Efficient uniform generation of random derangements with the expected distribution of cycle lengths

J. Ricardo G. Mendonça

Abstract
We show how to generate random derangements with the expected distribution of cycle lengths by two different techniques: random restricted transpositions and sequential importance sampling. The algorithms are simple to understand and implement and possess a performance comparable to or better than those of currently known methods. Our data suggest that the mixing time (in the total variance distance) of the algorithm based on random restricted transpositions is $O(n^a \log n^2)$ with $a \simeq \frac{1}{2}$ and $n$ the size of the derangement. For the sequential importance sampling algorithm we prove that it generates random derangements in $O(n)$ time with a small probability $O(1/n)$ of failing.

Keywords: Restricted permutation, permanent, random transposition walk, sequential importance sampling, mixing time

2010 MSC: 65C60, 68R05, 05A05

1. Introduction

Derangements are permutations $\sigma = \sigma_1 \cdots \sigma_n$ on $n \geq 2$ labels such that $\sigma_i \neq i$ for all $i = 1, \ldots, n$. Derangements are useful in a number of applications like in the testing of software branch instructions and random paths and data randomization and experimental design [4, 11, 24]. A well known algorithm to generate random derangements is Sattolo’s algorithm, that outputs a random cyclic derangement in $O(n)$ time [13, 21, 23, 27]. An $O(2n)$ algorithm to generate random derangements in general (not only cyclic derangements) has been given in [18, 20]. Algorithms to generate all $n$-derangements in lexicographic or Gray order have also been developed [2, 5, 15].

In this paper we propose two procedures to generate random derangements with the expected distribution of cycle lengths: one based on the randomization of derangements by random restricted transpositions (a random walk in the set of derangements) and the other based on a simple sequential importance sampling scheme. The generation of restricted permutations by means of sequential importance sampling methods is closely related with the problem of estimating the permanent of a matrix, an important problem in, e.g., graph theory, statistical mechanics, and experimental design [6, 7, 11]. Simulations show that the randomization algorithm samples a derangement uniformly in $O(n^a \log n^2)$ time, where $n$ is the size of the derangement and $a \simeq \frac{1}{2}$, while the sequential importance sampling algorithm does it in $O(n)$ time but with a small probability $O(1/n)$ of failing. The algorithms are straightforward to understand and implement and can be modified to perform related computations of interest in many areas.

2. Mathematical preliminaries

Let us briefly recapitulate some notation and terminology on permutations; for detailed accounts see [3, 8].

We denote a permutation of a set of $n \geq 2$ labels (an $n$-permutation), formally a bijection of $[n] = \{1, \ldots, n\} \subset \mathbb{N}$ onto itself, by $\sigma = \sigma_1 \cdots \sigma_n$, where $\sigma_i = \sigma(i)$. If $\sigma$ and $\pi$ are two $n$-permutations, their product is given by the

composition \( \sigma \pi = \sigma(\pi_1) \cdots \sigma(\pi_n) \). A cycle of length \( k \leq n \) in a \( n \)-permutation \( \sigma \) is a sequence of indices \( i_1, \ldots, i_k \) such that \( \sigma(i_1) = i_2, \ldots, \sigma(i_{k-1}) = i_k \), and \( \sigma(i_k) = i_1 \), completing the cycle. Fixed points are 1-cycles, transpositions are 2-cycles. An \( n \)-permutation with \( a_k \) cycles of length \( k \), \( 1 \leq k \leq n \), is said to be of type \((a_1, \ldots, a_n)\), with \( \sum_k ka_k = n \). For example, the 9-permutation 174326985 = (8)(6)(34)(2795)(1) has 5 cycles and is of type (3,1,0,1), where we have omitted the trailing \( a_9 = \cdots = a_0 = 0 \).

The number of \( n \)-permutations with \( k \) cycles is given by the unsigned Stirling number of the first kind \( s(n,k) \). Useful formulae involving these numbers are \( s(n,0) = 0 \), \( s(n,n) = 1 \), and the recursion relation \( s(n+1,k) = s(n,k-1) + ks(n,k) \). We have \( s(n,1) = 1 \), counting just the identity permutation \( id \), \( 1 \)-cycles. An \( n \)-permutation is a \( \pi \) such that \( \pi^{-1} \pi = id \). \( \pi \) is a \( \pi \)-cycle of length \( m \) if \( \pi \) has exactly \( m \) fixed points, that can be taken in \( \binom{n}{m} \) different ways, plus a transposition of the remaining two labels, and \( \binom{n}{1} \) is the \( k \)th harmonic number. Obviously, \( s(n,1) + \cdots + s(n,n) = n! \), the total number of \( n \)-permutations.

Let us denote the set of all \( n \)-derangements by \( D_n \). It is well known that
\[
d_n = |D_n| = n! \left( 1 - \frac{1}{1!} + \cdots + (-1)^n \frac{n^n}{n!} \right) = \left\lfloor \frac{n^n}{e} \right\rfloor, \quad n \geq 1,
\]
the so-called rencontres (or subfactorial, \( !n \)) numbers. Let us also denote the set of \( k \)-cycle \( n \)-derangements, irrespective of their type, by \( D_n^{(k)} \). Note that \( D_n^{(k)} = \emptyset \) for \( k > \lfloor n/2 \rfloor \). If we want to generate random \( n \)-derangements uniformly over \( D_n = D_n^{(1)} \cup \cdots \cup D_n^{(\lfloor n/2 \rfloor)} \), we must be able to generate \( k \)-cycle random \( n \)-derangements with probabilities
\[
P(\sigma \in D_n^{(k)}) = \frac{d_n^{(k)}}{d_n},
\]
where \( d_n^{(k)} = |D_n^{(k)}| \). The following proposition establishes the (little known, hard-to-find) cardinality of the sets \( D_n^{(k)} \).

**Proposition 2.1.** The cardinality of the set \( D_n^{(k)} \) is given by
\[
d_n^{(k)} = \sum_{j=0}^{k} (-1)^j \binom{n}{j} \binom{n-j}{k-j},
\]
(3)

**Proof.** The number of \( n \)-permutations with \( k \) cycles is \( s(n,k) \). Of these, \( n \binom{n-1}{k-1} \) have at least one fixed point, \( \binom{2}{k} \binom{n-2}{k-2} \) have at least two fixed points, and so on. Perusal of the inclusion-exclusion principle then furnishes the result.

**Proposition 2.2.** The numbers \( d_n^{(k)} \) obey the recursion relation
\[
d_n^{(k)} = n(d_n^{(k)} + d_{n-1}^{(k-1)}),
\]
with \( d_0^{(0)} = 1 \) and \( d_0^{(0)} = 0 \), \( n \geq 1 \).

Proposition 2.2 follows from (3) by index manipulations and the properties of the binomial coefficients and Stirling numbers of the first kind. The numbers \( d_n^{(k)} \) are sometimes called associated Stirling number of the first kind. Equation (4) generalizes the recursion relation \( d_{n+1} = n(d_n + d_{n-1}) \) for the rencontres numbers. Equation (3) recovers \( d_0^{(0)} = 0 \) and \( d_1^{(1)} = [\frac{n}{1}] = (n-1)! \) for \( n \geq 1 \), while we find that \( d_2^{(2)} = (n-1)!(H_{n-2} - 1) \) for \( n \geq 2 \). Another noteworthy identity, valid for \( n \) even, is \( d_n^{(n/2)} = (n/2 - 1)! \), the number of derangements \( \sigma \) with the property that \( \sigma^2 = id \), a.k.a. fixed-point-free involutions. We see that already for small \( n \) we have \( P(\sigma \in D_n^{(1)}) \approx e/n \) and \( P(\sigma \in D_n^{(2)}) \approx (H_{n-2} - 1)e/n \).

**Remark 2.3.** One can consider the distribution of \( n \)-derangements over possible cycle types (instead of cycle lengths) for a “finer” view of the distribution. The number of \( n \)-permutations of type \((a_1, \ldots, a_n)\) is given by Cauchy’s formula
\[
k_n(a_1, \ldots, a_n) = \frac{n!}{a_1! \cdots a_n!}.
\]
The analogue of (2) is given by \( P(\sigma \in K_n(0, a_1, \ldots, a_n)) = k_n(0, a_1, \ldots, a_n)/d_n \), where \( K_n(0, a_1, \ldots, a_n) \) is the conjugacy class formed by all \( n \)-permutations of type \((0, a_2, \ldots, a_n)\). For example, for cyclic derangements \( a_n = 1 \) and all other \( a_k = 0 \), and we obtain \( P(\sigma \in K_n(0, \ldots, 1)) = k_n(0, \ldots, 1)/d_n \approx e/n \), as before.
It is a classic result that data suggest that Algorithm T can generate a random pronounced. Figures for derangements of higher cycle number fluctuate more due to the finite size of the sample. The difference between attempting 2\(n\) random restricted transpositions there is a slight excess of probability mass in the \(n\)-derangement uniformly distributed over \(D_n\). By restricted transpositions we mean swaps \(\sigma_i \leftrightarrow \sigma_j\) avoiding pairs for which \(\sigma_i = j\) or \(\sigma_j = i\). Algorithm T describes the generation of random \(n\)-derangements according to this idea, where \(mix\) is a constant establishing the amount of random restricted transpositions to be attempted and \(rnd\) is a computer generated pseudorandom uniform deviate in \((0, 1)\).

Remark 3.1. Algorithm T is applicable only for \(n \geq 4\), since it is not possible to connect the even permutations 231 and 312 by a single transposition.

Our first approach to generate random \(n\)-derivations uniformly distributed over \(D_n\) consists in taking an initial \(n\)-derangement and to scramble it by random restricted transpositions enough to obtain a sample from the uniform distribution over \(D_n\). By restricted transpositions we mean swaps \(\sigma_i \leftrightarrow \sigma_j\) avoiding pairs for which \(\sigma_i = j\) or \(\sigma_j = i\). Algorithm T describes the generation of random \(n\)-derivations according to this idea, where \(mix\) is a constant establishing the amount of random restricted transpositions to be attempted and \(rnd\) is a computer generated pseudorandom uniform deviate in \((0, 1)\).

Remark 3.2. The minimum number of transpositions necessary to take a cyclic \(n\)-derangement into a \(k\)-cycle \(n\)-derangement is \(k - 1, 1 \leq k \leq \lceil n/2 \rceil\), since transpositions of labels that belong to the same cycle split it into two cycles,

\[
(ab)(i_1\cdots i_{a-1}i_ai_{a+1}\cdots i_{b-1}ib_{b+1}\cdots i_k) = (i_1\cdots i_{a-1}ib_{b+1}\cdots i_k)(i_{a+1}\cdots i_{b-1}ia) \tag{6}
\]

and, conversely, transpositions involving labels of different cycles join them into a single cycle. If Algorithm T is started with a cyclic derangement then one must set \(mix \geq n/2\).

We run Algorithm T for \(n = 64\) and different values of \(mix \geq n\) and collect data. Simulations were performed on Intel Xeon E5-1650 v3 processors running -03 compiler-optimized C code (GCC v. 5.4.0) over Linux kernel 4.15.0 at 3.50 GHz, while the numbers (3) were calculated on the software package Mathematica 11.3 [28]. We draw our pseudo-random numbers from Vigna’s superb xoshiro256+ generator [26]. Our results appear in Table 1. We see from that table that with \(mix = n\) random restricted transpositions there is a slight excess of probability mass in the lower \(k\)-cycle sets with \(k = 1, 2,\) and \(3\). Trying to scramble the initial \(n\)-derrangement by \(2n\) restricted transpositions performs better. The difference between attempting \(2n\) and \(n\log n\) random restricted transpositions is much less pronounced. Figures for derangements of higher cycle number fluctuate more due to the finite size of the sample. The data suggest that Algorithm T can generate a random \(n\)-derangement uniformly distributed on \(D_n\) with \(2n\) random restricted transpositions, employing \(4n\) psuedorandom numbers in the process. This is further discussed in Section 5.

Remark 3.3. It is a classic result that \(O(n\log n)\) transpositions are needed before a shuffle by unrestricted transpositions becomes “sufficiently random” [1, 10]. A similar analysis for random restricted transpositions over derangements is complicated by the fact that derangements do not form a group. Recently, the analysis of the spectral gap of

---

**Algorithm T** Random derangements by random restricted transpositions

**Require:** Initial cyclic \(n\)-derangement \(\sigma_1\sigma_2\cdots\sigma_n\)

1: \(mix \leftarrow\) number of restricted transpositions to attempt
2: \(\text{for } m = 1 \text{ to } mix \text{ do}\)
3: \(i \leftarrow [rnd \cdot n], j \leftarrow [rnd \cdot n]\)
4: \(\text{if } (\sigma_i \neq j) \land (\sigma_j \neq i) \text{ then}\)
5: \(\text{swap } \sigma_i \leftrightarrow \sigma_j\)
6: \(\text{end if}\)
7: \(\text{end for}\)

**Ensure:** For sufficiently large \(mix, \sigma_1\cdots\sigma_n\) is a random derangement uniformly distributed in \(D_n\)

3. Generating random derangements by random transpositions
the Markov transition kernel of the process provided the upper bound $m < Cn + an \log^2 n$, with $a > 0$ and $C \geq 0$ a decreasing function of $n$ [25]. This bound results from involved estimations and approximations and may not be very accurate. We are not aware of other rigorous results on this particular problem. Related results for the mixing time of the random transposition walk on permutations with “one-sided restrictions” ($\sigma_i \geq b_i$ for given $b_i \geq 1$) appear in [14].

### 4. Sequential importance sampling of derangements

#### 4.1. The SIS algorithm

Sequential importance sampling (SIS) is an importance sampling scheme with the sampling weights built up sequentially. The idea is particularly suited to sample composite objects $X = X_1 \cdots X_n$ from a complicated sample space $\mathcal{X}$ with many restrictions and for which the high-dimensional volume $|\mathcal{X}|$, from which the uniform distribution $P(X) = |\mathcal{X}|^{-1}$ follows, may not be easily calculable. However, since we can always write

$$P(X_1 \cdots X_n) = P(X_1)P(X_2 \mid X_1) \cdots P(X_n \mid X_1 \cdots X_{n-1}).$$

we can think of “telescoping” the sampling of $X$ by first sampling $X_1$, then use the updated information brought by the knowledge of $X_1$ to sample $X_2$ and so on. In Monte Carlo simulations, the right-hand side of (7) actually becomes $P_1(X_1)P_2(X_2 \mid X_1) \cdots P_n(X_n \mid X_1 \cdots X_{n-1})$, with the distributions $P_i(\cdot)$ estimated or inferred incrementally based on approximate weighting functions for the partial objects $X_1 \cdots X_{i-1}$.

Expositions of the SIS framework of interest to what follows appear in [9, 11].

Algorithm S describes a SIS algorithm to generate random derangements inspired by the analogous problem of sampling contingency tables with restrictions [9, 11] as well as by the problem of estimating the permanent of a matrix [16, 17, 22]. Our presentation of Algorithm S is not the most efficient for implementation; the auxiliary sets $I_i$, for instance, are not actually needed and were included only to facilitate the analysis of the algorithm, and the $n$ tests in line 4 can be reduced to a single test in the last pass, since all $I_i \neq \emptyset$ except perhaps $I_n$.

The distribution of cycle lengths in $10^{10}$ derangements generated by Algorithm S is presented in Table 1; there is excellent agreement between the data and the exact values.
4.2. Failure probability of the SIS algorithm

In the \(i\)th pass of the loop in Algorithm S, \(\sigma_i\) can pick (lines 5–6) one of either \(n-i\) or \(n-i+1\) labels, depending on whether label \(i\) has already been picked. This guarantees the construction of the \(n\)-derangement till the last but one element \(\sigma_{n-1}\). The \(n\)-derangement is completed only if the last remaining label is different from \(n\), such that \(\sigma_n\) does not pick \(n\). The probability that Algorithm S fails is thus given by

\[
\mathbb{P}(\sigma_n = n \mid \sigma_1 \cdots \sigma_{n-1}) = \mathbb{P}(\sigma_1 \neq n) \mathbb{P}(\sigma_2 \neq n \mid \sigma_1) \cdots \mathbb{P}(\sigma_{n-1} \neq n \mid \sigma_1 \cdots \sigma_{n-2}).
\]  

(8)

Now, according to Algorithm S, line 5, we have

\[
\mathbb{P}(\sigma_i \neq n \mid \sigma_1 \cdots \sigma_{i-1}) = 1 - \mathbb{P}(\sigma_i = n \mid \sigma_1 \cdots \sigma_{i-1}) = 1 - \frac{1}{\mathbb{E}(J_i \mid \sigma_1 \cdots \sigma_{i-1})},
\]  

(9)

where we write \(J_i\) for \(|J_i(\sigma_1 \cdots \sigma_{i-1})|\) in the argument of the expectation to improve readability, and the failure probability becomes

\[
\mathbb{P}(\sigma_n = n \mid \sigma_1 \cdots \sigma_{n-1}) = \prod_{i=1}^{n-1} \left( 1 - \frac{1}{E_i} \right).
\]  

(10)

where \(E_i\) stand for \(\mathbb{E}(J_i \mid \sigma_1 \cdots \sigma_{i-1})\). Expression (10) is but a probabilistic version of the inclusion-exclusion principle known as Poincaré’s formula in elementary probability.

The explicit computation of (10) is a cumbersome business, and we will not pursue it here. Otherwise, the following theorem establishes an easy upper bound on the failure probability of Algorithm S.

**Theorem 4.1.** Algorithm S fails with probability \(O(1/n)\).

**Proof.** Recall that in the \(i\)th pass of the loop in Algorithm S we have \(J_i = |J_i(\sigma_1 \cdots \sigma_{i-1})| = n-i\) or \(n-i+1\), such that the expectation \(E_i = \mathbb{E}(J_i \mid \sigma_1 \cdots \sigma_{i-1})\) obeys

\[
1 - \frac{1}{n-i} < \frac{1}{E_i} < 1 - \frac{1}{n-i+1}
\]  

(11)

and it immediately follows that

\[
\mathbb{P}(\sigma_n = n \mid \sigma_1 \cdots \sigma_{n-1}) = \prod_{i=1}^{n-1} \left( 1 - \frac{1}{E_i} \right) < \prod_{i=1}^{n-1} \left( 1 - \frac{1}{n-i+1} \right) = \frac{1}{n}.
\]  

(12)

\(\Box\)

**Remark 4.2.** In Appendix A we provide an improved upper bound to \(\mathbb{P}(\sigma_n = n \mid \sigma_1 \cdots \sigma_{n-1})\) based on an “independent sets” approximation that works remarkably well.
The measured failure rate for the SIS data in Table 1 is $1 - 0.985472 = 0.014528$, not far from $1/64 = 0.015625$. A sample of $10^4$ runs of Algorithm S of $10^6$ derangements each with $n = 64$ gives an average failure rate of 0.01453(12) with a sample minimum of 0.014130 and maximum of 0.014991, where the digits within parentheses indicate the uncertainty at one standard deviation in the corresponding last digits of the datum. Figure 1 depicts Monte Carlo data for the failure probability (10) against the upper bound $1/n$. Each data point was obtained as an average over $10^4$ runs of Algorithm S of $10^6$ derangements each except for $n = 512$, for which the runs are of $2 \times 10^5$ derangements each.

4.3. Uniformity of the SIS algorithm

In the SIS approach, the ensuing sampling probabilities may deviate considerably from the uniform distribution. An important aspect of Algorithm S is that it generates each $\sigma \in D_n$ with probability $1/d_n$, as the data in Table 1 suggest. We prove that this is indeed the case based on related results in [9, 16, 22].

**Definition 4.3.** We call the $n \times n$ matrix $A_n = (a_{ij})$ with 0 on the diagonal and 1 elsewhere the derangement matrix of order $n$.

The following well known property of $A_n$ clarifies its denomination and will be useful later.

**Lemma 4.4.** The permanent of $A_n$ is given by the $n$th rencontre number $d_n$.

**Proof.** The result is classic and we only outline its proof; for details consult [7]. The permanent of $A_n$ is given by

$$\text{per}A_n = \sum_{\sigma} \prod_{i=1}^{n} a_{i\sigma_i} = \sum_{i=1}^{n} a_{ij} \text{per}A_{n-1},$$

where the first sum is over all $n!$ permutations $\sigma$ of $[n]$ and the other sum is the Laplace (row) development of the permanent in terms of the submatrices $A_{n-1}^{(ij)}$ obtained from $A_n$ by deleting its $i$th row and $j$th column. Perusal of the Laplace development of per$A_n$ twice eventually leads to the recursion relation per$A_n = (n-1)(\text{per}A_{n-1} + \text{per}A_{n-2})$ with per$A_1 = 0$ and per$A_2 = 1$. But this is exactly the recursion relation for the rencontre numbers.

The next lemma elucidates the close relationship between the sets $J_i$ of Algorithm S and $A_n$.

**Lemma 4.5.** The product of the $E_i = \mathbb{E}(J_i \mid \sigma_1 \cdots \sigma_{i-1})$, $1 \leq i \leq n$, generated by Algorithm S is a one-sample unbiased estimator for per$A_n$.

**Proof.** We have to prove that $\mathbb{E}(E_1 \cdots E_n) = \mathbb{E}(E_1)\mathbb{E}(E_2 \mid \sigma_1) \cdots \mathbb{E}(E_n \mid \sigma_1 \cdots \sigma_{n-1}) = \text{per}A_n$. From Algorithm S, lines 3 and 7, it follows, with $J_i = [n] \setminus \{i, j_1, \ldots, j_{i-1}\}$ for some realization of $\{j_1, \ldots, j_{i-1}\}$, that

$$\mathbb{E}(J_i \mid \sigma_1 \cdots \sigma_{i-1}) = \sum_{j_i = 1}^{n} \mathbf{1}\{j_i \in J_i\} = \sum_{j_i \neq j_1, \ldots, j_{i-1}} \mathbf{1}\{j_i \in [n] \setminus \{i\}\},$$

Figure 1: Measured failure rate for Algorithm S against the upper bound $1/n$. Error bars in the data are much smaller than the symbols shown.
where \( \mathbb{I}\{P\} \) is the indicator function that equals 1 if \( P \) is true and 0 otherwise. Now if we write \( a_{ij} \) for \( \mathbb{I}\{j \in [n] \setminus \{i\}\} \) and multiply the expectations (14) we find that

\[
E(E_1 \cdots E_n) = \sum_{j_1} a_{1j_1} \cdots \sum_{j_n} a_{nj_n}.
\]  

Expression (15) is nothing but the expression for the permanent of a matrix with elements \( a_{ij} = 0 \) if \( j = i \) and 1 otherwise, that is, of the derangement matrix \( A_n \), and by Lemma 4.4 it follows that \( E(E_1 \cdots E_n) = \text{per} A_n \).

**Theorem 4.6.** Algorithm \( S \) samples \( D_n \) uniformly.

**Proof.** Algorithm \( S \) generates permutations \( \sigma \) with probability \( \mathbb{P}(\sigma) = \mathbb{P}(\sigma_1)\mathbb{P}(\sigma_2 | \sigma_1) \cdots \mathbb{P}(\sigma_n | \sigma_1 \cdots \sigma_{n-1}) \). Since

\[
\mathbb{P}(\sigma_i | \sigma_1 \cdots \sigma_{i-1}) = \frac{1}{E(J_i | \sigma_1 \cdots \sigma_{i-1})}
\]

we have

\[
\mathbb{P}(\sigma) = \frac{1}{E(J_1)} \frac{1}{E(J_2 | \sigma_1)} \cdots \frac{1}{E(J_n | \sigma_1 \cdots \sigma_{n-1})}.
\]

By Lemmas 4.4 and 4.5 the r.h.s. of (17) equals \( 1/\text{per} A_n = 1/d_n \), and we are golden.

5. Mixing time of the restricted transpositions shuffle

To shed some light on the question of how many random restricted transpositions are necessary to generate random derangements uniformly over \( D_n \), we investigate the convergence of Algorithm \( T \) numerically. This can be done by monitoring the evolution of the empirical probabilities along the run of the algorithm towards the exact probabilities given by (2).

Let \( \nu \) be the measure that puts mass \( \nu(k) = d_n^{(k)}/d_n \) on the set \( D_n^{(k)} \) and \( \mu_t \) be the empirical measure

\[
\mu_t(k) = \frac{1}{t} \sum_{i=1}^t \mathbb{I}\{\sigma_i \in D_n^{(k)}\},
\]

where \( \sigma_i \) is the derangement obtained after attempting \( s \) restricted transpositions by Algorithm \( T \) on a given initial derangement \( \sigma_0 \). The total variance distance between \( \mu_t \) and \( \nu \) is given by [1, 10]

\[
d_{TV}(t) = ||\mu_t - \nu||_{TV} = \frac{1}{2} \sum_{k=1}^{\lfloor n/2 \rfloor} |\mu_t(k) - \nu(k)|.
\]

The right-hand side of (19) can be seen as the “histogram distance” between \( \mu_t \) and \( \nu \) in the \( \ell_1 \) norm. Clearly, \( 0 \leq d_{TV}(t) \leq 1 \). This distance allows us to define \( t_{\text{mix}}(\varepsilon) \) as the time it takes for \( \mu_t \) to fall within distance \( \varepsilon \) of \( \nu \),

\[
t_{\text{mix}}(\varepsilon) = \min\{t \geq 0 : d_{TV}(t) < \varepsilon\}.
\]

It is usual to define the mixing time \( t_{\text{mix}} \) by setting \( \varepsilon = \frac{1}{2} \), or \( \varepsilon = \frac{1}{2} e^{-1} \approx 0.184 \), this last figure being reminiscent of the spectral analysis of Markov chains. We set \( \varepsilon = \frac{1}{2} e^{-1} \). This choice is motivated by the following pragmatic reasons:

(i) We want the derangements output by Algorithm \( T \) to be as uniformly distributed over \( D_n \) as possible, so the smaller the \( \varepsilon \) the better the assessment of the algorithm and the choice of the constant \( \text{mix} \);

(ii) Most of the probability mass is concentrated on a few cycle numbers (see Table 1 and Remark 5.1 below), such that even relatively small differences between \( \mu_t \) and \( \nu \) are likely to induce noticeable biases in the output of Algorithm \( T \);

(iii) With \( \varepsilon = \frac{1}{2} \), we found that \( t_{\text{mix}} < n/2 \), meaning that not even every possible derangement had chance to be generated if the initial derangement is cyclic (see Remark 3.2).
Remark 5.1. It is well known that the number of $k$-cycles of random $n$-permutations is Poisson distributed with mean $1/k$, such that as $n \rightarrow \infty$ the CLT implies that the length of the cycles of random permutations follow a normal distribution with mean $\log n$ and variance $\log n$; see, e.g., [3] and the references there in. [12] proved that the same holds for permutations with no cycles of length less than a given $\ell > 1$, using complex asymptotics of exponential generating functions; [18] and [20] provide the analysis for the particular case of derangements. Figure 2 displays the exact distribution of $k$-cycles for derangements with $n = 32768$ together with the normal density $N(\log n, \sqrt{\log n})$. For $n = 32768$ we obtain from equations (2)–(3) that $\langle k \rangle = 9.967 \cdots$ and $\sqrt{\langle k^2 \rangle - \langle k \rangle^2} = 2.872 \cdots$, while $\log n = 10.397 \cdots$ and $\sqrt{\log n} = 3.224 \cdots$. The distribution of cycle lengths in Figure 2 indeed looks close to a normal $N(\log n, \sqrt{\log n})$, albeit slightly skewed. We did not go to greater $n$ because Stirling numbers of the first kind are notoriously hard to compute even by computer algebra systems running on modern workstations. Recently, the cycle structure of certain types of restricted permutations (with $\sigma_i \geq i - 1$) was also shown to be asymptotically normal [19].

Starting with a cyclic derangement, i.e., with $\mu_0(1) = 1$ and all other $\mu_0(k) = 0$, we run Algorithm T and collect statistics on $d_{TV}(t)$. Figure 3 displays the average $\langle d_{TV}(t) \rangle$ over $10^6$ runs for $n = 128$. The behavior of $\langle d_{TV}(t) \rangle$ does not show sign of the cutoff phenomenon—a sharp transition from unmixed state ($d_{TV}(t_{mix} - \delta) \approx 1$) to mixed state ($d_{TV}(t_{mix} + \delta) \approx 0$) over a small window of time $\delta \ll t_{mix}$. Table 2 lists the average $\langle t_{mix} \rangle$ obtained over $10^6$ samples for larger derangements at $\epsilon = \frac{1}{4}e^{-1}$. An adjustment of the data to the form

$$t_{mix} = cn^{a} \log n^{2}$$

furnishes $a = 0.527(2)$ and $c = 0.90(1)$. Our data thus suggest that $t_{mix} \sim O(n^{a} \log n^{2})$ with $a = \frac{1}{2}$, roughly an $O(\sqrt{n})$ lower than the upper bound given by [25]. It is tempting to conjecture that $a = \frac{1}{2}$ (and, perhaps, that $c = 1$) exactly, cf. last two lines of Table 2, although our data do not support the case unequivocally.
6. Summary and conclusions

While simple rejection-sampling generates random derangements with an acceptance rate of \( \sim e^{-1} \approx 0.368 \), thus being \( O(e^{-n}) \) (plus the cost of verifying if the permutation generated is a derangement, which does not impact the complexity of the algorithm but impacts its runtime), Sattolo’s \( O(n) \) algorithm only generates cyclic derangements, and Martínez-Panholzer-Prodinger algorithm, with guaranteed uniformity, is \( 2n + O(\log^2 n) \), we described two procedures, Algorithms T and S, that are competitive for the efficient uniform generation of random derangements. We note in passing that Algorithm T can easily be used also to generate random fixed-point-free involutions.

We found, empirically, that \( O(n^4 \log n^2) \) random restricted transpositions with \( a \approx 0.5 \) suffice to spread an initial \( n \)-derangement over \( D_n \) uniformly. The fact that \( 2n > cn^4 \log n^2 \) for all \( n \geq 1 \) as long as \( a \leq 0.63 \) and \( c \leq 1 \) explains the good statistics (see Table 1) displayed by Algorithm T with \( \text{mix} = 2n \). There are currently very few analytical results on the mixing time of the random restricted transposition walk implemented by Algorithm T; the upper bound \( O(n \log n^2) \) obtained in [25] is roughly \( O(\sqrt{n}) \) above our empirical findings.

Algorithm T employs \( 2 \text{mix} \) pseudorandom numbers and Algorithm S employs \( O(n) \) pseudorandom numbers to generate an \( n \)-derangement uniformly distributed over \( D_n \). In this way, even if we set \( \text{mix} = c\sqrt{n} \log n^2 \) with some \( 1 < c \sim O(1) \), both algorithms perform better than currently known methods, with comparable runtime performances between them.

Acknowledgments

The author thanks Aaron Smith (U. Ottawa) for useful correspondence and suggestions on a previous version of the manuscript, the LPTMS for kind hospitality during a sabbatical leave in France, and FAPESP (Brazil) for partial support through grants nr. 2015/21580-0 and 2017/22166-9.

Appendix A. Improved upper bound for the failure probability of Algorithm S

In the \( i \)th pass of the loop in Algorithm S we have

\[
|J_i(\sigma_1 \cdots \sigma_{i-1})| = n - i + \sum_{j=1}^{i-1} \mathbb{I}(\{\sigma_j = i \mid \sigma_1, \ldots, \sigma_{j-1}\}).
\]

The difficulty in the calculation of \( E_i = \mathbb{E}(J_i \mid \sigma_1, \ldots, \sigma_{i-1}) \) resides in the calculation of \( \mathbb{E}(\{\sigma_j = i \mid \sigma_1, \ldots, \sigma_{j-1}\}) \).

We can simplify this calculation by ignoring the conditioning of the event (\( \sigma_j = i \)) on the event (\( \sigma_1, \ldots, \sigma_{j-1} \)), i.e., by ignoring correlations between the values assumed by the many \( \sigma_j \) along a “path” in the algorithm. This approximation is clearly better in the beginning of the construction of \( \sigma \), when \( j \) is small, than later. In doing so we obtain

\[
\mathbb{E}\left(\sum_{j=1}^{i-1} \mathbb{I}(\{\sigma_j = i \mid \sigma_1, \ldots, \sigma_{j-1}\})\right) = \sum_{j=1}^{i-1} \mathbb{E}(\{\sigma_j = i \mid \sigma_1, \ldots, \sigma_{j-1}\}) \approx \sum_{j=1}^{i-1} \mathbb{E}(\{\sigma_j = i\}) = \frac{i-1}{n-1}.
\]

Figure 3: Total variance distance \( \langle d TV(t) \rangle \) (averaged over 10^5 runs) between the empirical measure \( \mu_t \) (with \( \mu_0(1) = 1 \)) and the stationary measure \( \nu \) of the process defined by Algorithm T for \( n = 128 \). The dashed line indicates the level \( \epsilon = \frac{1}{2} e^{-1} \).
such that $E_i \approx n - i + \frac{i-1}{n-1}$. This approximate $E_i$ is greater than the true $E_i$, because conditioning $J_i$ on $\sigma_1 \cdots \sigma_{i-1}$ can only restrict, not enlarge, the set of indices available to $\sigma_i$. Numerical evidence supports this claim. We thus have that the approximate value of $1 - \frac{1}{E_i}$ is greater than its true value, and the failure probability (10) becomes bounded by

$$
P(\sigma_n = n \mid \sigma_1 \cdots \sigma_{n-1}) < \prod_{i=1}^{n-1} \left(1 - \frac{1}{n - i + \frac{i-1}{n-1}}\right) = \frac{1}{n-1} \prod_{i=1}^{n-1} \left[1 + \frac{1}{(n-2)(n-i)}\right]^{-1}.
$$

(A.3)

The surprisingly excellent agreement between this upper bound and the Monte Carlo data can be appreciated in Figure A.4; compare with Figure 1. Note how the data lie only very slightly below the upper bound (A.3).

Figure A.4: Measured failure rate for Algorithm S against the upper bound (A.3). Error bars in the data are much smaller than the symbols shown.
