We study the problem of a single hole in a Néel antiferromagnet and, using the magnon expansion and analytical methods, calculate the expansion coefficients of its wave function in the magnon basis. In a one-dimensional (1D) case, i.e., once the string potential is absent, the hole is “weakly” localized in a potential well, and the magnon coefficients decay exponentially. This behavior is in sharp contrast to the two-dimensional (2D) case for which the hole is subject to a string potential and is “strongly” localized with the coefficients decaying superexponentially. Thus, the superexponential decay of the wave function coefficients is a fingerprint of the existence of strings in doped antiferromagnets that can be recognized in the numerical or cold atom simulations of the 2D doped Hubbard model. Finally, the exact 1D result is only obtained once the magnon-magnon interactions are correctly included. Thus, we also unravel the crucial role played by the magnon-magnon interactions both in 1D and 2D models and in the understanding of the large qualitative difference between the weak and strong localization seen in the 1D and 2D spectral functions for a hole in a Néel antiferromagnet, as well as the quantitative correction of the 2D strings by magnon-magnon interaction.

PACS numbers: xxxx

A tendency towards particle delocalization is an ubiquitous phenomenon in quantum mechanics, for it is encoded in the Heisenberg uncertainty principle for momentum and position operators. Perhaps one of its most iconic examples is the so-called particle penetration under a potential barrier: even if the energy of the particle is below the potential amplitude, there exists a finite probability to find a particle outside the potential well. Yet, the particle wave function decays exponentially with an increasing distance from the potential well and the particle is considered localized. As an important feature, the potential acts here only locally and does not increase with the distance. This will be called “weak localization” in what follows.

The fact that a particle can go under a potential barrier has tremendous implications for the electron wave functions typically found in crystals. It allows for an electron tunneling under the potential barrier: even if the energy of the particle is below the potential amplitude, there exists a finite probability to find the particle outside the potential well. Yet, the particle wave function decays exponentially with an increasing distance from the potential well and the particle is considered localized. As an important feature, the potential acts here only locally and does not increase with the distance. This will be called “weak localization” in what follows.

Nevertheless, localization of electrons in crystals is possible. For instance, this can happen in the Mott insulators—crystals for which strong electron-electron interactions decide about electron localization. The Mott localization is still not fully-understood and is an area of active research—both for an integer filling, as well as in the doped case. This lack of a complete understanding of the problem is largely due to the fact that the most widely-used models describing the problem (e.g., two-dimensional (2D) Hubbard or t–J21,22 models) cannot be solved exactly and the wave function of an electron in a Mott insulator is not known in general.

Therefore, here we concentrate on one of the simplest, though still nontrivial and realistic,23 interacting electron problems—the half-filled t–Jz model4 with one extra hole added. Using an improved version of the recently developed magnon expansion (ME) method and analytic calculations, we unambiguously show that a single hole: (i) is in general “strongly” localized in the ground state and its wave-function coefficients decay superexponentially, i.e., much faster than in the textbook case of a single potential well, (ii) experiences “weak” localization, i.e., has the wave-function coefficients decaying exponentially, when not only the system dimensionality is lowered but also certain crucial interactions present in the system are included. The latter counter-intuitive result means that lowering dimensionality and adding interactions may in fact remove “strong localization” in favor of “weak localization” in a strongly correlated system.

MODEL AND METHODS

The Hamiltonian of the t–Jz model reads:

\[ H = -t \sum_{\langle ij \rangle \sigma} (\hat{c}_i^{\dagger} \hat{c}_j + H.c.) + J \sum_{\langle ij \rangle} (S_i^z S_j^z - 1/4) \tilde{n}_i \tilde{n}_j, \]  

where \( \tilde{n}_i = \sum_{\sigma}\hat{c}_i^{\dagger} \hat{c}_{i\sigma} \). It describes the constrained hopping of fermions \( \propto t \), in the restricted Hilbert space.
The energy cost of a single excited bond with the disruption of the AF background by the moving hole (blue square) which creates magnon excitations (red circles). As in the half-filled limit (i.e., one electron localized at each site). As in the half-filled case, the ground state of the model (1) is a Néel antiferromagnet; the problem studied here is that of a single hole introduced into the half-filled limit (i.e., the eigenstates of the Hamiltonian (1) for the case of a single hole localized at each site). As in the half-filled case, the ground state of the model (1) is a Néel antiferromagnet; the problem studied here is that of a single hole localized at each site.

The method used in the paper requires first to express the above model in the magnon language. To this end, the magnons are introduced here by means of the Holstein-Primakoff transformation which maps interacting spins on a boson problem, $S_i^z = \pm (\frac{1}{2} - n_i)$, $S_i^\pm = \sqrt{1 - n_i} b_i$, $S_i^z = b_i^\dagger b_i^\downarrow$. Here $n_i = b_i^\dagger b_i$, $b_i^\dagger$ is a magnon creation operator, and the sign $\pm$ alternates between the AF sublattices in the Néel antiferromagnet. At the same time, removing a spin generates a hole: for $\uparrow$-sublattice, $\tilde{c}_i^\uparrow = h_i^\dagger$, but removing an inverted spin also requires its realignment $\tilde{c}_i^\downarrow = h_i^\dagger S_i^z$; complementary operations generate a hole at $\downarrow$-sublattice. Crucially, the maximal number of bosons and holes has to be limited to maximally one at each site $i$ (constraint $C1$).

As a result, we get an exact representation of the $t$–$J_z$ model in the magnon language for $\alpha = 1$,

$$H = t \sum_{\langle ij \rangle} \left[ h_i^\dagger h_j \left( b_j^\dagger + b_j^\downarrow \right) \right] + H.c.$$

$$+ \frac{1}{2} J \sum_{\langle ij \rangle} \mathcal{P}_j \left( -1 + n_i + n_j - 2 \alpha n_i n_j \right) \mathcal{P}_i, \tag{2}$$

where $\mathcal{P}_i = 1 - h_i^\dagger h_i$. This ensures that the terms $\propto J$ are present only on bonds without holes in the $t$–$J_z$ model (constraint $C2$). Here the aforementioned constraint $C1$ is implicitly imposed, allowing us to omit the square roots in the hopping part $\propto t$. Most importantly, the last term in (2) is the only magnon-magnon interaction (at $\alpha = 1$) in this Hamiltonian—a constant term active only if two magnons (i.e., inverted spins) are present on the bond $\langle ij \rangle$. It is precisely this term which is neglected in the well-known linear spin wave (LSW) theory (at $\alpha = 0$).

FIG. 1. Probabilities $\{P_n\}$ of observing $n$ magnons in the ground state of single hole wave function as calculated using the ME method for different values of $J/t$ in the $t$–$J$ model in the 1D case (a1) and (b1) without magnon-magnon interactions, and the 2D case (c1) with and (d1) without magnon-magnon interactions. In (a1) [(b1)] the curves are obtained analytically (see text); in (c1) [(d1)] the curves are fits to the numerical results (points) assuming the same functional dependence as in (b1), cf. 32. The cartoons, (a2)–(d2), illustrate the differences between these four cases and show the energy cost $E$ associated with the disruption of the AF background by the moving hole (blue square) which creates magnon excitations (red circles).

The energy cost of a single excited bond $E = J/2$ is represented by a single red segment.

without double occupancies, i.e., $c^\dagger_{i\sigma} = c^\dagger_{i\sigma} (1 - n_{i\sigma})$, along bond $\langle ij \rangle$, and the exchange $\propto J > 0$ between the $z$ components of the $S = 1/2$ spins of the localized $c$-electrons. In what follows we study the properties of the eigenstates of the Hamiltonian (1) for the case of a single hole introduced into the half-filled limit (i.e., one electron localized at each site). As in the half-filled case, the ground state of the model (1) is a Néel antiferromagnet; the problem studied here is that of a propagation of a single hole in a Néel antiferromagnet.

The main numerical method, the ME, is a novel technique of solving the polaronic models, in the Green’s function formalism, through the expansion of the equations of motion. It has been successfully applied to several polaronic problems, including spin, orbital, and spin-orbital polarons. The central idea is that the relevant processes are limited to the hole’s neighborhood. Thus, one can perform the expansion in real space and

RESULTS

The central object that is calculated in this paper is the probability distribution \( \{ P_n \} \) of observing \( n \) magnons in the wave function for a hole doped into the \( \text{Néel} \) antiferromagnet. This is achieved by calculating the coefficients of the expansion of the ground state wave function of the half-filled \( t-J_z \) model (1) with a single added hole in the above-explained ‘magnon language’ basis using the ME method in the numerically converged case, which requires keeping up to ca. 100 bosons in the calculations.

The results, obtained for the one-dimensional (1D) chain and 2D square lattice, as well as for the case where the magnon-magnon interactions are either included (\( \alpha = 1 \)) or neglected (\( \alpha = 0 \)), are presented in Figs. 1(a1)–1(d1). We observe that, irrespectively of the value of the spin exchange \( J \), the functional dependence is always the same in all but one case: the probabilities \( \{ P_n \} \) decay superexponentially with the growing number of magnons \( n \). It is only in the 1D case, and even there only once the problem is treated exactly, i.e., the magnon interactions are properly included, that this decay is qualitatively weaker and becomes merely exponential.

This qualitative difference between the 1D case with interacting magnons and all of the other cases is further elucidated by the analytic calculations which are in perfect agreement with the above 1D numerical results. This is because in the 1D case we are able to derive an exact analytic form of \( P_n \). In the case of the full 1D model (1) we obtain an exponential decay of the probabilities,

\[
P_n = A \exp(-n/l),
\]

with \( A \) and \( l \) given in (2), see Fig. 1(b1). However, once the magnon-magnon interactions are neglected in the 1D chain, a superexponential decay is observed,

\[
P_n = B \left( J \frac{1}{2} - \frac{\omega_0}{n} + 2t/J \right)^2 
\]

\[
\simeq B \left( t/J \right)^n \Gamma^{-1} \left( \frac{1}{2} - \varepsilon_{gs} + n + 1 \right)^2,
\]

see Fig. 1(a1). (Here \( J \) is the Bessel function of the first kind and the explicit equations for the constants \( B, \varepsilon_{gs} \) are given in (2).) Crucially, however, the latter superexponential decay is also found by fitting to the 2D numerical results, both with and without magnon interactions [see Figs. 1(d1) and 1(c1)]. This confirms that the 2D case behaves similarly to the 1D case without magnon-magnon interactions, as already observed above.

DISCUSSION

Let us now try to gain some intuitive understanding of the results presented above. It turns out that this can be rather easily achieved by looking at the cartoon figures, showing the hole propagation in a \( \text{Néel} \) antiferromagnet in all four studied cases, see Fig. 1(a2)–(d2). Let us first concentrate on probably the easiest case, i.e., on the 1D model without magnon-magnon interactions (\( \alpha = 0 \) or the LSW case), cf. Fig. 1(a2). Here, a single hole hop to the nearest-neighbor site \((i+2)\) generates a boson at site \((i+1)\) and thus \( n_{i+1} = 1 \). Since after the previous step also \( n_i = 1 \), the term \( J(n_{i+1} + n_i)/2 \) in (2) increases the energy of this state by \( J \) once magnon interactions are absent. Therefore, not only the further the hole moves the more magnons are created, but also an energy cost \( \omega_0 \equiv J \) is paid after creating each magnon according to the LSW theory, while there is no mechanism to reduce energy due to magnons arising on the hole’s path. The well-known linear string potential found in the 2D case is clearly observed here, see Fig. 1(a2). Crucially, such a phenomenon is absent once the magnon-magnon interactions are turned on in 1D [cf. Fig. 1(b2)]: in that case, even though the hole creates magnons at each step of its motion, there is no energy cost associated with this process as the \(-\alpha J n_{i+1} n_i \) term in the \( t-J_z \) Hamiltonian (2) cancels completely the energy cost in LSW after creating all but the first magnon. This shows why the magnon-magnon interactions play such a unique role in the 1D case.

The above simple understanding changes substantially in the 2D case. Here the magnon-magnon interactions are no longer qualitatively relevant, since, unlike in 1D case, the energy associated with creating a magnon during hole motion cannot be canceled completely by the magnon-magnon interactions, see Fig. 1(c2)–(d2). This shows that the string-like picture is valid in the 2D model even when the magnon interactions are included—in agreement with Ref. 31.

Optical lattice experiments

The recent optical lattice experiments, as well as numerical simulations of the 2D doped Hubbard model, reported on the histograms of the lengths of strings of misaligned spins in the ground state wave function. As this quantity can be reliably approximated by the aforementioned probability distribution \( \{ P_n \} \), this means that a detailed study of the functional form of such histograms can be used to verify to what extent the hole is localized in the 2D Hubbard model.

On the other hand, as already stated, this work allows us to formulate a condition for the observation of a linear string potential in the ground state wave function for a hole in an antiferromagnet: Its coefficients in the “magnon language” basis (i.e., \( \{ P_n \} \)) need to decay superexponentially. Therefore, we can conclude that, if
the above-mentioned histograms observed in the optical lattice experiments: (i) showed a superexponential decay with the growing string length \(l\), then this would strongly indicate that a linear string potential is indeed present in the 2D doped Hubbard model; (ii) showed merely an exponential decay, then the presence of a linear string potential would be ruled out.\(^{51}\)

While the latest optical lattice experiments\(^{46–48}\) still show too few data points to unambiguously conclude whether the observed dependence is exponential or superexponential, we suggest that future optical lattice experiments might be capable of delivering more conclusive data.

**Spectral functions**

The above calculations show how the ground state properties of the \(t-J_z\) model depend on the dimensionality of the problem as well as on the inclusion of the magnon-magnon interactions. This has implications primarily for the optical lattice experiments. However, also the excited states are affected in a somewhat similar manner and this has implications for the understanding of the spectral function \(A(k, \omega)\) of a number of correlated compounds (see below).

Thus, we start by defining the spectral function \(A(k, \omega)\) in the usual way,

\[
A(k, \omega) = -\frac{1}{\pi} \Im G(k, \omega + i\delta),
\]

where \(G(k, \omega) = \langle \Phi_0 | \hat{c}_k^\dagger (\omega - \mathcal{H} + E_0)^{-1} \hat{c}_k | \Phi_0 \rangle\) is the momentum dependent Green’s function (the spin index \(\sigma\) can be suppressed here), and \(|\Phi_0\rangle\) is the ground state of (1) in the half-filled limit (Néel antiferromagnet) with energy \(E_0\).

As the spectral function is calculated using the ME method, we first need to express it in the magnon language—it turns out then that the constrained electron Green’s function transforms into the hole Green’s function, \(G_\delta(k, \omega) = \langle \Phi_0 | \hat{h}_k^\dagger (\omega - H + E_0)^{-1} \hat{h}_k | \Phi_0 \rangle\).

In 1D chain the spectral function \(A(\omega)\) is always momentum-independent, but as the results obtained using the ME method show, its form depends crucially on the inclusion of the magnon-magnon interactions, see Fig. 2(a). If these interactions are included, it consists of a single dispersionless \(\delta\)-like peak at low energy, which indicates a quasiparticle-like state with infinite mass (a bound state), accompanied by an incoherent spectrum at higher energies. On the other hand, when this interaction is switched off in the LSW approach [by putting \(\alpha = 0\) in (2)], the calculated 1D spectral function is ladder-like, suggesting that the string-like potential builds up\(^{24,28,29,31}\), see Fig. 2(a). The latter demonstrates how a particular 1D antiferromagnetic problem can be described in the “magnon language”—a problem complementary to the application of the “spinon language”\(^{20,22}\) to magnons in the 2D non-frustrated antiferromagnet\(^{25–27}\).

![FIG. 2. Spectral function \(A(\omega)\) of a single hole in the 1D \(t-J_z\) model with \((\alpha = 1)\) and without \((\alpha = 0)\) magnon-magnon interactions calculated using: (a) the ME method, (b) the analytically exact or SCBA approach. Parameters: \(J = 0.4t\), broadening \(\delta = 0.05t\); the bound state at the low-energy onset of \(A(\omega)\) splits off from the continuum at larger \(J/t\) (lower \(\delta\)).](image)

First, this striking difference between the 1D spectral function with / without magnon-magnon interactions is also recovered using other methods. Taking advantage of an exact analytical result for the \(t-J_z\) model obtained in the spinon language and using the continued fractions\(^\text{35,36}\), we obtain the *same* spectrum as that of the full model in the ME method, see Fig. 2(b). This shows that the exact result can also be recovered using the magnon language—provided that the magnon interactions are taken into account.\(^{55}\)

Second, a ladder-like solution is obtained when the widely-used self-consistent Born approximation (SCBA) method\(^{24}\) is applied to the polaronic model with the magnon-magnon interactions switched off, see Fig. 2(b). Interestingly, this spectrum differs a bit with respect to the one obtained using the ME method, the reason for this being that the above-mentioned constraints \(C1\) and \(C2\) are typically implicitly neglected in the SCBA method (but are automatically taken into account in the ME method). Thus, by comparing with the well-known 1D result\(^{55}\) obtained in the “spinon language” we have shown that one spinon corresponds here to an infinite number of magnons, suggesting why the LSW theory fails.
FIG. 3. Spectral function $A(k, \omega)$ (5) of a single hole in the 2D $t$-$J_z$ model with ($\alpha = 1$) and without ($\alpha = 0$) magnon-magnon interactions calculated using: (a) the ME method, (b) the SCBA approach following Ref. 31. All parameters as in Fig. 2 and $k \equiv \Gamma = (0, 0)$.

A radically different situation occurs in the 2D case, as evident from the spectral functions calculated within the ME, see Fig. 3(a). Here, irrespectively of whether the magnon-magnon interactions are included or not, the spectrum is ladder-like, suggesting that the string-like potential [24–29,31–34] develops always in the 2D model. Note that, on a qualitative level, this result can also be obtained by implementing the SCBA equations derived in Ref. 31, with the main difference between the two methods attributed to the fact that the vertex corrections are neglected by definition within the SCBA (note that the vertex corrections vanish in one dimension and hence we did not need to discuss them above).

It is remarkable that the distances between neighboring maxima found in the ladder spectrum in SCBA are lower when magnon-magnon interactions are present, see Fig. 3(b), which indicates that the string potential grows then in a slower way with increasing distance. This is indeed confirmed by a slower superexponential decrease of the wave function coefficients $\{P_n\}$, cf. Figs. 1(c1) and 1(d1). Thus we conclude that the SCBA contains a systematic error which is cured by including magnon-magnon interactions. The spectrum found in the ME is not reproduced as the constraints $C1kC2$ are absent. Also in the spectra obtained from the ME maxima appear more frequently when magnon-magnon interactions are included, see Fig. 3(a).

One might ask if the physics related to the spectral functions studied above is observable. There exists a number of compounds which can possibly be modeled by the $t$–$J_z$ Hamiltonian—these are predominantly the 1D Ising-like antiferromagnetic chains of BaCo$_2$V$_2$O$_8$ [56–58] and SrCo$_2$V$_2$O$_8$ [59], the 2D ferromagnets with alternating orbital order found in K$_2$CuF$_4$ [41] and Cs$_2$AgF$_4$ [43], and maybe even partially the high-$T_c$ cuprates [60]. Thus, we expect that the angle resolved photoemission spectra (ARPES) obtained on these crystals should be qualitatively similar to the spectra shown in Figs. 2–3 (once the magnon-magnon interactions are included). This, however, could have already been predicted using the existing results reporting the spectral functions of the 1D [35,36] and 2D [24–29,31–34] $t$–$J_z$ model. A far more interesting consequence of the spectral function study is merely theoretical: it shows that the qualitative differences between the 1D and 2D spectral functions originates solely in the different role played by the magnon-magnon interactions in the 1D and 2D models.

CONCLUSIONS

We showed that a single hole is “strongly” localized in a 2D Néel antiferromagnet, for its coefficients in the magnon language basis decay superexponentially. It is then only in the 1D case and when the interactions between magnons are correctly included that a “weak” localization sets in—the coefficients decay exponentially—just as in the textbook example of a particle in a potential well. This result has two important consequences. First, on the pragmatic side, it may serve as a fingerprint of the existence of a (long sought-after) linear string potential in the doped 2D antiferromagnets, that can be observed in the recent optical lattice simulations [49,50] of the 2D doped Hubbard model. Second, on the more abstract level, the use of the magnon language not only in 2D but also in 1D model allows us to understand the (well-known) qualitative differences between the 1D and 2D spectral functions for a single hole in a Néel antiferromagnet and attribute them to the crucial role played by the magnon-magnon interactions in one dimension.

Finally, we point out that the present distinction between “weak” and “strong” localization of a hole in the $t$–$J_z$ model is reminiscent of weak [61] and strong [62,63] localization in quantum disordered systems on a lattice. In contrast to the quantum disorder, in the present strongly correlated system “weak” localization occurs only in one dimension when magnons are destroyed on the hole path. A smooth crossover from diffusive electron motion to perfect electron localization with increasing amplitude of disorder is replaced here by the first order quantum phase transition from “weak” to “strong” localization when magnon-magnon interaction...
is switched off and string potential develops. Therefore, the paradigm that all electrons are strongly localized in a Mott insulator applies only beyond one dimension.

SUPPLEMENTAL MATERIAL

In what follows we derive explicit formulae for the probabilities \( \{ P_n \} \) of observing \( n \) magnons in the single hole ground state of the \( t-J_z \) model on the Bethe lattice. This result will be later applied to the case of the one-dimensional (1D) chain and to obtain an approximate formula for the \( P_n \) on a two-dimensional (2D) square lattice.

We start by choosing the basis, \( \beta = \{|n\} \), where \( n \in \mathbb{N} \), and \( |n\) denotes a normalized sum of states with \( n \) magnons in a chain connecting the hole with a site at which the hole was created. In this basis the matrix of the \( t-J_z \) Hamiltonian \( \mathcal{H} \) for both interacting and non-interacting magnons becomes tridiagonal,

\[
\mathcal{M}(\mathcal{H}) = \begin{bmatrix}
    a_1 & b_1 & 0 & 0 & \cdots \\
    b_1 & a_2 & b_2 & 0 & \cdots \\
    0 & b_2 & a_3 & b_3 & \cdots \\
    \vdots & \vdots & \ddots & \ddots & \ddots 
\end{bmatrix}.
\]

Using the Gaussian elimination procedure for a finite matrix and taking the limit \( n \to \infty \), one can reduce the equation for the coefficients \( v_n \) of the ground state vector \( \vec{v} \) corresponding to the ground state energy \( \varepsilon_{\text{GS}} \),

\[
\mathcal{M}(\mathcal{H} - \varepsilon_{\text{GS}} I) \vec{v} = 0,
\]

into a recurrence relation,

\[
v_n = \begin{cases} 
    v_0 & \text{if } n = 0, \\
    -c_n v_{n-1} & \text{if } n > 0, 
\end{cases}
\]

\[
c_n = \frac{b_n}{a_{n+1} - b_{n+1} c_{n+1}}. \tag{9}
\]

For the case of the matrix of the 1D \( t-J_z \) Hamiltonian \( \mathcal{H} \) with the magnon-magnon interactions included, calculated with respect to the energy \( E_0 \) of the half-filled system, we have \( a_1 = J, a_2 = a_3 = \ldots = \frac{3}{2} J, b_1 = -t\sqrt{2}, b_2 = b_3 = \ldots = -t \), so the recurrence relation simplifies to

\[
v_n = \begin{cases} 
    v_0 & \text{if } n = 0, \\
    -c_1 v_0 & \text{if } n = 1, \\
    -c_2 v_{n-1} & \text{if } n > 1, 
\end{cases}
\]

where \( c_1 = (\varepsilon_{\text{GS}} - J)/t\sqrt{2} \) and \( c_2 = c_1/\sqrt{2} \). Normalization of the vector \( \vec{v} \) requires \( |v_0|^2 \) to be equal to the residue of the Green’s function at the quasiparticle energy \( \varepsilon_{\text{GS}} \), i.e.,

\[
|v_0|^2 = z_{-1} = \lim_{\omega \to \varepsilon_{\text{GS}}} (\omega - \varepsilon_{\text{GS}}) G(\omega) = \frac{J}{\sqrt{J^2 + 16t^2}}. \tag{11}
\]

Finally, we obtain analytical expressions for the probability \( P_n \) of finding \( n \) magnons in the single hole ground
state,

\[ P_n = \begin{cases} |v_0|^2 = \frac{j}{\sqrt{j^2 + 16\varepsilon^2}} & \text{if } n = 0, \\ 2|c_2|^{2n}|v_0|^2 = \frac{2j}{\sqrt{j^2 + 16\varepsilon^2}} \left( \frac{j - \sqrt{j^2 + 16\varepsilon^2}}{4\varepsilon} \right)^{2n} & \text{if } n > 0. \end{cases} \]  

(12)

The above geometric progression can also be expressed in terms of the exponential function,

\[ P_{n>0} = A \exp \left( -\frac{n}{T} \right), \]  

(13)

where \( A = 2|v_0|^2 \) and \( T^{-1} = 2\ln(|c_2|) \).

For the case where the interactions between magnons are neglected \((\alpha = 0)\), the coefficients of the matrix become \( a_1 = J, \ a_{n>1} = (n - \frac{1}{2})J, \ b_1 = -t\sqrt{2}, \ b_2 = b_3 = \ldots = -t \). Therefore, the recurrence relation cannot be simplified but one can express the coefficients \( c_n \) as continued fractions which, due to the linear dependence appearing on the diagonal, can be further expressed in terms of the Bessel functions of the first kind \(\text{J}_n\),

\[ c_{n>1} = \frac{b_2}{a_2 - \frac{b_2}{a_3 - \ldots}} = -\frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+} + n}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+} + n}}(\frac{2\varepsilon}{T})}, \]  

(14)

\[ c_1 = \frac{b_1}{a_1 - b_2c_2} = -\frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})} \sqrt{2}. \]  

(15)

The ground state energy \( \varepsilon_{gs} \) must satisfy the relation, \( \varepsilon_{gs} - J = \Sigma(\varepsilon_{gs}) \), with

\[ \Sigma(\omega) = -2\frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})}. \]  

(16)

Similarly to the interacting case the normalization of the ground state vector is given by the value of the residue of the non-interacting Green’s function at the pole \( \omega = \varepsilon_{gs} \),

\[ |v_0|^2 = \lim_{\omega \to \varepsilon_{gs}} \frac{1}{1 - \frac{j^2}{4\varepsilon^4} \Sigma(\omega)}. \]  

(17)

Here, neither \( \varepsilon_{gs} \) nor \( |v_0|^2 \) are given explicitly in the non-interacting case but given an expression for \( \Sigma(\omega) \) one can calculate them numerically. Finally, using the recurrence relation for \( v_n \), most of the Bessel functions cancel out which leads to a simple formula for the probability \( P_n \) of finding \( n \) magnons in the single hole ground state,

\[ P_n = \begin{cases} |v_0|^2 \quad & \text{if } n = 0, \\ 2|v_0|^2 \left( \frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+} + n}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})} \right)^2 & \text{if } n > 0. \end{cases} \]  

(18)

Furthermore, for \( 0 < x < \sqrt{n+1} \) the Bessel functions can be expanded, leading to

\[ J_n(2x) \simeq \frac{1}{\Gamma(n+1)} \left( \frac{x}{2} \right)^n, \]  

(19)

so for large \( n \) the string length probabilities can be approximated as

\[ P_n \simeq B \left[ \frac{1}{\Gamma\left(\frac{3}{2} - \frac{\omega}{\omega_p^{+} + n}\right)} \left( \frac{t}{J} \right)^n \right], \]  

(20)

where

\[ B = \frac{2|v_0|^2}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})}. \]  

(21)

In the case of a 2D square lattice, one can try to fit similar functions to the data obtained from the ME calculations assuming the same functional dependence as the one calculated for the Bethe lattice with coordination number \( z = 4 \). In this way we obtain the formulae for the 2D case, with \( \epsilon \) and \( z \) as the fitting parameters. For interacting magnons these read

\[ P_n = \begin{cases} |v_0|^2 \quad & \text{if } n = 0, \\ \frac{1}{3} |v_0|^2 \left( \frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+} + n}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})} \right)^2 & \text{if } n > 0. \end{cases} \]  

(22)

and for the non-interacting case,

\[ P_n = \begin{cases} \frac{1}{3} |v_0|^2 \quad & \text{if } n = 0, \\ \frac{1}{3} |v_0|^2 \left( \frac{\text{J}_{2 - \frac{\omega}{\omega_p^{+} + n}}(\frac{2\varepsilon}{T})}{\text{J}_{2 - \frac{\omega}{\omega_p^{+}}}(\frac{2\varepsilon}{T})} \right)^2 & \text{if } n > 0. \end{cases} \]  

(23)

where the value of \( |v_0|^2 \) is taken as the data point corresponding to the pure hole state with no magnons.
