Abstract

Weighted bipolar argumentation frameworks determine the strength of arguments based on an initial weight and the strength of their attackers and supporters. They find applications in decision support and social media analysis. Mossakowski and Neuhaus recently introduced a unification of different models and gave sufficient conditions for convergence and divergence in cyclic graphs. We build up on this work, incorporate additional models and extend results in several directions. In particular, we explain that the convergence guarantees can be seen as special cases of the contraction principle. We use this observation to unify and to generalize results and add runtime guarantees. Unfortunately, we find that guarantees obtained in this way are bought at the expense of open-mindedness, that is, the ability to move strength values away from the initial weights. However, we also demonstrate that divergence problems can be solved without giving up open-mindedness by continuizing the models. Finally, we integrate the Duality property that assures a symmetric impact of attack and support relations into the framework by Mossakowski and Neuhaus.

1 Introduction

Abstract argumentation (Dung 1995) allows modeling arguments and their relationships in order to decide which arguments should be accepted and which should be rejected. We focus on weighted bipolar argumentation frameworks here that start with an initial weight of arguments and adapt this weight based on the strength of their attackers and supporters (Baroni et al. 2015; Rago et al. 2016; Amgoud and Ben-Naim 2017; Mossakowski and Neuhaus 2018; Potyka 2018). These frameworks can be applied to tasks like decision support (Baroni et al. 2013; Rago et al. 2016), social media analysis (Leite and Martins 2011; Alsinet et al. 2017) or information retrieval (Thiel et al. 2017). Initial weights can be defined manually based on the reputation of arguments’ sources or computed automatically based on statistics like the number of likes or retweets of an argument. Sentiment analysis tools can be used to extract attack and support relations automatically as well.

Mossakowski and Neuhaus recently introduced an elegant unification of different approaches by decomposing their semantics into an aggregation function that aggregates the strength of attackers and supporters and an influence function that adapts the initial weight based on the aggregate (Mossakowski and Neuhaus 2018). Different aggregation and influence function yield different semantics from the literature and axioms proposed in (Amgoud and Ben-Naim 2016a; Amgoud and Ben-Naim 2016b; Amgoud and Ben-Naim 2017) can be guaranteed by demanding simple properties of these functions. (Mossakowski and Neuhaus 2018) also provided first sufficient conditions for the convergence of bipolar weighted argumentation models in cyclic graphs. They gave convergence results for sum- and max-based aggregation functions and influence functions whose derivatives can be bounded. As we will show, these results can be seen as special cases of the Contraction Principle from Real Analysis (Rudin 1976) and can be generalized in a uniform way by replacing the differentiability condition from (Mossakowski and Neuhaus 2018) with Lipschitz continuity. While this is not a weaker condition in general, it is actually satisfied by all functions considered in (Mossakowski and Neuhaus 2018) and allows to generalize the convergence results to non-differentiable influence functions and more general aggregation functions like the product considered for the QuAD algorithms in (Baroni et al. 2015; Rago et al. 2016).

However, we also show that these convergence guarantees are bought at the expense of open-mindedness. That is, as the convergence guarantees of a semantics obtained from the contraction principle get stronger, its ability to change the initial weights get weaker. We also give some new divergence examples based on a family of graphs from (Mossakowski and Neuhaus 2018). We find that continuizing the models as proposed in (Potyka 2018) solves the divergence problems.

Before closing the paper, we integrate the recently introduced Duality property (Potyka 2018) into the framework by Mossakowski and Neuhaus.

2 BAGs and Modular Semantics

We consider weighted bipolar argumentation graphs (BAGs) as considered in (Amgoud and Ben-Naim 2017) and (Mossakowski and Neuhaus 2018).

Definition 1 (BAG). A BAG is a tuple $\mathcal{A} = (\mathcal{A}, w, R, S)$, where $\mathcal{A}$ is an $n$-dimensional vector of arguments, $w \in [0, 1]^n$ is a weight vector and $R$ and $S$ are binary relations on $\mathcal{A}$ called attack and support.
The parent vector \( g_i \in \{-1, 0, 1\}^n \) of argument \( A_i \) is the vector with entries \( g_{ij} = -1\) (1) iff \( A_i \not\subseteq A_j \). We visualize BAGs by means of directed graphs, where nodes show the arguments with their initial weights, solid edges denote attacks and dashed edges denote supports. The indegree of \( A_i \), defined as indegree\( (A_i) = \sum_{j=1}^n |g_{ij}| \), is the number of attackers and supporters of \( A_i \).

**Example 1.** Figure 1 shows the directed graph for the BAG \( \{(a, b, c), (0.6, 0.9, 0.4), \{(a, b), (a, c), \{(b, c), (c, b)\}\} \). The parent vector of \( b \) is \( g_2 = (-1, 0, 1) \) and shows that \( b \) is attacked by \( a \) and supported by \( c \). Hence, indegree\( (b) = 2 \).

Given a BAG \( A \), we want to compute strength values for every argument. This can be accomplished by means of different acceptability semantics (Amgoud and Ben-Naim 2017). Following (Mossakowski and Neuhaus 2018), we regard acceptability semantics as partial functions in order to take account of divergence problems.

**Definition 2 (Acceptability Semantics).** An acceptability semantics is a partial function \( \text{Deg}_S \) that maps a BAG \( A = (A, w, R, S) \) with \( n \) arguments to an \( n \)-dimensional vector \( \text{Deg}_S(A) \in [0, 1]^n \). We call the \( i \)-th component \( \text{Deg}_S(A)_i \), the final strength or acceptability degree of \( A_i \).

A modular acceptability semantics as introduced in (Mossakowski and Neuhaus 2018) is an acceptability semantics that works by first aggregating the strength of attackers and supporters and then adapting the initial weight based on the aggregated value. This is accomplished by an aggregation and an influence function, which satisfy some additional properties that guarantee that axioms from (Amgoud and Ben-Naim 2017) are satisfied. While all properties are interesting from a semantic perspective, only a subset is relevant for convergence investigations. We restrict to such a subset in order to keep the presentation simple.

The aggregation and influence function in (Mossakowski and Neuhaus 2018) were supposed to be continuous. We make a stronger assumption here and assume that they are Lipschitz-continuous. Intuitively, this means that the growth of these functions is bounded by a constant. Lipschitz-continuity is also implied by the convergence conditions in (Mossakowski and Neuhaus 2018). Formally, a function \( f : X \rightarrow Y \) is called Lipschitz-continuous with Lipschitz constant \( \lambda \) iff \( \|f(x) - f(y)\| \leq \lambda \|x - y\| \). The sets \( X \) and \( Y \) will contain real numbers, vectors or matrices here. We consider the maximum norm for matrices defined by \( \|A\| = \max\{\sum_{j=1}^n |a_{ij}| \mid 1 \leq i \leq n \} \) for an \( m \times n \)-matrix \( A = (a_{ij}) \). That is, \( \|A\| \) is the largest absolute row sum in \( A \). For the special case that \( x \in \mathbb{R}^n \) is a vector (an \( n \times 1 \)-matrix), \( \|x\| \) is the largest absolute value in \( x \). Using the maximum norm simplifies the investigation, but does not mean any loss of generality because all norms are equivalent in \( \mathbb{R}^n \) (the difference between two norms can be bounded by a constant factor).

The aggregation function requires information about the attackers and supporters, the influence function requires information about the initial weight. In (Mossakowski and Neuhaus 2018), this information has been given as an additional argument. We regard this information as parameters of the function to make the notation a little less cumbersome. We also have to express that the aggregation function depends only on the parents. As discussed in (Mossakowski and Neuhaus 2018), this demand corresponds to the directionality property in (Amgoud and Ben-Naim 2017). In order to phrase directionality, we define an equivalence relation for every (parent) vector \( g \in \{-1, 0, 1\}^n \). Two (strength) vectors \( s_1, s_2 \) are called equivalent with respect to a parent vector \( g \), written as \( s_1 \equiv_g s_2 \) iff \( s_{1,i} = s_{2,i} \) whenever \( g_i \neq 0 \). That is, the strength vectors must be equal at all parent indices. In the following, for a function \( f \), we let \( f^k \) denote the function that is obtained by applying \( f \) \( k \) times, that is, \( f^1 = f \) and \( f^{k+1} = f^k \circ f \).

**Definition 3 (Basic Modular Semantics).** A semantics \( \text{Deg}_S \) is called a basic modular semantics if there exists

1. an aggregation function \( \alpha_g : [0, 1]^n \rightarrow \mathbb{R} \) such that for all parent parameters \( g \in \{-1, 0, 1\}^n \)
   - \( \alpha_g(s_1) = \alpha_g(s_2) \) whenever \( s_1 \equiv_g s_2 \), (Directionality)
   - \( \alpha_g \) is Lipschitz-continuous, (Lipschitz-\( \alpha \))
   - \( \alpha_g(s) = 0 \) whenever \( g = 0 \), (Stability-\( \alpha \))
2. an influence function \( \iota_w : \mathbb{R} \rightarrow [0, 1] \) such that for all weight parameters \( w \in \mathbb{R} \)
   - \( \iota_w \) is Lipschitz-continuous, (Lipschitz-\( \iota \))
   - \( \iota_w(0) = w \) (Stability-\( \iota \))

and for all BAGs \( A = (A, w, R, S) \), we have

\[
\text{Deg}_S(A) = \lim_{k \rightarrow \infty} f^k_S(w).
\]

where \( f_S : [0, 1]^n \rightarrow [0, 1]^n \) is defined by \( f_i = \iota_{w_i} \circ \alpha_{g_i} \) for all \( i = 1, \ldots, n \) and is called the update function of \( \text{Deg}_S \).

In practice, for the \( i \)-th argument \( A_i \), its parent vector \( g_i \) serves as the parameter of \( \alpha_{g_i} \) and its initial weight \( w_i \) serves as the weight parameter for \( \iota_{w_i} \). Stability-\( \alpha \) and Stability-\( \iota \) assure that the final strength of an argument without parents will just be its initial weight. This corresponds to the stability property from (Amgoud and Ben-Naim 2017).

Intuitively, modular semantics compute strength values iteratively. They start with the initial strength vector \( s^{(0)} = w \). Then, in the \( k \)-th step, the strength of argument \( s^{(k)} \) is computed by first applying the aggregation function to \( s^{(k-1)} \) and then applying the influence function to \( \alpha_{g_i}(s^{(k-1)}) \). That is, \( s_i^{(k)} = \iota_{w_i}(\alpha_{g_i}(s^{(k-1)})) \) for \( k > 0 \).

Table 1 shows some examples for different aggregation and influence functions from the literature. More examples can be found in (Mossakowski and Neuhaus 2018).

**Proposition 1.** The functions in Table 7 are valid aggregation and influence functions. They are, in particular, Lipschitz-continuous with the provided Lipschitz constants.
Aggregation Functions

- **Sum**: $\alpha^S_g : [0, 1]^n \to \mathbb{R}$, $\alpha^S_g(s) = \sum_{i=1}^n g_i \cdot s_i$
- **Product**: $\alpha^P_g : [0, 1]^n \to [-1, 1]$, $\alpha^P_g(s) = \prod_{i=1}^n (1 - s_i)$, $\alpha^P_g(s) = \prod_{i=1}^n (1 - s_i)$
- **Top**: $\alpha^{\text{max}}_g : [0, 1]^n \to [-1, 1]$, $\alpha^{\text{max}}_g(s) = M_g(s) - M_{-g}(s)$, where $M_g(s) = \max\{0, g_1 \cdot s_1, \ldots, g_n \cdot s_n\}$.

Influence Functions

- **Linear($\kappa$)**: $i^l_w : [-\kappa, \kappa] \to [0, 1]$, $i^l_w(s) = w - \frac{s}{\kappa} \cdot \max\{0, -s\} + \frac{1 - w}{\kappa} \cdot \max\{0, s\}$, $\lambda^l_w = \frac{1}{\kappa} \max\{w, 1 - w\}$
- **Euler-based**: $i^e_w : \mathbb{R} \to [w^2, 1]$, $i^e_w(s) = 1 - \frac{1 - w^2}{1 + w \cdot e^s}$, $\lambda^e_w = 1$
- **QMax($\kappa$)**: $i^q_w : \mathbb{R} \to [0, 1]$, $i^q_w(s) = w - w - h\left(-\frac{s}{\kappa}\right) + w \cdot h\left(-\frac{s}{\kappa}\right)$, where $h(x) = \frac{\max\{0, x\}^2}{1 + \max\{0, x\}^2}$, $\lambda^q_w = \frac{1}{\kappa} \max\{w, 1 - w\}$

Table 1: Some aggregation and influence functions with corresponding Lipschitz constants.

Proof. Stability and Directionality can be easily checked from the definitions.

For Lipschitz-continuity, we will repeatedly use the fact that if the derivative of a function is bounded by $B$, then it is Lipschitz-continuous with Lipschitz constant $B$. This can be seen from the intermediate value theorem (Rudin 1976).

We will also use the fact that the derivative of a continuously differentiable function corresponds to a matrix of partial derivatives (the Jacobian matrix) (Rudin 1976).

**Sum**: The sum-aggregation function is continuously differentiable and $\frac{d\alpha^S_g}{ds_i} = g_i$. Hence, $\|\alpha^S_g(s)\| = \sum_{i=1}^n |g_i|$.

**Product**: The product-aggregation function is continuously differentiable and $\frac{d\alpha^P_g}{ds_i} = -\prod_{j \neq i} (1 - s_j)$ if $g_i = -1$, $\frac{d\alpha^P_g}{ds_i} = \prod_{j \neq i} (1 - s_j)$ if $g_i = 1$ and $\frac{d\alpha^P_g}{ds_i} = 0$ otherwise. All derivatives are bounded from above by 1 and non-zero only if $g_i \in \{-1, 1\}$. Therefore, $\|\alpha^P_g(s)\| = \sum_{i=1}^n |g_i|$.

**Top**: For vectors $s, s' \in [0, 1]^n$, we have $|M_g(s) - M_g(s')| = |\max\{0, g_1 \cdot s_1, \ldots, g_n \cdot s_n\} - \max\{0, g_1 \cdot s'_1, \ldots, g_n \cdot s'_n\}| \leq |1 - 0| = 0$. Hence $|\alpha^{\text{max}}_g(s) - \alpha^{\text{max}}_g(s')| = |M_g(s) - M_g(s') - (M_g(s') - M_g(s'))| \leq |M_g(s) - M_g(s')| - |M_g(s) - M_g(s')| \leq 2$. If $g$ contains only 1 (0) non-zero element, only one (zero) differences can be non-zero. Therefore, the slope is bounded by $\min\{2, \sum_{i=1}^n |g_i|\}$.

**Linear($\kappa$)**: the function is not differentiable at 0. However, the right derivative is $\frac{1}{\kappa}w$ and the left derivative is $-\frac{w}{\kappa}$. Overall, the slope is bounded at every point by $\frac{1}{\kappa} \max\{w, 1 - w\}$.

**Euler-based**: (Mossakowski and Neuhaus 2018) showed in the proof of Theorem 8 that the derivative of the Euler-based semantics is bounded strictly from above by $\frac{1}{\kappa}$.

**QMax($\kappa$)**: The squared maximum $\max\{0, x^2\}$ is differentiable with derivative $\max\{0, 2x\}$. Hence, the quotient rule of differentiation implies that the derivative of $h(x)$ is $\max\{0, 2x\} \cdot \frac{1 + \max\{0, x^2\}}{\max\{0, x^2\}} = \frac{2x - 0}{1 + \max\{0, x^2\}} = 1$. Hence, the chain rule of differentiation implies that the derivative of $h\left(\frac{s}{\kappa}\right)$ is $\frac{s}{\kappa}$.

Linearity of the limit implies differentiability of $i^q_w$. The derivative is piecewise linear with a discontinuity at 0. The derivative is 0 for $s = 0$, $-w \cdot h\left(-\frac{s}{\kappa}\right) = -\frac{s}{\kappa}$ for $s < 0$ and $w \cdot h\left(\frac{s}{\kappa}\right) = \frac{s}{\kappa}$ for $s > 0$. Overall, the derivative is bounded by $\frac{1}{\kappa} \max\{w, 1 - w\}$.

All aggregation functions that we consider here work by computing an aggregated attack and support value independently and subtracting these values. The sum-aggregation function has been used for the Euler-based semantics in (Amgoud and Ben-Naim 2017) and for the quadratic energy model in (Potyka 2018). It aggregates strength values by summing them up. The product-aggregation can be seen as the aggregation function of the DF-QuAD algorithm (Rago et al. 2016). Intuitively, the aggregate for attack and support is initially 1 and the aggregates are decreased by multiplying with $(1 - s)$ for an attacker or supporter with strength $s$. The top-aggregation function has been used for the top-based semantics in (Amgoud and Ben-Naim 2017b) for support-only graphs and has been generalized to bipolar graphs later in (Mossakowski and Neuhaus 2018). It takes only the strongest attacker and supporter into account.

We consider three influence functions. The linear($\kappa$) influence function has a parameter $\kappa$ that we call its conservativeness for reasons that will become clear later. The function linear(1) can be seen as the influence function of the DF-QuAD algorithm in (Rago et al. 2016). It moves the strength to 0 or 1 directly proportional to the aggregated strength values. This yields easily interpretable results, but requires that the aggregation function yields values between 1 and 1. Hence, it cannot be combined with the sum-aggregation function. More generally, linear($\kappa$) requires that the aggregation function yields values between $-\kappa$ and $\kappa$. The Euler-based influence function has been used for the Euler-based semantics in (Amgoud and Ben-Naim 2017). It has some nice properties but causes an asymmetry between attack and support as we discuss later. The QMax influence function used for the quadratic energy model in (Potyka 2018) avoids this asymmetry. We consider again a generalized version with a parameter for the conservativeness.
the quadratic energy model by QE. We also add a conservatism parameter to DFQ and QE.

### 3 Convergence and Open-Mindedness

As shown in (Mossakowski and Neuhaus 2018), modular acceptability semantics always converge for acyclic graphs. The claim remains true for basic modular semantics. However, it is actually not necessary to compute the strength for all arguments in every iteration because the strength of \( A \) depends only on the strength of \( A_1, \ldots, A_{i-1} \). Hence, it suffices to compute only \( s_i \) in iteration \( i \). Then the overall runtime is linear.

As discussed in the introduction, the convergence guarantees for cyclic BAGs in (Mossakowski and Neuhaus 2018) can be generalized using the contraction principle. A contraction is a Lipschitz-continuous function with Lipschitz-constant strictly smaller than 1. The contraction principle states intuitively that every contraction has a unique fixed-point that can be reached by applying the function repeatedly starting from an arbitrary point.

**Lemma 1** (Contraction Principle). If \( S \) is a complete metric space and if \( f : S \rightarrow S \) is a contraction, then there exists one and only one \( x^* \in S \) such that \( f(x^*) = x^* \). In particular, \( \lim_{n \rightarrow \infty} f^n(x) = x^* \) for all \( x \in S \).

A proof of the contraction principle can be found, for example, in (Rudin 1976). The set \([0, 1]^n\) of strength vectors with distance \( d(x, y) = \|x - y\|\) defined by the maximum norm is indeed a complete metric space. Given a BAG with \( n \) arguments such that \( (\omega, \circ \alpha_i) \) is a contraction for all \( i = 1, \ldots, n \), the contraction principle guarantees that the strength values converge. The convergence results in (Mossakowski and Neuhaus 2018) can be seen as special cases of the following result. In particular, Lipschitz-continuity implies that the strength values converge in linear time, that is, \( \|f_S^k(w) - s^*\| \leq 10^{-n} \) for all \( k > C \cdot n \), where \( C \) is a constant that decreases with the Lipschitz constants.

**Proposition 3** (Convergence and Complexity for Cyclic BAGs). Let \( A \) be a BAG, let \( \deg_S \) be a basic modular semantics and let \( \lambda_{A,S} = \max_{1 \leq i \leq n} \lambda_{A_i}^\alpha \cdot \lambda_{A_i}^\omega \). If \( \lambda_{A,S} < 1 \), then the update function \( f_S \) of \( \deg_S \) is a contraction with unique fixed point \( s^* = \deg_S(A) \). Furthermore, \( \|f_S^k(w) - s^*\| \leq \epsilon \) for all \( k > \frac{\log \epsilon}{\log \lambda_{A,S}} \).

**Proof.** First note that Lipschitz-continuous functions are closed under function composition, for if \( g_1 : Y \rightarrow Z \) and \( g_2 : X \rightarrow Y \) are Lipschitz-continuous with Lipschitz constants \( \lambda_1, \lambda_2 \), then

\[
\|g_1(g_2(x)) - g_1(g_2(y))\| \leq \lambda_1 \cdot \|g_2(x) - g_2(y)\| \leq \lambda_1 \cdot \lambda_2 \cdot \|x - y\|.
\]

That is, \( g_1 \circ g_2 \) is Lipschitz-continuous with Lipschitz constant \( \lambda_1 \cdot \lambda_2 \). Hence, \( \omega, \circ \alpha_i \) is Lipschitz-continuous with Lipschitz constant \( \lambda_i^\alpha \cdot \lambda_i^\omega \). That is, \( f_S \) is a contraction and the claim follows from the contraction principle.

For the convergence guarantee, note that

\[
\|f_S(w) - s^*\| = \|f_S(w) - f_S(s)\| \leq \lambda_{A,S} \|w - s^*\|.
\]

It follows by induction that \( \|f_S^k(w) - s^*\| \leq \lambda_{A,S}^k \|w - s^*\| \). Since all strength values must be in \([0, 1]\), \( \|w - s^*\| \leq 1 \). Therefore,

\[
\|f_S^k(w) - s^*\| \leq \lambda_{A,S}^k = \exp(k \cdot \log \lambda_{A,S})
\]

\[
< \exp\left(\frac{\log \epsilon}{\log \lambda_{A,S}} \cdot \log \lambda_{A,S}\right) = \epsilon.
\]

The inequality in the second line holds because \( \lambda_{A,S} < 1 \) implies \( \lambda_{A,S} < 0 \). Hence, \( k > \frac{\log \epsilon}{\log \lambda_{A,S}} \) implies \( k \cdot \log \lambda_{A,S} < \frac{\log \epsilon}{\log \lambda_{A,S}} \cdot \log \lambda_{A,S} \) and the inequality follows because the exponential function is monotonically increasing.

(Mossakowski and Neuhaus 2018) proved individual convergence results for aggregation with sum and top. Both can be seen as special cases of Proposition 3.
Hence, convergence follows from Proposition 3.

Proof. We consider only the semantics in Table 2. As explained in (Mossakowski and Neuhaus 2018), the Euler-based semantics is guaranteed to converge when the indegree is not larger than 4. We get similar guarantees for DFQ(κ) and QE(κ).

Corollary 1. DFQ(κ) and QE(κ) converge whenever

- indegree(Ai) < κ for all arguments Ai or
- indegree(Ai) ≤ κ and 0 < wi < 1 for all arguments Ai.

Proof. We prove the claim only for DFQ(κ), the proof for QE(κ) is analogous.

1. DFQ(κ) uses product aggregation and the linear(κ) influence function. Since 0 ≤ wi ≤ 1, \(\{w_i, 1 - w_i\} \leq 1\). Hence, \(\max_{1 \leq i \leq n} \lambda^0_i \leq \max_{1 \leq i \leq n} \frac{\indegree(A_i)}{κ} < 1\) and convergence follows from Proposition 3.

2. 0 < wi < 1 implies \(\{w_i, 1 - w_i\} < 1\). Hence, \(\max_{1 \leq i \leq n} \lambda^0_i \cdot \lambda^1_i < \max_{1 \leq i \leq n} \frac{\indegree(A_i)}{κ} < 1\) and convergence follows from Proposition 3.

Figure 2 illustrates the behaviour of DFQ(1) and QE(1) for A(1, 0.9, 0.1), where the green and blue dots show the strength of argument a1 and b1 over a number of iterations. Both models start jumping between the same two states after a small number of iterations. Since A(1, 0.9, 0.1) has indegree 2, the example in Figure 2 shows that the bound for DFQ(1) and QE(1) given in Corollary 1 cannot be improved significantly. Figure 3 shows that we can solve the divergence problem by increasing the conservativeness parameter κ of the semantics. However, as we will explain soon, this comes at a cost. We could give more divergence examples for DFQ(κ) and QE(κ) with larger κ based on the family A(k, vα, vβ), but the examples get less tight for increasing κ and so we defer from doing so.

Figure 3: Convergence of QE(2.1) (left) and DFQ(1.9) (right) for A(1, 0.9, 0.1).

(Mossakowski and Neuhaus 2018) showed that semantics that use top for aggregation and an influence function with derivative bounded from above strictly by \(\frac{1}{4}\) are guaranteed to converge. This can also be seen from Proposition [3] because the Lipschitz constant of top is 2 and the condition on the derivative implies that the influence function is Lipschitz-continuous with Lipschitz constant \(\frac{1}{2}\). Hence, when using the Euler-based influence functions or influence functions that scale the influence of the aggregated value down by a constant κ similar to Linear(κ) and QMax(κ), the semantics converges in general. However, this guarantee comes at a cost. The bound imposed on the growth of the influence function limits the semantics’ ability to adapt the initial weight. I would argue that a semantics should be able to move the strength values arbitrarily close to the extreme values 0 or 1 if sufficient evidence against or for the argument is given. We formalize this in the following definition.

Definition 4 (Open-Mindedness). An influence function \(\iota : [l, u] \rightarrow [0, 1]\) is called open-minded if \(\lim_{a \rightarrow l} \iota(a) = 0\) and \(\lim_{a \rightarrow u} \iota(a) = 1\).

A basic modular semantics with aggregation function \(\alpha : [0, 1]^n \rightarrow [l, u]\) is called open-minded when its influence function restricted to the domain \([l, u]\) is open-minded.

Note that we do not demand that the influence function ever yields the extreme values 0 or 1 (this would be in conflict with the Resilience axiom from (Amgoud and Ben-Naim 2017)), we only demand that it is possible to get arbitrarily close to these bounds. The Euler-based influence function is actually not open-minded because \(\lim_{a \rightarrow -\infty} \iota^{\alpha}(a) = 1 - \frac{1}{1+w^2} = w^2\). Hence, the Euler-based semantics is not open-minded since it does not admit final strength values smaller than \(w^2\). Linear(κ) and QMax(κ) are open-minded influence functions and DFQ(1) and QE(κ) are open-minded semantics. However, DFQ(κ) is not open-minded for \(κ > 1\). Also, none of the semantics with general convergence guarantees from (Mossakowski and Neuhaus 2018) are open-minded. These negative results are all special cases of the following proposition.

Proposition 4. Consider a basic modular semantics with aggregation function \(\alpha : [0, 1]^n \rightarrow [-B, B]\) and influence function \(\iota\) whose Lipschitz constant is bounded by \(L\). Then for every BAG \(A = (A, w, R, S)\) with \(n\) arguments, the following bound is true for all \(i = 1, \ldots, n\):

\[w_i - B \cdot \lambda^i \leq \deg_{\alpha}(A)_i \leq w_i + B \cdot \lambda^i\]
### Continuous Modular Semantics

In (Potyka 2018), it has been proposed to use continuous models rather than discrete ones in order to deal with cyclic BAGs. Roughly speaking, discrete models work by applying an update formula to the initial weights repeatedly until the process converges. In case of basic modular semantics, the update formula is given by the function \((\iota_a \circ \alpha_{g_i})\). Continuous models work in a more descriptive way by describing the continuous change of arguments’ strength based on the strength of their attackers and supporters. This is done by means of differential equations. If the system of differential equations is designed carefully, it yields a unique solution \(\sigma^A : \mathbb{R}_0^+ \rightarrow \mathbb{R}^n\). Intuitively, the \(i\)-th component \(\sigma^A_i(t)\) tells us the strength of the \(i\)-th argument at (continuous) time \(t\) and the final strength values correspond to the limit \(\lim_{t \rightarrow \infty} \sigma^A_i(t)\). Just like the limit \(\lim_{k \rightarrow \infty} f^S_k(w)\) for discrete basic modular semantics may not exist, the limit \(\lim_{t \rightarrow \infty} \sigma^A_i(t)\) may not exist. However, if we can continuize a discrete model, the discrete model can actually be seen as a coarse approximation of the continuous model as explained in (Potyka 2018). In particular, the continuous model may still converge when its discrete counterpart diverges as we will demonstrate soon. While there are currently no strong analytical guarantees for continuous models in cyclic BAGs, no divergence examples have been found either and experiments show that they can converge quickly for large cyclic BAGs with thousands of arguments. Furthermore, sufficient conditions have been given under which discrete models can be continuized. The results can actually be simplified and generalized to all basic modular semantics. The key property of the aggregation and influence functions is again Lipschitz continuity.

**Proposition 5** (Continuizing Basic Modular Semantics),

Let \(\text{Deg}_S\) be a basic modular semantics with aggregation function \(\alpha_g\) and influence function \(\iota_a\).

1. For all BAGs \(A\), the system
   \[
   \frac{ds_i}{dt} = (\iota_{w_i} \circ \alpha_{g_i})(s) - s_i
   \]
   with initial conditions \(s_i(0) = w_i\) for \(i = 1, \ldots, n\) has a unique solution \(\sigma^A : \mathbb{R}_0^+ \rightarrow \mathbb{R}^n\).

2. If \(\sigma^A\) converges and \(s^* = \lim_{t \rightarrow \infty} \sigma^A(t)\), then \(s^*_i\) is a fixed-point of the update function \(f^S\) of \(\text{Deg}_S\).

3. If \(A\) is acyclic, the discrete and continuized model converge to the same limit.

4. If \(\sigma^A\) converges and \(f^S\) is a contraction, then the discrete and continuized model converge to the same limit.

**Proof.** 1. Lipschitz continuity of \((\iota_{w_i} \circ \alpha_{g_i})\) allows us to apply existence and uniqueness theorems for nonlinear systems of ordinary differential equations from (Polyanin and Zaitsev 2017) Section 7.1.2) that imply the claim.

2. If \(\sigma^A\) converges, then all derivatives \(\frac{ds}{dt}\) must go to 0. Hence, in the limit \(0 = (\iota_{w_i} \circ \alpha_{g_i})(s^*) - s^*_i\). That is, \(f_i(s^*) = (\iota_{w_i} \circ \alpha_{g_i})(s^*) = s^*_i\).

3. Analogous to the proof of Proposition 16 in (Potyka 2018), one can show that \(\sigma^A\) converges to the same limit as the algorithm given in Proposition 2 for acyclic BAGs.

4. If \(f^S\) is a contraction, the contraction principle implies that \(f^S\) has a unique fixed-point. Since \(\sigma^A\) converges to such a fixed-point according to Item 2, both models must converge to the same limit. 

As opposed to the continuization result in (Potyka 2018), the proposition does not assume continuous differentiability of the update function and therefore applies to more general

Table 3: Strength values of \(a\) under different semantics and increasing number of attackers \(k\) for BAG from Example 2
acceptability semantics like the DF-QuAD algorithm from (Rago et al. 2016) (DFQ(1) in Table 2).

We demonstrate in Figure 4 that continuizing discrete models can solve divergence problems. Whereas QE(1) and DFQ(1) diverged for $A(1,0.9,0.1)$ (Figure 2), their continuized counterparts (Figure 4) converge. The intuitive reason for this is best explained by numerical solution techniques that approximate the continuous model $\sigma^A: \mathbb{R}_{>0}^n \rightarrow \mathbb{R}^n$. The most naive technique is Euler’s method. In our context, it initializes the strength values with the initial conditions given by the initial weights. This is the value of $\sigma^A(0)$. In order to compute $\sigma^A(\delta)$ for some small $\delta > 0$, Euler’s method uses a first-order Taylor approximation. That is, $\sigma^A(\delta)_i$ is approximated by $s(\delta)_i = s(0)_i + \frac{ds(0)_i}{dt} \cdot \delta$ for all $i = 1, \ldots, n$. Notice that $\frac{ds}{dt}$ is given by our differential equations in (1). Having obtained the approximation $s(\delta) \approx \sigma^A(\delta)$, we can move on approximating $\sigma^A(2 \cdot \delta)_i$ by $s(2 \cdot \delta)_i = s(\delta)_i + \frac{ds(\delta)_i}{dt} \cdot \delta$. In this way, we can approximate $\sigma^A(t)$ for all $t > 0$ until the strength values converge. To summarize Euler’s method, we initialize $s_i(0) = w_i$ for all $i = 1, \ldots, n$ and let then $s_i((k+1) \cdot \delta) = s_i(k \cdot \delta) + \frac{ds(k \cdot \delta)_i}{dt} \cdot \delta$. We call $\delta$ the step-size and we can improve the approximation quality by decreasing $\delta$. As $\delta \rightarrow 0$, the approximation error goes to 0 by differentiability of $\sigma^A$.

In order to understand the relationship between discrete and continuous models, let us plug in equation (1) in our approximation scheme. Our update is then $s_i((k+1) \cdot \delta) = s_i(k \cdot \delta) + ((\epsilon_w \circ \alpha_{g})(s(k \cdot \delta)) - s_i(k \cdot \delta)) \cdot \delta$. If we use the step size $\delta = 1$, the equation simplifies to $s_i(k+1) = (\epsilon_w \circ \alpha_{g})(s(k))$. Notice that this is exactly the discrete update procedure. That is, in the discrete update procedure, the intermediate result $f_S^k(w) = f_S^k(s(0))$ can be seen as a very coarse approximation of the value $\sigma^A(k)$ of the corresponding continuous model $\sigma^A$. Due to this coarseness, we may actually jump from the function graph of the true solution to the function graph of a solution for different initial conditions. This may cause divergence when the algorithm starts jumping back and forth between two function graphs. We can avoid these jumps by decreasing $\delta$. We illustrate this in Figure 5 for DFQ(1) and the BAG $A(1,0.9,0.1)$. As we decrease $\delta$ from 1 to 0.8, the oscillations already become weaker, but the step size is not sufficiently small to avoid divergence. For $\delta = 0.5$, the oscillations die out and the true limit shown in Figure 5 is eventually reached.

Note that we refer to Euler’s method only for didactic reasons. The results in Figure 4 were computed using the classical Runge-Kutta method RK4 that provides much stronger approximation guarantees (Polyanin and Zaitsev 2017).

5 Duality Property

Before closing this paper, we generalize a symmetry property introduced in (Potyka 2018) to the setting from (Mossakowski and Neuhans 2018). Intuitively, our symmetry property should assure that attackers move the strength from the initial weight towards 0 in the same way as supporters move the strength from the initial weight towards 1. This can be described by constraints on the aggregation and influence function as follows.

Definition 5 (Duality). A basic modular semantics satisfies Duality iff

1. $\alpha_g(s) = -\alpha_{-g}(s)$ for all $s \in [0,1]^n$ and
2. $1 - \epsilon(1-w)(a) = \epsilon_w(-a)$ for all $w \in [0,1]$.

The aggregation condition says that when we switch the role of attackers and supporters (replace $g$ with $-g$), the aggregated strength value should just switch sign. For the special case $w = 0.5$, the influence condition says that a positive aggregate must have the same distance to 1 as the negative aggregate has to 0. If $w \neq 0.5$, there is a natural asymmetry because the initial weight is now either closer to 0 or 1. However, a negative aggregate for weight $w$ should still yield the same distance to 0 as the positive aggregate yields to 1 for weight $1-w$. In the following proposition, we give a more intuitive interpretation of Duality.

Proposition 6. Let $\text{Deg}_S$ be a basic modular semantics that satisfies Duality and let $A = (A, w, R, S)$ be a BAG such that $\text{Deg}_S(A) = s^* \neq \perp$. If there are $A_i, A_j$ such that

1. $g_i = -g_j$ or, more generally, $\alpha_{g_i}(s^*) = -\alpha_{g_j}(s^*)$.
2. $w_i = 1 - w_j$.

then $\text{Deg}_S(A)_i = 1 - \text{Deg}_S(A)_j$.
Figure 6: Duality Example.

Table 4: Initial weight and strength values for arguments in Figure 6 under semantics from Table 2.

**Example 3.** Consider the BAG in Figure 9. Table 4 shows the strength values for the three semantics from Table 2. The asymmetry of the Euler-based semantics can already be seen from the subgraph with indices 1. Whereas the support of $x_1$ increases the strength of $b_1$ by 0.15, its attack decreases the strength of $a_1$ only by 0.11. Both the DF-QuAD algorithm and the quadratic energy model induce a symmetrical impact for attacks and supports. As we move the strength away from 0.5, there is a natural asymmetry caused by the fact that the distance from the initial weight to 0 and 1 is now different. However, attack and support should still behave in a dual manner. For the subgraph with indices 2, the initial weight of $a_2$ and $b_2$ is moved away from 0.5 by 0.2 in different directions. Again, the increase caused by a support should equal the decrease caused by an attack. For the DF-QuAD algorithm, the change is 0.42, for the quadratic energy model 0.19. Similarly, for the subgraph with indices 3, the DF-QuAD algorithm causes a change of 0.08, the quadratic energy model a change of 0.03.

In Table 1 all building blocks other than the Euler-based influence functions can be selected in order to satisfy duality as we show in the following proposition.

**Proposition 7.** The Sum-, Product- and Top-aggregation functions satisfy the aggregation duality condition. The Linear($\kappa$) and QMax($\kappa$) influence functions satisfy the influence duality condition.

**Proof.** Sum:

$$\alpha^S_g(s) = \sum_i g_i \cdot s_i = - \sum_i (-g_i) \cdot s_i = -\alpha^-S_g(s).$$

Product:

$$\alpha^P_g(s) = \prod_{i: g_i = 1} (1 - s_i) - \prod_{i: g_i = 1} (1 - s_i)$$

$$= -(-\prod_{i: g_i = 1} (1 - s_i) + \prod_{i: g_i = 1} (1 - s_i))$$

$$= -\alpha^-P_g(s).$$

Top:

$$\alpha^{\text{Top}}_g(s) = M_g(s) - M_g(\neg s) = -(M_g(s) + M_g(\neg s))$$

$$= -\alpha^{\text{Top}}_g(s).$$

Linear($\kappa$):

$$1 - \iota^1_{(1-w)}(a)$$

$$= w + \frac{1 - w}{\kappa} \cdot \max\{0, -a\} - \frac{w}{\kappa} \cdot \max\{0, a\}$$

$$= \iota^0_w(-a).$$

QMax($\kappa$):

$$1 - \tau^q_{(1-w)}(a)$$

$$= w + \frac{1 - w}{\kappa} \cdot h(-a) - \frac{w}{\kappa} \cdot h(a)$$

$$= \tau^\circ_w(-a).$$

Since the DF-QuAD algorithm and the quadratic energy model are constructed from these building blocks, an immediate consequence is that they satisfy duality.

### 6 Related Work

In the basic abstract argumentation framework introduced in [Dung 1995], arguments can only be attacked by other arguments. **Bipolar argumentation frameworks** [Angoud, Cayrol, and Lagasque-Schiex 2004; Oren and Norman 2008; Cayrol and Lagasque-Schiex 2013] add an additional support relation. While classical semantics can only accept or reject arguments (Baroni, Caminada, and Giacomin 2011), various proposals have been made to allow for a more fine-grained evaluation. Among others, it has been suggested to apply tools from probabilistic reasoning (Hunter and Thimm 2014, Prakken 2018, Hunter, Polberg, and Potyka 2018, Kienstra et al. 2018) or to rank arguments based on fixed-point equations (Besnard and Hunter 2001, Leite and Martins 2011, Correia, Cruz, and Leite 2014).
