pi}; w; x)}[\Pi_{SWM}(\hat{\pi}; x)] = \Pi_{SWM}(\hat{\pi}; x)$. In other words, we can choose the error rates in an arbitrary way (even in an ex-post way) without changing the expected net-payoff of each agent under any realized event outcome. This gives us the flexibility to tune the maximal amount of money each agent can win or lose in the game, while preserving the properties ((a)-(f)) inherited from WSWM.

Given reports $\hat{\pi}$ and wagers $w$ but not the event outcome $x$, the error rate pair that guarantees no wager violation under any outcome $x \in \mathcal{X}$ and any realization of the randomness induced by SWM may not be unique. We propose Algorithm 3 to select a pair of error rates $e_0, e_1$ after the reports and wagers are collected, such that at least one agent loses all his wager in the worst case w.r.t. the event outcome and the randomness of the mechanism.

We name the mechanisms SWME when we use Algorithm 3 to select the error rates for SWM.

Algorithm 3 Error Rate Selection Algorithm

1: Collect the predictions $\hat{\pi}$ and wagers $w$.
2: For each agent $i \in \mathcal{N}$, compute $r_i = \frac{1}{2} \left( 1 - \frac{w_i}{w_N} \right) (s_i^w - s_i^b) + \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} (s_j^w - s_j^b) + \frac{1}{2} \left( 1 - \frac{w_i}{w_N} \right) (s_i^w + s_i^b) + \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} (s_j^w + s_j^b)$.
3: For each agent $i \in \mathcal{N}$, compute $r_i = \frac{1}{2} \left( 1 - \frac{w_i}{w_N} \right) (s_i^w - s_i^b) + \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} (s_j^w - s_j^b)$.
4: If $\min_{j \in \mathcal{N}} \{ r_j \} = 0.5$, set $e_i^1 = e_i^0 = 0, \forall i$, else set $e_i^1 = e_i^0 = \min_{j \in \mathcal{N}} \{ r_j \}, \forall i$.

Lemma 2. SWME has no wager violation and when there exists at least one report $\hat{\pi}_i \neq 0.5$, at least one of the agents loses all his wager in the worst case w.r.t. the event outcome and the randomness of SWME.

6.3 Proof of Lemma 2

Proof. In this proof, we use Brier Score as the scoring rule used by the mechanism, i.e., $s_x(\hat{\pi}) = 1 - (x - \hat{\pi})^2$, and $\hat{\pi}_i$ is agent $i$’s report of $\mathbb{P}(X = 1)$. The proof can be extended to other strictly proper scoring rule within $[0, 1]$.

We first consider the corner case where all agents reports 0.5. It can be verified that in Algorithm 2, $\min_{i \in \mathcal{N}} r_i = 0.5$, and the algorithm sets $e_i^1 = e_i^0 = 0, \forall i$ and SWME is reduced to WSWM. Thus, no wager violation happens.

Next, we consider the scenario that $\exists \hat{\pi} \in \mathcal{N}, \hat{\pi} \neq 0.5$. In this scenario, we first prove that, in Algorithm 2 $\forall i, r_i \in (0, 0.5)$.

We have $\forall i, s_i^w, s_i^b \in [0, 1], s_i^w \leq s_i^b$ (the equality only holds when $\hat{\pi}_i = 0.5$), $s_i^w + s_i^b \in [0.5, 1]$. Let

$$A = (1 - \frac{w_i}{w_N})s_i^w - \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} s_j^b$$

and

$$B = (1 - \frac{w_i}{w_N})(s_i^w + s_i^b) - \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} (s_j^w + s_j^b).$$

We have $r_i = \frac{1}{2} + \frac{2A - B}{2r_i + 1 - 2r_i}, A > -1, B \in (0, 1)$ and $2A - B = \sum_{j \in \mathcal{N} \setminus \{i\}} \frac{w_j}{w_N} (s_j^w - s_j^b) + (1 - \frac{w_i}{w_N})(s_i^w - s_i^b) > 0$ (there exists at least one agent $i \in \mathcal{N}$ that $\hat{\pi}_i \neq 0.5$). Therefore, $2A - B \in (0, 1)$. We have $r_i = \frac{1}{2} + \frac{2A - B}{2r_i + 1 - 2r_i} \in (0, 0.5)$.

Next, we prove that if let $r_i$ be a variable, and let $e_i^1 = r_i$, the worst cast net-payoff $\pi_i^w$ (w.r.t. the event outcome and the randomness of the mechanism) of agent $i$ is a decreasing function of $r_i$.

In the worst case of agent $i$, $\varphi \circ \pi_{s_2} (\hat{\pi}_i) = (1 - \pi_i)(s_2^w - s_2^b) \pi_{s_2} (\hat{\pi}_i) = (1 - \pi_i)(s_2^w - s_2^b) \pi_{s_2} (\hat{\pi}_i)$ and $\pi_i^w = w_i (\frac{A - Br_i}{1 - 2r_i})$. We have $\frac{\partial \pi_i^w}{\partial r_i} = w_i A (1 - 2r_i) < 0$. Therefore, $\pi_i^w$ is decreasing with $r_i$.

Finally, it is easy to verify that when $r_i = \frac{1}{2} + \frac{2A - B}{2r_i + 1 - 2r_i}$, $\pi_i^w = -w_i$.

Therefore, when we set for each agent $i \in \mathcal{N}, e_i^0 = e_i^1 = \min_{j \in \mathcal{N}} r_j$, no agent can lose more than his wager and agent $i^* = \arg\min_{j \in \mathcal{N}} r_j$ loses all his wager in the worst case. \(\square\)

\textsuperscript{5}The expectation is taken over the randomness of the mechanism conditioned on the event outcome.
Note Lemma 2 doesn’t imply PO for SWME - if there exist two agents who have different predictions and have wager left even in their own worst cases, they can form a profitable bet against each other. We propose a variant of SWME to fix this caveat in next subsection.

Random partition SWME (RP-SWME) Lemma 2 implies that when agents are partitioned into groups of two, there will not exist side bets. Also a smaller number of agents imposes less restrictions in selecting the error rates, and thus each agent’s wager can be fully leveraged in the randomization step. We would like to note that this is a very unique property of SWME: as both shown in [6] and our experimental results, existing wagering mechanisms (including DCA) incurs low risk when the number of agents is small. This not only implies that SWME is particularly suitable for small group wagering but also points out a way of further improving the risk property of SWME, i.e. via randomly partitioning agents into smaller groups. We formally present the random partition SWME in Mechanism 4. We will show in next Section that the random partitioning achieves all properties (a)-(h).

Mechanism 4 Random Partition SWME (RP-SWME)
1: Partition agents into groups of two. If \( N \) is odd, leave one group with three agents.
2: Run SWME for each group.

6.4 Properties of SWME and RP-SWME

Theorem 2. Both (SWME) and (RP-SWME) satisfy properties (a)-(g). (RP-SWME) satisfies (h).

Proof. We provide full proofs in Section 2.4 of the supplemental material, but we give the arguments for establishing surrogate wager’s ex-post budget balance (despite of the randomness), incentive compatibility, and Pareto optimality.

(a) Individual rationality and (b) (strictly) incentive compatibility First consider SWME. For an arbitrary profile of reports \( \hat{\mathbf{p}} \) and wagers \( \mathbf{w} \), Algorithm 5 outputs an profile \( \mathcal{E} \) of error rates of all agents. Denote by \( \hat{\varphi}_E(\cdot) \) the corresponding surrogate function specified using the error rate profile \( \mathcal{E} \) for agent \( i \). For each \( i \) and \( j \in N \):

\[
\mathbb{E}_{X \sim p_i, X_j} \left[ \hat{\varphi}_E^i \circ s_{X_j}(\hat{p}_j) \right] = p_i \mathbb{E}_{X_j|X=1}[\hat{\varphi}_E^i \circ s_{X_j}(\hat{p}_j)] + (1 - p_i) \mathbb{E}_{X_j|X=0}[\hat{\varphi}_E^i \circ s_{X_j}(\hat{p}_j)] \\
= p_i \cdot s_X(\hat{p}_i) + (1 - p_i) \cdot s_X(\hat{p}_j) \\
= \mathbb{E}_{X \sim p_i}[s_X(\hat{p}_j)],
\]

using Corollary 1. Then (using linearity of expectation, note \( \hat{\mathbf{X}} \) encode the randomness in \( \Pi_i^{SWME} \))

\[
\mathbb{E}_{X \sim p_i, \mathbf{X}} \left[ \Pi_i^{SWME}(\hat{\mathbf{p}}, \mathbf{w}, X) \right] \\
= \frac{w_i W_{N\setminus\{i\}}}{W_N} \left( \mathbb{E}_{X \sim p_i, \hat{X}_i} [\hat{\varphi}_E^i \circ s_{\hat{X}_i}(\hat{p}_i)] - \sum_{j \in N \setminus \{i\}} \frac{w_j}{W_{N\setminus\{i\}}} \mathbb{E}_{X \sim p_i, \hat{X}_j} [\hat{\varphi}_E^i \circ s_{\hat{X}_j}(\hat{p}_j)] \right) \\
= \mathbb{E}_{X \sim p_i} \left[ \frac{w_i W_{N\setminus\{i\}}}{W_N} \left( s_X(\hat{p}_i) - \sum_{j \in N \setminus \{i\}} \frac{w_j}{W_{N\setminus\{i\}}} s_X(\hat{p}_j) \right) \right] \\
= \mathbb{E}_{X \sim p_i} \left[ \Pi_i^{WS}(\hat{\mathbf{p}}, \mathbf{w}, X) \right].
\]

Note the above holds for any possible reports (\( \forall \mathcal{E} \)). Thus the incentive properties of WSWM will preserve, i.e., IR and SIC. The proof for RP follows immediately, as RP-SWME first runs a random partition, which does not depend on agents’ reports and wagers, and then runs SWME for each group of agents after the partition.

(c) Ex-post budget balance This can be shown via writing down the sum of net-payoffs defined in Eqn. 3. Our note below Eqn. 3 also states that the budget balance property doesn’t depend on the specific forms of the scoring functions therein. We formally present the deduction as follows:
\[
\sum_{i} \Pi_{i}^{SWME}(\hat{p}_{i}, w_{i}, \cdot) = \sum_{i} \frac{w_{i} W_{N \setminus \{i\}}}{W_{N}} \left( \varphi \circ s_{\tilde{E}_{i}}(\hat{p}_{i}) - \sum_{j \in N \setminus \{i\}} \frac{w_{j} W_{N \setminus \{i\}}}{W_{N}} \cdot \varphi \circ s_{\tilde{E}_{j}}(\hat{p}_{j}) \right) \\
= \sum_{i} \left( \frac{w_{i} W_{N \setminus \{i\}}}{W_{N}} \varphi \circ s_{\tilde{E}_{i}}(\hat{p}_{i}) - \sum_{j \neq i} \frac{w_{j} W_{N \setminus \{j\}}}{W_{N}} \cdot \varphi \circ s_{\tilde{E}_{j}}(\hat{p}_{j}) \right) \\
= \sum_{i} \left( \frac{w_{i} W_{N \setminus \{i\}}}{W_{N}} \varphi \circ s_{\tilde{E}_{i}}(\hat{p}_{i}) - \frac{w_{i} W_{N \setminus \{i\}}}{W_{N}} \cdot \varphi \circ s_{\tilde{E}_{i}}(\hat{p}_{i}) \right) = 0.
\]

The above also shows that for each group from the random partition of (RP-SWME), ex-post budget balance is satisfied. Thus, we also proved ex-post budget balance for (RP-SWME).

**d) Sybilproofness:** SWME is sybilproof as we proved that the expected payoffs of SWME are the same as WSWM (and WSWM is Sybilproof). RP-SWME is also Sybilproof as a corollary of Lemma 3.

**Lemma 3.** If a (randomized) wagering mechanism \(\mathcal{W}\) is (weakly) budget-balanced, (weakly) incentive compatible, Sybilproof, then the mechanism \(\mathcal{W}^{*}\) that first uniformly randomly pairs agents in groups of two and then runs mechanism \(\mathcal{W}\) for each group is still Sybilproof.

**Proof.** We prove the claim for the case that an agent is only allowed to create two identities. The claim holds in general, as we can always merge two identities into one without decreasing the payoff, following the result of the case of two.

Fixing an arbitrary belief \(p_{i}\) of agent \(i\), we denote the \(E^{\mathcal{W}}_{i}(\hat{p}, w) := E_{X \sim p_{i}, D^{\mathcal{W}}(\hat{p}, w, X) \mid \Pi_{i}(\hat{p}, w, X = x)}\), where \(D^{\mathcal{W}}(\cdot)\) is the distribution specified by mechanism \(\mathcal{W}\). Suppose an agent \(i\) divides its wager \(w_{i}\) into two wagers \(w_{1i}, w_{2i}\), and reports two predictions \(\hat{p}_{1i}, \hat{p}_{2i}\) correspondingly. We have \(\forall \hat{p}_{1i}, \hat{p}_{1i}, w_{1i}, w_{2i}, \hat{p}_{-i}, w_{-i}, x,\)

\[
E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{2i}, \hat{p}_{-i}, w_{1i}, w_{2i}, w_{-i}) \\
= \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) + \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{2i}, w_{1i}, w_{2i}) + \frac{1}{N} \left( E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{1i}, w_{1i}, w_{1i}) + E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{2i}, w_{1i}, w_{2i}) \right) \\
\leq \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) + \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{2i}, w_{1i}, w_{2i}) \tag{\(\mathcal{W}\) is (weakly) budget balance) \\
\leq \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) + \frac{1}{N} E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) \tag{\(\mathcal{W}\) is (weakly) incentive compatible) \\
\leq \sum_{i \neq j} \frac{1}{N} E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) \tag{\(\mathcal{W}\) is sybilproof) \\
\leq \sum_{i \neq j} \frac{1}{N - 1} E^{\mathcal{W}}_{i}(\hat{p}_{1i}, \hat{p}_{j}, w_{1i}, w_{j}) = E^{\mathcal{W}^{*}}_{i}(\hat{p}_{1i}, \hat{p}_{-i}, w_{1i}, w_{-i})
\]

Therefore, \(\mathcal{W}^{*}\) is sybilproof.

**e) Anonymity:** For SWME, this proof can follow from the fact that the randomness (error rate selection) in SWME and tRP-SWME depends only on the reports and wagers of agents and do not depend on the identities of agents and the fact that the expected net-payoffs of agents are the same with those of WSWM (Corollary 1), which is anonymous [3]. RP-SWME only adds a random partition of agents in SWME and the partition does not depend on the identities of agents. Thus, RP-SWME is also anonymous.
(f) **Neutrality:** For SWME, this proof can follow from the fact that the randomness (error rate selection) in SWME and tRP-SWME depends only on the reports and wagers of agents and do not depend on the labeling of the outcomes and the fact that the expected net-payoffs of agents are the same with those of WSWM (Corollary 1), which is neutral [3]. RP-SWME only adds a random partition of agents in SWME and the partition does not depend on the labeling of the outcomes. Thus, RP-SWME is also neutral.

(g) **Non-arbitrage opportunity:** Now we prove that SWME does not allow arbitrage opportunity. The idea is simple and straight-forward: fix the set of prediction $p_i$ and wagers $w$. First notice the fact that under each possible realization $\tilde{x}_i$, $\tilde{x}_{-i}$ can be any possible realizations. Since $s_{\tilde{x}_i=1}(p_i)$ and $s_{\tilde{x}_i=0}(p_i)$ have opposite monotonicity, we know there does not exist an interval for risklessly predictions.

The above non-arbitrage opportunity is *ex-post*, but the arbitrage opportunity persists when agents evaluate the conditional expectation of his score with respect to the random flipping step (which is the same as WSWM), which remains a concern when each agent participates in multiple event forecasts. This concern will be resolved when we apply the idea of surrogate wagering to the non-arbitrage wagering mechanism (NAWM). For details please refer to Section 7.1.

For RP-SWME, it runs SWME on each pair of agents after the random partition. Therefore, agents also have no arbitrage opportunity.

**Pareto optimality** In RP-SWME, any pair of agents with different beliefs have a positive probability to be partitioned into a sub-group. Applying Lemma 2 at least one of them loses all his wager in the worst case. Thus, by Definition 2, RP-SWME is PO.

### 6.5 Wager with noisy ground truth

The above method also points out a way to implement a wagering mechanism with a noisy ground truth, as SWM is able to remove the noise in outcomes in expectation. The ability to wager with noisy ground truth provides informative information to agents who participated in a wagering mechanism immediately only when a noisy copy of outcome is available. Due to space limitation, we present the key idea below, while not re-defining all properties w.r.t. $\tilde{X}$ instead of $X$ - the changes are rather straight-forward.

Suppose we know a noisy estimate $\tilde{X}$ on $X$, and denote the error rate of $\tilde{X}$ as $\tilde{e}_1, \tilde{e}_0$ (which we know, and agents trust us in knowing these two numbers), we will be able to reproduce our surrogate wager mechanism by plugging $\tilde{X}, \tilde{e}_1, \tilde{e}_0$ into Eqn. (2), if we ignore the PO property for now. We similarly will have the wager violation issue pointed out earlier - we however do not have the control of the error rates directly. An easy fix is via the following affine transformation of the wagering scores: suppose under the worst case, the random flipping will incur $-scale \cdot w_i$ wager score (net-payoff) with $scale > 1$. We can then rescale every agent’s wager score by $1/scale$. Note the above affine transformation does not affect the incentive and other properties of the original surrogate wagering mechanism, as $E[\phi \circ \Pi_0^{WS} (\cdot)] = \frac{1}{scale} \cdot E[\Pi_0^{WS} (\cdot)]$. To achieve PO, we can further random partition agents into groups of two and flip on $\tilde{X}$ according to certain error rates $\tilde{e}_0^i, \tilde{e}_1^i$ for each agent $i$. Let $\tilde{X}_i$ be the flipped outcome. We can establish the error rates of $\tilde{X}_i$ w.r.t. the ground truth $X$ and $\tilde{e}_0^i, \tilde{e}_1^i$ by following equations:

$$P(\tilde{X}_i = 1 | X = 0) = \sum x \in \{0,1\} P(\tilde{X}_i = 1, \tilde{X} = x | X = 0)$$

$$= \sum x \in \{0,1\} P(\tilde{X}_i = 1 | \tilde{X} = x, X = 0) \cdot P(\tilde{X} = x | X = 0)$$

$$= \tilde{e}_0^i \cdot (1 - \tilde{e}_0) + (1 - \tilde{e}_1^i) \cdot \tilde{e}_0,$$

and similarly $P(\tilde{X}_i = 0 | X = 1) = \tilde{e}_1^i \cdot (1 - \tilde{e}_1) + (1 - \tilde{e}_0^i) \cdot \tilde{e}_1$. It’s easy to see that when $\tilde{e}_1 + \tilde{e}_0 \neq 1$, we can tune the error rates of $\tilde{X}$ via tuning $\tilde{e}_1^i, \tilde{e}_0^i$. This step corresponds to the error selection step in SWME, i.e., Algorithm 3.

---

6We didn’t apply the scaling in SWME when there exists other options, as the scaling will effectively decrease the expected payment of each agent.
7 Extensions of SWM

We discuss a couple of useful extensions of SWM: i). one is instead of building on WSWM, we show the idea of surrogate idea can also build upon another deterministic wagering mechanism NAWM. (ii). We extend our results to a multi-outcome setting.

7.1 Surrogate NAWM

We note that the bias removal procedure adopted in SWM does not rely the specific underlying wagering mechanism heavily. We demonstrate the idea with a non-arbitrage wagering mechanism (NAWM, [5]).

Notice that since $\Pi_{\mathcal{N}}(\cdot)$ is not linear in the surrogate scores of each agent, the budget balance argument is not as easy as in the WSWM case. Nonetheless we notice the following fact proved in [5]:

$$\Pi_{\mathcal{N}}(\tilde{p}_i, \tilde{p}_{-i}, w, X = x) = \Pi_{\mathcal{N}}^{WS}(\tilde{p}_i, \tilde{p}_{-i}, w, X = x) - \Pi_{\mathcal{N}}^{WS}(\tilde{p}_i, \tilde{p}_{-i}, w, X = x)$$

where $\tilde{p}_i$ denotes the average prediction from $j \neq i$. Then we can safely apply the surrogate idea to the first WSWM scoring term:

$$\varphi \circ \Pi_{\mathcal{N}}^{WS}(\tilde{p}_i, \tilde{p}_{-i}, w, \tilde{X} = \tilde{x}) = \varphi \circ \Pi_{\mathcal{N}}^{WS}(\tilde{p}_i, \tilde{p}_{-i}, w, \tilde{X} = \tilde{x}) - \Pi_{\mathcal{N}}^{WS}(\tilde{p}_i, \tilde{p}_{-i}, w, X = x)$$

This mechanism will enjoy the higher risk property introduced by surrogate wagering, as well as the non-arbitrage (in conditional expectation) brought in by NAWM.

7.2 Multi-outcome events

For simplicity, our previous discussions focused largely on the binary outcome scenario. As promised, we now show that our results extend to the non-binary events. Recall that there are $M$ outcomes, denoting as $[0, 1, 2, ..., M-1]$. Denote the following confusion matrix

$$C = \begin{bmatrix}
  c_{0,0} & c_{0,1} & \cdots & c_{0,M-1} \\
  c_{1,0} & c_{1,1} & \cdots & c_{1,M-1} \\
  \cdots & \cdots & \cdots & \cdots \\
  c_{M-1,0} & c_{M-1,1} & \cdots & c_{M-1,M-1}
\end{bmatrix}$$

and each entries $c_{j,k}$ indicates the flipping probability for generating a surrogate outcome: $c_{j,k} = \Pr[\tilde{X}_i = k | X = j]$. The core challenge of this extension is to find an unbiased operator $\varphi$. Writing out the conditions for unbiasedness (s.t. $\mathbb{E}_{X_i \sim [s]}[\varphi \circ s_{X_i \sim [\tilde{x}]}(\tilde{p})] = s_x(\tilde{p})$), we need to solve the following set of functions to obtain $\varphi(\cdot)$ (short-handing $\varphi \circ s_x(\tilde{p})$ as $\varphi_x(\tilde{p})$):

$$s_0(\tilde{p}) = c_{0,0} \cdot \varphi_0(\tilde{p}) + c_{0,1} \cdot \varphi_1(\tilde{p}) + \cdots + c_{0,M-1} \cdot \varphi_{M-1}(\tilde{p})$$

$$s_1(\tilde{p}) = c_{1,0} \cdot \varphi_0(\tilde{p}) + c_{1,1} \cdot \varphi_1(\tilde{p}) + \cdots + c_{1,M-1} \cdot \varphi_{M-1}(\tilde{p})$$

$$\vdots$$

$$s_{M-1}(\tilde{p}) = c_{M-1,0} \cdot \varphi_0(\tilde{p}) + c_{M-1,1} \cdot \varphi_1(\tilde{p}) + \cdots + c_{M-1,M-1} \cdot \varphi_{M-1}(\tilde{p})$$

Denote by $s(\tilde{p}) = [s_0(\tilde{p}); s_1(\tilde{p}); \ldots; s_{M-1}(\tilde{p})]$, and $\varphi(\tilde{p}) = [\varphi_0(\tilde{p}); \varphi_1(\tilde{p}); \ldots; \varphi_{M-1}(\tilde{p})]$. Then the above equation becomes equivalent with the following system of equation: $s(\tilde{p}) = C \cdot \varphi(\tilde{p})$. Choose a $C$ with full rank. For instance when $M > 2$ we can set $c_{j,j} = \frac{2}{M}$, $c_{j,k} = \frac{1}{2(M-1)}$, $k \neq j$. Not hard to verify that such a $C$ is indeed full rank. Then we are ready to solve for $\varphi(\tilde{p})$ as follows:

$$\varphi(\tilde{p}) = C^{-1} \cdot s(\tilde{p}).$$

(4)

With defining above unbiased surrogate operator, all other discussions generalize fairly straight-forwardly - such a $\varphi$ will give us the same equation as established in the lemma below for the non-binary event outcome setting:

**Lemma 4.** Define $\varphi(\cdot)$ as Eqn. (4), and flip $X_i$ using $C, x$. Then $\mathbb{E}_{X_i \sim [x]}[\varphi \circ s_{X_i \sim [\tilde{x}]}(\tilde{p})] = s_x(\tilde{p})$.

We include a detailed example of $\varphi$ for three-outcome events below.

\footnote{Though the randomization device already grants us the non-arbitrage property, we pick this mechanism for its simplicity for presentation, as NAWM also extends from WSWM. ii. we will show in experiments later that we empirically observe higher risk when applying this surrogate based randomized NAWM.}
Example of $\varphi$ for three-outcome events

Example 1. An example with $M = 3$. Suppose we flip the outcome using the uniform-error confusion matrix:

$$C = \begin{bmatrix} 0.5 & 0.25 & 0.25 \\ 0.25 & 0.5 & 0.25 \\ 0.25 & 0.25 & 0.5 \end{bmatrix} \Rightarrow C^{-1} = \begin{bmatrix} 3 & -1 & -1 \\ -1 & 3 & -1 \\ -1 & -1 & 3 \end{bmatrix}$$

Therefore we obtain a closed-form of $\varphi$:

$$\varphi_0(\hat{p}) = 3s_0(\hat{p}) - s_1(\hat{p}) - s_2(\hat{p})$$

$$\varphi_1(\hat{p}) = -s_0(\hat{p}) + 3s_1(\hat{p}) - s_2(\hat{p})$$

$$\varphi_2(\hat{p}) = -s_0(\hat{p}) - s_1(\hat{p}) + 3s_2(\hat{p})$$

8 Evaluation

In this section, we evaluate LWS and RP-SWME with extensive simulations. We first compare the efficiency of LWS and RP-SWME with that of other existing deterministic (weakly) incentive compatible mechanisms WWM, NAWM and DCA. The results show that the two randomized wagering mechanisms outperform the three deterministic wagering mechanism. Then, we compare the variance of payoff and the probability of winning money within the two randomized wagering mechanisms. The results show that RP-SWME is better than LWS in these two matrices.

8.1 Simulation Setup

We simulate both the binary events and the multi-outcome events. For binary events, we generated six sets of agents’ predictions and wagers according to the combinations of three different prediction models and two different wager models. With a little abuse of notation, we denote that an event happens with probability $\phi$. Therefore we obtain a closed-form of $\phi$:

$$\varphi_0(\hat{p}) = 3s_0(\hat{p}) - s_1(\hat{p}) - s_2(\hat{p})$$

$$\varphi_1(\hat{p}) = -s_0(\hat{p}) + 3s_1(\hat{p}) - s_2(\hat{p})$$

$$\varphi_2(\hat{p}) = -s_0(\hat{p}) - s_1(\hat{p}) + 3s_2(\hat{p})$$

1. Uniform model: For each event, $p_i$ is independently drawn from a uniform distribution over $[0, 1]$.

2. Logit-Normal model: This model assumes that $p_i$, when being mapped to the real line by a logit function as $\log \left( \frac{p_i}{1-p_i} \right)$, is independently drawn from a Normal distribution $\mathcal{N}(\log(q^{-1/\alpha}))$, i.e., $p_i \sim \text{Logit-Normal} \left( \log(q^{-1/\alpha}), \sigma^2 \right)$. $q, \alpha, \sigma^2$ are model parameters. This model is proposed and used to estimate the happening probability of the event in [19], where $q$ is regarded as an estimator of the happening probability and $\alpha$ models the under-confident effect on human forecasters. Based on a real prediction dataset over 1300 forecasters and 69 geopolitical events collected in [19], this model outperforms most existing models to estimate the happening probability of events, which leads us to believe this model a good alternate to generate prediction data. In our simulations, we adopted $\alpha = 2$, which best fits the aforementioned real prediction dataset, $\sigma^2 = 1$, and $q$ is drawn uniformly from $[0, 1]$ for each event.

3. Synthetic model: this synthetic model is introduced from a set of simulation studies in [20, 21, 19]. The model assumes that the happening probability of an event to be predicted by $N$ is given by $q = \Phi(\sum_{i=1}^{N} u_i)$, where $\Phi$ is the cumulative distribution function of a standard normal distribution and $u_i$ is independently drawn from $\mathcal{N}(0, 1)$. Each agent knows the true probability generating model and $u_i$ but not $u_j, \forall j \neq i$. Accordingly, each agent’s calibrated belief of the happening probability of the event is given by $p_i = \Phi(\frac{u_i}{\sqrt{2N-1}})$.

We use two models to generate the wagers of agents:

1. Uniform model: All agents’ wagers are equal to 1.

2. Pareto model: This model assumes that the wager $w_i$ of agent $i$ follows the Pareto distribution, which is often adopted to model the distribution of wealth in a population. In the simulations of [6], the authors selected the shape parameter and scale parameter of the Pareto distribution as 1.16 and 1 correspondingly, which is the distribution depicted as “20% of the population has 80% of the wealth”. We adopted the same parameters for comparison purpose.
For events with multiple outcomes, we simulated three sets of data with the number of possible outcomes 3, 6, 9 correspondingly. In each set, we drew the predictions from uniform distribution over the whole probability space and drew the wagers according to the Uniform model.

8.2 Comparison of efficiency of wagering mechanisms

We show that LWS and RP-SWME are more efficient than existing deterministic (weakly) incentive compatible mechanisms WSWM, NAWM and DCA. We evaluate the efficiency by two metrics: Average individual risk and Average money exchange rate.

Individual risk is the percent of wager that an individual agent can lose in the worst case w.r.t. the event outcome and the randomness of the mechanisms. The average individual risk is an indicator of Pareto optimality, because the average individual risk equal to 1 (i.e., no one can commit to secure a positive wager before the wagering game) is a sufficient condition of Pareto optimality. Money exchange rate is the total amount of money exchanged in the game after the outcome of a wagering mechanism is realized, divided by the total amount of wagers. Average money exchange rate measures the efficiency of an average wagering game.

In our simulations, we vary the number of agents for 2 to 50 with a step of 2. For each number of agents, we
randomly generate 1000 events and the agents’ predictions and wagers for each of the six combinations of prediction models and wager models, and take the average of individual risk and money exchange rate over the 1000 events. When calculating the money exchange, we use the expectation of the money exchange over all possible outcomes according to the happening probability of each outcome. This happening probability is either specified in the model generating the predictions, or otherwise, drawn from a uniform distribution over the corresponding probability space.

In the simulations, both RP-SWME and LWS achieve the highest average individual risk (approximately 1) under all conditions (# of outcomes, # of agents, prediction models, and wager models) we simulated (Figure 1, 2). In contrast, the best of the deterministic mechanisms DCA, only achieves an approximate 1 average individual risk when the wagers of agents are uniform and the number of participants is more than 30 (Figure 1a-1c). Its average individual risk drops to 0.6 when the wagers of agents follows the Pareto distribution (Figure 1d-1f). This result shows that the two randomized mechanisms effectively remove the opportunity for side bet and take use of all the wagers before the outcome is realized.

LWS doubles the money exchange rate of the second best alternative, hitting a more than 80% money exchange rate under all conditions we simulated (Figure 3, 4). On the other hand, RP-SWME also defeats the other two incentive-compatible deterministic wagering mechanisms in expected money exchange under all conditions we simulated (Figure 3, 4). Meanwhile, it also outperforms DCA when the number of agents is small (Figure 3).
In particular, when the prediction follows the synthetic model, where the predictions are much closer to each other as the number of participants increases, the money exchange rate of the two incentive compatible deterministic wagering mechanisms, WSWM and NAWM converge to zero. However, the two randomized wagering mechanisms still keep a large money exchange rate (Figure 3c, 3f).

8.3 Comparison of randomness properties of RP-SWME and LWS

In this section, we compare the standard variance of payoffs and the probability of not losing money of RP-SWME and LWS. We evaluated these two metrics w.r.t. to the prediction accuracy, which is measured based on the distance of a prediction to the outcome, i.e., Accuracy = 1 − |\(x - p_i\)|.

In the evaluation, we run 10000 wagering instances under these two mechanisms and recorded the prediction accuracy of each agent in each instance and the corresponding net-payoff. Then, we group these agents into 10 groups that correspond to 10 consecutive accuracy intervals. In each group, we calculate the standard variance and the percent of agents winning money. For fair comparison, we normalize the net-payoff of each agent by its own wager.

We simulate binary events. We generate two set of simulated data. In both sets, we varied the number of agents from 2 to 50 with a set of 2, and under each number, we generated 10000 instances. In each instance, the agents’ predictions are drawn from the Uniform model, while the wagers are drawn from the Uniform model in one set and drawn from the Pareto model in the other set.

Our results show that under all conditions we simulate, RP-SWME has a much smaller variance in agents’ net-payoff and the variance is steady across agents with different prediction accuracy. In contrast, the LWS has a much larger variance in net-payoff, which increases with the prediction accuracy (Figure 5). On the other hand, RP-SWME has a much larger probability of not losing money and this probability increases with the prediction accuracy, while LWS has a much smaller such probability (Figure 6). In brief, while both RP-SWME and LWS can effectively improve the efficiency of wagering, RP-SWME provides much less uncertainty than LWS does and thus, may be regarded as a more attractive alternative for deterministic wagering mechanisms.

9 Conclusion

We extend the design of wagering mechanism to its randomized space. We propose two of them: Lottery Wagering Mechanisms (LWM) and Surrogate Wagering Mechanisms (SWM). We demonstrate the power of randomness by theoretically proving that they both satisfy a set of desirable properties, including Pareto efficiency which is missing in exiting wagering literature. We also carried out extensive experiments to support our theoretical findings. SWM is also robust to noisy outcomes, which makes it a preferred alternative in practice.

---

We use it as measurement of accuracy for two reasons: i. it is linear in prediction \(p_i\), ii. it has an inject to Brier Score
