Abstract—The Third Generation Partnership Project (3GPP) released its first 5G security specifications in March 2018. This paper reviews the 5G security architecture, requirements and main processes and evaluates them in the context of known and new protocol exploits. Although the security has been enhanced when compared to previous generations, our analysis identifies some unrealistic system assumptions that are critical for security as well as a number protocol edge cases that render 5G systems vulnerable to adversarial attacks. For example, null encryption and null authentication are supported and can be used in valid system configurations and certain key security functions are still left outside of the scope of the specifications. Moreover, the entire 5G security architecture relies on the assumption of impractical carrier and roaming agreements and the management of public keys from all global operators. As a result, existing threats such as International Mobile Subscriber Identity (IMSI) catchers are prevented only if the serving network enforces optional security features and if the UE knows the public key of every single network operator. The comparison with 4G LTE protocol exploits reveals that the 5G security specifications, as of Release 15, do not fully address the user privacy and network availability concerns, where one edge case can compromise the privacy, security and availability of 5G users and services.

Keywords—Security, 5G, 3GPP Release 15, LTE

I. INTRODUCTION

The Third Generation Partnership Project published its fifteenth release of the mobile communication system specifications in March 2018, setting the foundations for the 5th generation of mobile communication (5G). With ground breaking upgrades at the radio layer, the New Radio (NR) standard implements an advanced physical layer that supports millimeter wave communications and antenna arrays for massive multiple-input, multiple-output (MIMO) systems [1]. In parallel, the core network (5GC) has been redesigned for enhanced flexibility and service versatility. The goal of 5G networks is to support a higher capacity, higher data rates, reduced latency, and massive device connectivity to enable the tactile Internet, augmented and virtual reality, and smart connected vehicles [2].

As with its preceding generations—2G, 3G and the 4G Long Term Evolution (LTE)—, security is of capital importance for 5G communication networks and services. Mobile systems provide connectivity to billions of civilians all over the world. Moreover, cellular communication networks are the connectivity cornerstone for current and emerging critical infrastructure, including the smart grid, first responder units, and advanced military ad-hoc networks. The advent of 5G will enable new networks and applications, including next generation vehicular networks for assisted and autonomous driving and smart cities and communities [3].

Motivated by the inherent security weaknesses of legacy 2G networks, such as the lack of mutual authentication between the network and the user equipment (UE), security has been one of the key design considerations for mobile communications. LTE implements strong encryption and integrity protection algorithms, backed with a mutual authentication system based on symmetric keys that are securely stored in the Universal Subscriber Identification Module (USIM), or SIM, and the operator’s Home Subscriber Server (HSS) [4]. Nevertheless, security research over the recent years identified a series of vulnerabilities inherent to the LTE protocol. For example, a substantial number of pre-authentication messages are sent in the clear and this can be exploited to launch Denial of Service (DoS) attacks and obtain location information of mobile subscribers from their UEs [5–7].

The first release of the LTE specifications, Release 8, was published in 2007. The main security vulnerabilities were not identified and reported in open literature until much later. One of the reasons for this was the lack of available and affordable tools for LTE security research. LTE software libraries running on personal computers and using commercial off-the-shelf software-defined radio peripherals did not reach a sufficient level of maturity until recent years. Once they became available, though, a wave of excellent security research in the area of LTE mobile communications emerged and identified numerous protocol vulnerabilities [8, 9].

As for LTE, security is a key consideration and core aspect for the definition and specification of 5G networks. Since the inception of the communication protocols for NR and 5GC, there has been a substantial effort in addressing the known LTE protocol exploits, with particular focus on preventing International Mobile Subscriber Identifier (IMSI) catchers or Stingrays [10]. As a result, the 5G protocol introduces the
concept of the Subscriber Permanent Identifier (SUPI) and Subscriber Concealed Identifier (SUCI) [4]. More importantly, the 5G specifications introduce a security architecture that is based on a Public Key Infrastructure (PKI) and allows verifying and authenticating control plane messages that originate at the 5GC.

Despite the efforts to design a secure architecture for 5G, there is still a number of insecure protocol edge cases. These can be exploited by an adversary to both deny the service to subscribers as well as intercept sensitive user information. Moreover, the 5G protocol specifications are based on arguably unrealistic assumptions that could likely result in an insecure network configuration. Specifically, the cornerstone of 5G security is the presence of the operator’s public key in the SIM card. Full security against protocol exploits is only achievable under the assumption that all SIMs in all mobile devices have the public keys of all operators in the world. In addition, all operators must keep the corresponding private key well secured. Not only is the key management and rotation unfeasible and left outside the standard specifications, but political and operator disagreements would most likely result in the lack of global adoption of the key distribution mechanism. Insecure protocol implementation and IMSI catching can be the consequences.

This paper presents a thorough analysis of the current 5G protocol security specifications [11]. As part of this study, protocol vulnerabilities are identified and contextualized, analyzing the potential security threats. The requirements and assumptions for 5G security are discussed, with specific focus on global adoption and the resulting consequences. The paper analyzes the architecture and procedures for the radio access network security; a corresponding analysis of the 5GC security is beyond the scope of this study.

The remainder of this manuscript is organized as follows. Section II provides an overview of the 5G security architecture and components. Section III discusses the main 5G security requirements and procedures of the 3GPP Release 15 specifications. Section IV provides a detailed analysis of the main security challenges of the proposed 5G specifications, highlighting the potential risk of protocol exploits and sensitive information leaks. The security vulnerabilities are then contextualized within the known LTE protocol exploits in Section V. Finally, Section VI summarizes our findings and proposes research directions to tackle the identified security vulnerabilities of the current 5G specifications.

II. OVERVIEW OF THE 5G SECURITY ARCHITECTURE

The 5G security architecture spans across the UE, radio access network, core network and application [11]. The architecture is correspondingly organized into an application stratum, a serving stratum, and a transport stratum. Figure 1 shows a simplified diagram of the serving stratum and the transport stratum. Different security features are defined across the network and end user components, which combined create a secure system design:

- Network access security (I): Set of features and mechanisms that enable a UE to authenticate and securely access network services.
- Network domain security (II): A set of features that enable core network nodes to securely exchange signaling data and user plane data.
- User domain security (III): A set of features that secure the user access to mobile equipment and mobile services.
- Service-Based Architecture (SBA) domain security (IV): A set of features in the SBA domain, including network element registration, discovery, and authorization, as well as protection for the service-based interfaces.
- Visibility and configurability of security (not shown in I): A set of features that enable users to be informed whether a security feature is in operation or to configure security features.

The 5G specifications define a number of network functions and their interfaces, enabling the data flow between the radio access network (RAN), core network (CN), and external networks. Figure 2 illustrates a simplified 5G reference network architecture. The 5G network functions and security features specify a flexible, yet secure design for developing 5G mobile communication systems.

Table I describes some important 3GPP network concepts and components that are used for defining and analyzing the 5G security architecture, requirements and procedures in the remainder of this paper.
### TABLE I
3GPP ACRONYMS AND CONCEPTS.

<table>
<thead>
<tr>
<th>Acronym</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>5G-GUTI</td>
<td>5G Global Unique Temporary Identifier, used for limiting the signaling of the SUPI for security purposes.</td>

### III. MAIN 3GPP 5G SECURITY REQUIREMENTS AND PROCEDURES

The 5G security architecture is constructed on the basis of defining a series of security requirements, features and procedures [11], which we summarize in continuation. Table II captures the main security requirements and the corresponding procedures for the 5G RAN. This table highlights, in italics, some of the requirements and procedures that can lead to security vulnerabilities. These security vulnerabilities and their potential impacts are further discussed in subsequent sections.

#### A. Key Framework

The 5G security procedures are built on top of a hierarchical key derivation, distribution, and management framework. Keys are stored in a number of network entities. The long term key $K$ is stored by the ARPF of the UDM layer, with the USIM holding the user corresponding copy of that symmetric key. All other keys are derived from it. The key generation and distribution is detailed in [11] and omitted here.
<table>
<thead>
<tr>
<th>Scope</th>
<th>Security requirements</th>
<th>Procedures</th>
</tr>
</thead>
</table>
| General | • Mitigation of bidding down attacks.  
| | • Mutual authentication.  
| | • UE, access and serving network authorization.  
| | • Allowance for unauthenticated emergency services. | Authentication procedures using EAP-AKA and 5G AKA authentication methods. |
| UE and gNB | • User and signaling data confidentiality protection through cyphering. gNB triggered, considering UE security capabilities and SN’s list of security capabilities. Null encryption supported. Confidentiality protection optional to use.  
| | • User and signaling data integrity and replay protection. gNB triggered, considering UE security capabilities and SN’s list of security capabilities. Null integrity protection supported. Integrity protection of user data optional to use. RRC and NAS signaling protection mandatory, but exceptions exists, including unauthenticated emergency sessions. | Key derivation, distribution and agreements from a key hierarchy, supporting 128 bit key and 256 bit key encryption. For every key in a network entity, there is a corresponding key in the UE, with the root key stored in the USIM. |
| UE | • Secure storage and processing of subscription credentials using a tamper resistant secure hardware component.  
| | • Subscriber privacy through use of temporary and concealed subscriber identities (5G-GUTI and SUPI). Null-scheme supported and shall be used when public key not provisioned by home network, which controls subscriber privacy and the provisioning and updating of keys. | If provisioned by the home operator, the USIM shall store the home network public key used for concealing the SUPI. |
| gNB | • Authorized setup and configuration by O&M through certificates, the use of which is optional.  
| | • Key management, optional for the 5G PKI-based architecture.  
| | • Secure environments for keys, UP and CP data storage and processing. | Authentication and key derivation may be initiated by the network as often as the operator decides when an active NAS connection exists. |

B. Authentication and Home Control

3GPP establishes EAP-AKA (EAP for AKA) and 5G AKA as the authentication methods that must be supported by both 5G UEs and the 5GC. These security modes are used for mutual authentication and subsequent service security and encryption procedures. 5G UEs use the secure 5G-GUTI, or SUCI, in their registration requests to initiate the authentication process using the method they select. When EAP-AKA is used, the UE acts as the peer, while the 5GC SEAF and AUSF act as the pass-through and back-end authentication servers, respectively. 5G AKA enhances EPS AKA [4] by providing the home network with proof of successful authentication of the UE from the visited network.

Increased home control is considered useful for preventing certain types of frauds. The proposed 5G framework supports implementing such procedures, but they are considered beyond the scope of the standards specifications: the actions taken by the home network to link authentication confirmation (or the lack thereof) to subsequent procedures are subject to operator policy and are not standardized [11]. As for a number of other security procedures, the abundance of functions left out of the scope of the protocol specifications can result in insecure edge cases.

C. Security Contexts

The 5G security specifications define a number of security contexts for different scenarios: a single 5G serving network, across multiple serving networks, and between 5G and EPS networks. When a UE is registered with two serving networks, both networks must independently maintain and use a separate security context. When the UE is registered to two serving networks in the same public land mobile network (PLMN), 3GPP and non-3GPP, the UE establishes two independent NAS plane connections with those networks, but uses a common NAS security context consisting of a single set of keys and security algorithms.

D. State Transition and Mobility

Procedures for maintaining or disregarding a security context during state transition and handover are also defined, to some extent, in [11]. The specifications state that it is up to the
operator’s policy how to configure the selection of handover types. This decision is a function of the operator’s security requirements, thus leaving the security during handovers as an opt-in feature instead of enforcing it through the standard. This could result in a number of operators implementing potentially insecure handover procedures.

E. Non-Access Stratum

Cryptographic separation and replay protection of two active NAS connections is supported through a common NAS security context, which has parameters that are specific to each NAS connection. NAS uses 128-bit ciphering algorithms for integrity and confidentiality protection. Note that both null encryption and null integrity protection are supported. If the UE has no NAS security context, the initial NAS message is sent in the clear and contains the subscription identifier (e.g. SUCI or GUTIs) and UE security capabilities, among others.

F. Radio Resource Control

The RRC integrity and confidentiality protection is provided by the packet data convergence protocol (PDCP) layer between UE and gNB and no layers below PDCP shall be integrity protected. Replay protection shall be activated when integrity protection is activated, except when the selected integrity protection algorithm is NIA0 (null integrity protection). RRC integrity checks are performed both in the ME and the gNB. In case where a failed integrity check is detected after the start of the integrity protection, the concerned message shall be discarded.

G. User Plane

The SMF shall provide UP security policy for a protocol data unit (PDU) session to the gNB during the PDU session establishment procedure. If UP integrity protection is not activated for data radio bearers (DRBs), the gNB and the UE shall not integrity protect the traffic of such DRB. If UP ciphering is not activated for DRBs, the gNB and the UE shall not cipher the traffic of such DRB. The local SMF can override the confidentiality option in the UP security policy received from the home SMF.

H. Subscription ID Privacy

The SUCI is the concealed version of the 5G permanent subscription identifier SUPI. It is transmitted over the air to prevent exposing the SUPI. The SUCI is constructed from the SUPI using the operator’s public key. The null protection scheme is used for unauthenticated emergency sessions, when so configured by the home network, or when the operator public key has not been provisioned.

The 5G specifications also define a temporary identifier, the 5G-GUTI, to minimize the exposure of the SUPI/SUCI. 5G-GUTI is to be reassigned based on UE triggers. It is left to the implementation to determine the rate of 5G-GUTI reassignment.

IV. Security Challenges and Potential Vulnerabilities in 5G

As introduced in Sections [11] and [12], 5G mobile networks implement a security architecture similar to that of LTE systems, with the key difference in how trust and security is established. Pre-5G communication systems base all security functions on symmetric keys that are securely stored both in the SIM and the HSS. Based on the shared secret key $k_s$, a 4G UE can authenticate the network and the network can authenticate the UE. The encryption and integrity protecting keys are derived from $k_s$ [4]. This basic symmetric key security architecture results in the inability of a communication endpoint, the UE, to verify the authenticity and validity of any message exchanged prior to the NAS Attach cryptographic handshake. This is widely acknowledged as the root cause of most known LTE protocol exploits [6], [7], [12].

The 5G security architecture is proposed to tackle the challenge of pre-authentication messages and render IMSI catchers ineffective in the context of 5G communications. By introducing the concept of operator public keys and certificates, 5G systems provide the tools for establishing a root of trust between the end user and the mobile operator under the umbrella of the 5G PKI architecture. Leveraging the public keys and certificates burned into the SIM card, operators can craft and sign messages with their corresponding secret key and these messages can be validated by a UE. In addition, 5G UEs are able to identify themselves without the need of ever disclosing the SUPI in the clear.

This new security framework and architecture is considered fundamental for securing emerging 5G mobile networks. However, an in-depth analysis of the security architecture highlights a number of remaining security weaknesses that need to be addressed. Table III identifies some of the 5G security challenges, their root causes and impacts. For any communication protocol, including LTE, independently of how strong a security architecture is and how sophisticated its cryptographic algorithms are, it only takes one single edge case or insecure function, to defeat the entire system. For example, although in LTE the IMSI should only be sent in the clear the very first time a mobile phone is switched on, there is a use case in which the network can request, via a pre-authentication message, that the UE identifies itself using its IMSI.

The 5G security infrastructure is only resilient if there is full global compliance. This requires that operators manage loading in each SIM a public key or certificate for every other operator in every country, without exception. It is more likely, however, that some operators will not opt-in to implement all 5G security features or not implement them rigorously based on the fact that most practical details of the implementation of the 5G PKI are left explicitly outside of the scope of 3GPP TR 33.899 [11]. Moreover, it is also anticipated that some countries will ban the certificates from certain other countries or operators, something that is already being observed [13]. As such, a global adoption and rigorous implementation of the
<table>

</tbody>
</table>

5G security features and procedures is highly unlikely.

Since a SIM will not have public keys or certificates for all mobile operators and countries, a UE/operator has two choices: (1) explicitly block any missing operator/country and deal with the resulting public relations and media coverage consequences, or (2) allow this edge case that would defeat all security procedures. The 5G security specifications adopt option (2), explicitly stating that the subscriber identity will not be protected if the serving network is not provisioned for the user’s USIM (see Table II, UE row). It is important to note that this implies that IMSI/SUPI catching in 5G would still be likely possible.

Moreover, in addition to the challenges of effectively operating a complex PKI, researchers are already finding weaknesses of the cryptographic operations defined in [11]. The authors of [14] use formal verification tools to analyze the 5G AKA algorithms and demonstrate that the protocol fails in meeting several security goals, which are explicitly required. The study also shows that the 5G protocol lacks other critical security properties. These findings put pressure on 5G. Unlike in the case of LTE, where most security research and resulting protocol weaknesses were identified once the protocol was defined, implemented and globally deployed, the security research community is moving fast with 5G and can identify weaknesses as the specifications are written.

V. IMPACT OF LTE PROTOCOL EXPLOITS ON 5G

The LTE security architecture was designed to address the challenges of previous generations. The first generation of mobile networks (1G) lacked support for encryption and this was one of the main drivers for the introduction of 2G digital mobile communications. Legacy 2G networks do not support mutual authentication and use an encryption algorithm that is outdated [15]. Security weaknesses of mobile communication systems have been widely investigated using open-source implementations of both the base station and the UE protocol stacks. LTE implements specific functionalities to guarantee the confidentiality and authenticity of mobile networks and messages, using much stronger cryptographic algorithms and explicit mutual authentication between the UE and the eNodeB. This makes 4G LTE inherently more secure than prior generations.

Nevertheless, LTE is vulnerable and the existence of LTE protocol vulnerabilities has been known for some time, although these have not been publicly discussed until recently. The openness of the standard, the large community of researchers, and the availability of SDR software libraries enabled a number of excellent LTE security analyses [5], [9], [17]–[19]. Despite the stronger cryptographic algorithms and mutual authentication, UEs and base stations exchange a substantial amount of pre-authentication messages that can be exploited to launch denial of service (DoS) attacks [12], [20], catch IMSIs [21] or downgrade the connection to an insecure GSM link [6], [7], [19]. Researchers also found new privacy and location leaks in LTE [22]. Table IV summarizes some of the major LTE protocol exploits that were identified over the past few years and discusses how these could impact 5G networks.

Most of the LTE protocol security vulnerabilities were studied and dissected by the security working group of 3GPP [23]. As a result from that study, specific security goals for 5G mobile networks were set to address the problem of IMSI catchers, pre-authentication messages and location leaks. Device and user tracking leveraging the Radio Network Temporary Identifier (RNTI) [22] are not considered because RNTIs are claimed to be short lived IDs that cannot be leveraged for privacy leaks. Recent research however demonstrated that the RNTI can be used to track subscribers [5].

The LTE protocol specifications also show vulnerable edge cases that, despite being rarely executed, are still supported by the protocol. For example, although it is very unlikely that a UE would ever transmit an Attach Request message using its IMSI as the identifier, the protocol describes specific scenarios in which this would occur. For example, when recovering from a network error where the EPC has lost the UE’s TMSI. In this case, the network can trigger the mobile device to re-transmit the Attach Request message with its IMSI in the clear [24]. In a nutshell, most active LTE protocol exploits occur because of
a combination of the protocol supporting insecure edge cases and the implicit trust UEs have before a secure connection can be established [6].

Similarly, and as discussed in this paper, the 5G specifications define certain security features motivated by the challenges observed in previous generations. Despite the proposed security features being highly sophisticated and robust against adversary attacks, the 5G protocol specifications still include a number of supported edge cases that facilitate bypassing all security functions. As discussed in Section [V], it takes only one operator or country not adhering to the specifications for all 5G UEs to be susceptible to being tricked into an insecure communication mode.

The 5G security specifications leave out most details of the implementation of most security features [11]. For example, all aspects of the key management for operator public keys residing in the subscribers’ USIMs are left out of the scope of the specifications, as well as the structure of the certificate and how or whether keys are ever rotated. In addition, the lawful interception requirement imposed on mobile communication networks, enabled by the support for null encryption and null integrity protection, result in insecure modes of communication, which can be exploited as demonstrated for LTE.

VI. CONCLUSIONS AND RESEARCH DIRECTIONS

Wireless communication security has always been of critical importance and will be more so as technology evolves to 5G. Traditionally used for mostly non-critical voice communication, many of the current and emerging data and control communication systems that leverage cellular access networks have stringent requirements in terms of integrity and privacy of user data. Applications include tactical communication, first responder ad-hoc networks, and mission-critical IoT.

This paper provides a critical analysis of the recently published 5G security specifications. It highlights a number of insecure edge cases and limitations that result from infeasible requirements. Despite aiming at addressing the known security vulnerabilities of LTE networks, the 5G specifications are still potentially vulnerable to the same types of adversarial attacks.

It is most critical to ensure that no insecure corner cases are supported by the 5G standard. In particular, null authentication, null encryption, downgrading attacks, and IMSI/SUPI catching, shall not be facilitated in any mode of operation. The success of such security mechanisms should not rely on infeasible requirements or optional implementations. While the 5G security architecture made a substantial leap in the right direction with the proposed PKI and efforts in preventing privacy leaks, security research and development is still necessary to fully address the known and new security vulnerabilities of mobile communication systems. Standardization bodies, researchers, regulators, and industry all need to work together to accomplish a securer design, development and deployment of emerging and future mobile communication and control systems.

NOTE

This manuscript is currently under submission. We are gathering feedback for this pre-print and from the paper submission reviewers. All feedback and comments will be incorporated in the final version, which will clarify a few details of our analysis of the 5G security specifications.
